This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

+ *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.

+ *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.

+ *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.

+ *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at `http://books.google.com/`

PREFACE

TO

THE FIFTH VOLUME.

THE NINE YEARS which have elapsed since this work was commenced have witnessed important changes in the modes of viewing and representing the constitution of chemical compounds. The old system of notation, founded on the dualistic theory of chemical combination, and the atomic weights adopted in Gmelin's Handbook and other standard works of older date, may now be regarded as belonging to the past; and even the new system introduced by Gerhardt has undergone considerable modification, the atomic weights which that chemist assigned to many of the metals having been doubled, and his system of typical representation having been developed into the modern theory of atomicity. These changes and developements are explained in the article CLASSIFICATION by Professor G. C. Foster, and the articles ATOMIC WEIGHTS, and METALS, ATOMIC WEIGHTS AND CLASSIFICATION OF, by Dr. Odling. The smaller atomic weights of many of the metals ($Ba=68{\cdot}7$; $Hg = 100$; $Zn = 32{\cdot}5$, &c.) having been adopted in the earlier part of the Dictionary, it was thought advisable, in first introducing the larger ones, to distinguish them by doubled symbols ($Bba = 137$, $Hhg = 200$, &c.); but in the latter part of the work these double symbols, which are rather clumsy, have been abandoned, and the ordinary symbols used, with accents or dashes, when necessary, to indicate the equivalent value.

In bringing the Dictionary to a conclusion I have to regret that it is in some respects less complete than I could wish. Although it has extended considerably beyond the limits originally contemplated, the space has still been found too narrow for the adequate treatment of many important subjects. I have however endeavoured to give some notice of every compound discovered up to the time of the publication of each Part of the

74252

work, and where full description was impossible, reference is given to the original sources of information. The earlier volumes are necessarily somewhat behind the present state of knowledge, but should the work meet with the success for which we hope, this deficiency may perhaps be made good by a Supplement.

In conclusion I have to tender my best thanks to those gentlemen who have enriched the work by their valuable contributions. Several of these articles have taken rank as classical treatises on their respective subjects, and to them the work will be in a great measure indebted for such success as it may attain.

HENRY WATTS.

LONDON: *May*, 1868.

LIST OF CONTRIBUTORS.

EDMUND ATKINSON, Ph.D. F.C.S.
Professor of Chemistry at the Royal Military College, Sandhurst.

FRANCIS T. CONINGTON, M.A. F.C.S. (the late)
Fellow of Corpus Christi College, Oxford, and Examiner in Natural Science at that University; Author of a 'Handbook of Chemical Analysis.'

WILLIAM DITTMAR, Esq.
Principal Assistant in the Chemical Laboratory of the University of Edinburgh.

FREDERICK FIELD, F.R.S. F.R.S.E.
(lately) Professor of Chemistry at St. Mary's Hospital.

GEORGE C. FOSTER, B.A. F.C.S.
Professor of Physics at University College, London.

MICHAEL FOSTER, M.D.
Lecturer on Practical Physiology and Histology at University College, London.

EDWARD FRANKLAND, Ph.D. F.R.S.
Foreign Secretary of the Chemical Society; Professor of Chemistry at the Royal Institution of Great Britain, and at the Royal School of Mines.

FREDERICK GUTHRIE, Ph.D. F.C.S.
Professor of Chemistry at the Royal College, Mauritius.

M. L'ABBÉ A. HAMY,
Paris.

MICHAEL HANHART, Esq.
Lithographer.

A. W. HOFMANN, LL.D. F.R.S. V.P.C.S.
Professor of Chemistry at the University of Berlin.

WILLIAM S. JEVONS, M.A.
Cobden Professor of Political Economy at Owens College, Manchester; (lately) Gold Assayer in the Sydney Royal Mint.

CHARLES E. LONG, Esq. F.C.S. (the late)
Analytical Chemist.

WILLIAM ODLING, M.B. F.R.S.
Secretary to the Chemical Society, and Professor of Chemistry at St. Bartholomew's Hospital, Author of a 'Manual of Chemistry.'

BENJAMIN H. PAUL, Ph.D. F.C.S.
Consulting Chemist.

THOMAS RICHARDSON, Ph.D. F.R.S. &c. (the late)
Reader in Chemistry at the University of Durham.

HENRY E. ROSCOE, Ph.D. F.R.S. F.C.S.
Professor of Chemistry at Owens College, Manchester.

WILLIAM J. RUSSELL, Ph.D. F.C.S.
Of University College, London.

J. A. WANKLYN, F.R.S.E. F.C.S.
Professor of Chemistry at the London Institution.

C. GREVILLE WILLIAMS, F.R.S.
Author of a 'Handbook of Chemical Manipulation.'

ARTHUR WINCKLER WILLS, Esq.
Analytical and Manufacturing Chemist, Wolverhampton. (W. W.)

⁂ Articles communicated by the several contributors are signed with their initals; articles taken from URE's *Dictionary of Chemistry* (fourth edition, 1831) are signed with the letter U; those which have no signature are by the Editor.

DICTIONARY OF CHEMISTRY.

Q

QUADRANTOXIDE. A term applied by H. Rose to oxides containing 4 atoms of metal to 1 atom of oxygen, such as suboxide of silver Ag^4O: better called *tetrametallic oxides* (see Oxides, iv. 304).

QUADRI and **QUADRO.** Prefixes synonymous with Tetra: *e.g.* $SnCl^4$ = Quadrichloride or Tetrachloride of tin.

QUARTZ. Native crystalline anhydrous silica, SiO^2, occurring either in distinct crystals, often of large size, or in crystalline aggregates, or massive.

The crystals belong to the hexagonal system, being six-sided prisms with pyramidal summits, made up of the two opposite rhombohedrons, $+R$ and $-R$, with the corresponding prism ∞R; hemihedral or tetartohedral, exhibiting the modifications described under Crystallography (ii. 139—143). For R, the principal axis = 1·100. Angle $R : R$ (terminal) = 94° 15′. For the hexagonal pyramid, the angle of the terminal edges = 133° 4′; of the lateral edges = 103° 34′. Cleavage very imperfect, parallel to R and ∞R. Twins are of frequent occurrence, the face of composition being either the basal plane, oR, or a plane truncating the pyramidal edge, or the face R. The two crystals compounded parallel to oR, sometimes penetrate one another very irregularly, while the external planes are regular and even (Dana, ii. 146). Distorted crystals also occur, sometimes curved, as in figure 355 (ii. 166).

Hardness = 7. Specific gravity = 2·5—2·8; according to Beudant, = 2·6413—2·6541; according to Hauy, = 2·6701. Lustre vitreous, sometimes inclining to resinous. Colourless when pure (rock-crystal); but often exhibiting various shades of yellow, red, brown, green, blue, and black, from admixture of oxide of iron and other metallic oxides. Streak, of the pure varieties, white; of the impure, often the same as the colour, but much paler. Transparent to opaque. Fracture perfect conchoïdal to subconchoïdal. Tough; brittle; friable. Infusible alone before the blowpipe, but with carbonate of sodium it fuses readily, and with effervescence, to a transparent glass.

Quartz exhibits numerous varieties, arising from peculiar modes of formation and crystallisation, or from impurities. They may be divided into three groups—namely, the vitreous varieties, exhibiting the bright glassy lustre of broken quartz-crystals; the chalcedonic varieties, exhibiting the glistening subvitreous or waxy lustre and translucency of chalcedony; and the jaspery varieties, having the dull lustre and colours and the opacity of jasper. The varieties belonging to the second and third groups have been already described. (See Chalcedony, i. 844; Jasper, iii. 442; and the names of the several varieties.)

The vitreous group includes: α. *Rock-crystal*, or pure crystallised quartz. An asteriated variety contains whitish impurities or opaque particles, arranged along the diametral planes.—β. *Amethyst:* clear purple or bluish-white quartz-crystal, the colour being generally ascribed to a small percentage of oxide of manganese. According to Heintz, however, it is due to a compound containing iron and sodium.—γ. *Rose-quartz:* rose-red or pink; transparent or nearly so, with vitreous lustre; usually massive, and often much cracked. The colour is probably due to manganese, but is attributed by Fuchs to oxide of titanium, and by Berthier to organic matter.—δ. *False topaz:* a light-yellow pellucid variety of quartz-crystals, resembling yellow topaz, but distinguished therefrom by its crystalline form, and the absence of cleavage.—ε. *Smoky* *quartz* or *Cairngorm-stone* has a brownish smoky tint, sometimes pellucid.—ζ. *Milky quartz:* one of the most common varieties, massive, vitreous, with a milk-white colour. Sometimes it has a greasy lustre, and is then called *greasy quartz*.—η. *Prase* is a leek-green variety of massive quartz.—θ. *Aventurin quartz* is minutely spangled throughout the mass with yellow scales. It is usually translucent, and of a grey, brown, or reddish-brown colour.—ι. *Siderite:* a blue variety from Golling, near Saltzburg.—κ. *Ferruginous quartz* is of an opaque red, brownish-red, or ochre-yellow colour, due to oxide of iron. It occurs in distinct crystals, sometimes minute and aggregated into masses, like the grains of sand in sandstone.

Quartz in some of its varieties occurs in almost every rock-stratum. It is an essential ingredient of granite, gneiss, mica-slate, and other allied rocks. The chalcedonic varieties occur principally in the vesicular cavities of basaltic and allied rocks. Flint occurs imbedded in chalk. Hornstone is sometimes imbedded in limestone. Jasper is also associated with limestone, and with basaltic rocks and porphyry.

Quartz-crystals sometimes occur of enormous size. A group in the Museum of the University at Naples weighs nearly half a ton. The British Museum also possesses some very large specimens.

Quartz is distinguished: 1. By its *hardness*, scratching glass with facility.—2. *Infusibility*, not fusing alone before the blowpipe.—3. *Insolubility*, not being attacked by water or acids.—4. *Uncleavability;* one variety indeed is tabular, but true cleavage is never observed.—5. The reaction with soda (p. 1). It is only pure quartz, however, that forms a clear glass.

QUARTZ-PORPHYRY. See Porphyry (iv. 691).—For analyses of several varieties of this rock, see Tribolet (Ann. Ch. Pharm. lxxxvii. 327; Jahresb. 1853, p. 868).

QUASSIA-CAMPHOR. A substance which separates from an aqueous infusion of quassia-wood, in white crystalline plates, lighter than water, and having the odour of the wood. (Bennerscheidt, Handw. d. Chem. vi. 741.)

QUASSIN. *Quassiin. Quassite.* $C^{10}H^{12}O^{3}$? (Winckler, Report, Pharm. liv. 85.—Wiggers, Ann. Ch. Pharm. xxi. 40.)—The bitter principle of quassia-wood (*Quassia amara*, L.). To extract it, the concentrated aqueous infusion of the wood, after being freed from pectin and other substances by treatment with slaked lime, is evaporated to dryness; the residue is digested in alcohol of 80 or 90 per cent.; the alcoholic solution is evaporated; the yellow, bitter, crystalline substance which remains is treated with a very small quantity of absolute alcohol; the resulting alcoholic solution is mixed with a large quantity of ether; and the filtered ethereal solution, after being concentrated by evaporation, is poured into a small quantity of water.

The liquid, if then left to itself, gradually deposits quassin in small white opaque prisms—very bitter, inodorous, and permanent in the air. It melts when heated, and forms, on cooling, a transparent, yellowish, very brittle mass. At a higher temperature it becomes more fluid, turns brown, carbonises, and then yields acid products free from ammonia; 100 pts. of water at 12° dissolve 0·45 pt. of quassin. Its solubility is increased by the presence of very soluble saline substances or organic acids. It contains, according to Wiggers, 65·7 per cent. carbon, and 6·9 hydrogen, agreeing very closely with the formula $C^{10}H^{12}O^{3}$. The aqueous solution gives a white precipitate with tannin, but is not precipitated by iodine, chlorine, mercuric chloride, iron-salts, or lead-salts. It dissolves without coloration in oil of vitriol, and in nitric acid of specific gravity 1·25; hot nitric acid converts it into oxalic acid.

QUASSITE. Syn. with Quassin.

QUEEN'S METAL. An alloy consisting of 9 pts. tin, 1 antimony, 1 lead, and 1 bismuth.

QUERÆSCITRIN. $C^{41}H^{46}O^{25}$. (Rochleder, Ann. Ch. Pharm. cxii. 112.)—A substance extracted by alcohol from the leaves of the chestnut (? horse-chestnut).* It forms fine yellow crystalline grains of the size of poppy-seeds, and is resolved by hydrochloric acid into quercetin and glucose:

$$C^{41}H^{46}O^{25} + 3H^{2}O = C^{23}H^{16}O^{10} + 3C^{6}H^{12}O^{6}.$$

QUERCETAMIDE. An ammoniacal solution of quercetin left to itself for two months, and then treated with hydrochloric acid, deposits unaltered quercetin; but on adding ammonia to the acid filtrate, quercetamide is obtained, as an orange-yellow precipitate, which alters very quickly on exposure to the air. At a temperature of 145° to 150°, this body is formed in twelve hours, but in a less pure state. It is amorphous, slightly soluble in water, more soluble in alcohol, ether, hydrochloric acid, and excess of ammonia. (Schützenberger and Paraf, Zeitschr. Ch. Pharm. 1862, p. 41.)

---

* The substance is said by Rochleder to occur "in den Kastanienblättern;" but the name *queræscitrin*, which he gives to it, would seem to imply that it was obtained from the horse-chestnut (*Æsculus Hippocastanum*). See Quercetin.

QUERCETIC ACID. $C^{17}H^{12}O^8$, or $C^{21}H^{14}O^{10}$, or $C^{15}H^{10}O^7$? (Hlasiwetz, Ann. Ch. Pharm. cxii. 96.—Zwenger and Dronke, *ibid.* Suppl. i. 261; also cxxiii. 153.—Hlasiwetz and Pfaundler, J. pr. Chem. xciv. 65; Jahresb. 1864, p. 561.)—A compound formed, together with phloroglucin and other products, by the action of boiling potash on quercetin:

$$\underset{\text{Quercetin.}}{C^{23}H^{16}O^{10}} + H^2O = \underset{\text{Quercetic acid.}}{C^{17}H^{12}O^8} + \underset{\text{Phloroglucin.}}{C^6H^6O^3} \text{ (Hlasiwetz).}$$

$$\underset{\text{Quercetin.}}{3C^{13}H^{10}O^6} + H^2O = \underset{\text{Quercetic acid.}}{C^{21}H^{14}O^{10}} + \underset{\text{Phloroglucin.}}{3C^6H^6O^3} \text{ (Zwenger and Dronke).}$$

$$\underset{\text{Quercetin.}}{C^{27}H^{18}O^{12}} = \underset{\text{Quercetic acid.}}{C^{15}H^{10}O^7} + \underset{\text{Morin.*}}{C^{12}H^8O^5} \text{ (Hlasiwetz and Pfaundler).}$$

Preparation.—A hot very concentrated solution of 3 pts. potassium-hydrate is boiled down in a silver basin with 1 pt. quercetin, and the residue is heated, till a sample dissolved in water on a watch-glass no longer gives a flocculent precipitate (paradatiscetin) with hydrochloric acid, and the residue quickly turns dark-red at the edges; it is then immediately diluted with water, and neutralised with hydrochloric acid. After being left to cool and stand for a while, it is filtered from the separated flocks, which contain quercetin and paradatiscetin; the filtrate is evaporated to dryness; the residue exhausted with alcohol; the alcohol distilled off from the brown tincture; and the residue diluted with water. On adding neutral acetate of lead to this solution, quercetate of lead is precipitated (phloroglucin remaining in solution), which may be decomposed under water by sulphydric acid. After the sulphide of lead has been filtered off and washed with boiling water, the solutions are evaporated in a current of hydrogen, and the crystals, which separate after some days, are collected and decolorised by recrystallisation, with addition of animal charcoal (Hlasiwetz). Or the neutralised solution, mixed with one-fourth of its volume of alcohol, may be shaken up with ether, the ether evaporated, and the residue dissolved in water, and treated with acetate of lead as above. (Hlasiwetz and Pfaundler.)

Properties.—Quercetic acid crystallises in slender silky needles, which effloresce in a warm atmosphere, and give off 15·49 per cent. water between 120° and 131° ($C^{17}H^{12}O^8.HO^2$ requires 15·47 per cent.). The composition of the anhydrous acid, according to calculation and analysis, is as follows:

	Calculation.			*Mean of analyses.*
	Hlasiwetz. $C^{17}H^{12}O^8$	Zwenger and Dronke. $C^{21}H^{14}O^{10}$	Hlasiwetz and Pfaundler. $C^{15}H^{10}O^7$	Hlasiwetz.
Carbon . . .	59·30	59·15	59·60	59·44
Hydrogen . . .	3·48	3·28	3·31	3·73
Oxygen . . .	37·22	37·57	37·09	36·83
	100·00	100·00	100·00	100·00

The last formula agrees best with the analyses, but it does not afford so ready an explanation as the others of the simultaneous formation of phloroglucin from quercetin (p. 5).

Quercetic acid dissolves sparingly in cold, easily in boiling *water*; it is soluble also in *alcohol* and *ether*. The aqueous solution turns yellow when exposed to the air. A very dilute solution, when exposed to the air, acquires first a yellow, then a splendid carmine colour. The acid dissolves with red-brown colour in *oil of vitriol*, and is precipitated by water in red flocks, forming purple solutions with ammonia and potash (Hlasiwetz).—It is coloured black-blue by *ferric chloride*, or in very dilute solution, a splendid bright blue (Hlasiwetz). When dissolved in water together with *urea* it forms a compound, and with excess of *urea*, a product of decomposition (Pfaundler). By fusion with *potash*, it is converted into protocatechuic and quercimeric acids:

$$\underset{\text{Quercetic acid.}}{C^{15}H^{10}O^7} + H^2O + O = \underset{\text{Protocatechuic acid.}}{C^7H^6O^4} + \underset{\text{Quercimeric acid.}}{C^8H^6O^5}.$$

---

* The morin is said to be further transformed into phloroglucin, with simultaneous formation of oxalic acid; but the mode of decomposition is not given.

Diaceto-quercetic acid. $C^{21}H^{16}O^{10} = C^{17}H^{10}(C^2H^3O)^2O^8$? (Pfaundler, Ann. Ch. Pharm. cxix. 813.)—Obtained by heating quercetic acid with chloride of acetyl to 100° in a sealed tube, expelling the excess of the chloride after the action is over, and drenching the residual glutinous mass with water. It then remains in resinous flocks, which may be purified by washing with water and crystallisation from alcohol. It is decomposed by heat, with formation of acetic acid. It reduces alkaline solutions of copper- and silver-salts; scarcely colours a solution of ferric chloride.

The above reaction also gives rise to the formation of a second product, probably *monoacetoquercetic acid*, which remains dissolved in alcohol, after the diaceto-compound has crystallised out, and is precipitated by water in white flocks; it colours ferric chloride deep green. (Pfaundler.)

QUERCETIN. *Meletin.*—A product of the decomposition of quercitrin and similar bodies, discovered in 1854 by Rigaud (Ann. Ch. Pharm. xc. 283), and further examined by Hlasiwetz (*ibid.* cxii. 96), who assigned to it the formula, $C^{23}H^{16}O^{10}$; by Zwenger and Dronke (*ibid.* Suppl. i. 21, and cxxiii. 153), who adopt the formula $C^{13}H^{10}O^6$, proposed by Wurtz (Ann. Ch. Phys. [3] xlii. 244); and lastly by Hlasiwetz and Pfaundler (J. pr. Chem. xciv. 65; Jahresb. 1864, p. 560), who regard it as $C^{27}H^{18}O^{12}$.

Quercetin is produced, together with sugar or a similar body, by boiling quercitrin (Rigaud), rutin (Rochleder and Hlasiwetz), or robinin (Zwenger and Dronke), with aqueous mineral acids, and separates during the boiling and on cooling, partly only after the liquid has been left at rest for some time. It is likewise obtained in the preparation of quercitrin by the method presently to be described (p. 6), and by the decomposition of several substances identical or isomeric with quercitrin, viz.—*α.* A yellow colouring-matter from ripe horse-chestnuts, likewise found in the full but not in the undeveloped leaves, and in the flowers (Rochleder).—*β.* A yellow dye from hops.—*γ.* A yellow dye from the berries of the sea-buckthorn or sallowthorn (*Hippophaë rhamnoïdes*).—*δ.* *Flavin*, a yellow-brown powder from North America (ii. 655).—*ε.* The green leaves and the flowers of plants contain either quercitrin or quercetin. (Filhol, J. Pharm. [3] xli. 151.)

Rhamnetin and thujetin are regarded by Hlasiwetz as identical with quercetin, which however is doubted by Bolley in the case of rhamnetin.

Quercetin forms either small, very slender, bright-yellow needles, which do not polarise light, or a lemon-yellow powder. It contains water of crystallisation, which, according to Hlasiwetz, is not completely expelled at 120°, or even between 200° and 220°. Hlasiwetz originally assigned to hydrated quercetin dried at various temperatures the formulæ $4C^{23}H^{16}O^{10}.H^2O$, $2C^{23}H^{16}O^{10}.H^2O$, and $C^{23}H^{16}O^{10}.H^2O$. According to the more recent experiments of Hlasiwetz and Pfaundler, anhydrous quercetin is $C^{27}H^{18}O^{12}$, and there are two hydrates containing $2C^{27}H^{18}O^{12}.H^2O$ and $C^{27}H^{18}O^{12}.H^2O$. [For analyses, see Gmelin's *Handbook*, xvi. 492, and the memoir of Hlasiwetz and Pfaundler above cited.]

Quercetin melts above 251° to a yellow liquid, without decomposition when quickly heated, and solidifies in the crystalline form on cooling. At a higher temperature, or when slowly heated even to 230°—250°, it sublimes with partial decomposition in yellow needles. It is inodorous, permanent in the air, and neutral.

Quercetin is nearly insoluble in cold, and but slightly soluble in boiling *water*, forming a yellow solution; easily in *alcohol* even when very dilute, much less freely in *ether*. It dissolves without decomposition in warm *acetic acid*, and in warm concentrated *hydrochloric acid*. From solution in alcoholic hydrochloric acid it separates on concentration in deep orange-yellow crystals.—Cold *nitric acid* dissolves it readily, and on heating the solution, oxalic acid is formed, together with a small quantity of picric acid.

Quercetin dissolves easily in alkaline liquids, forming golden-yellow solutions, from which it is precipitated in flocks by acids. It forms with *potash* the compound $C^{27}H^{18}O^{12}.K^2O$, or $C^{27}H^{16}K^2O^{12}.H^2O$, a corresponding compound with *soda*, and with *zinc-oxide* the compound $C^{27}H^{18}O^{12}.Zn''H^2O^2$. (Hlasiwetz and Pfaundler.)

The alcoholic solution of quercetin forms a brick-red precipitate with *neutral acetate of lead.*—*Ferrous chloride* colours the alcoholic solution dark-red, but scarcely affects the aqueous solution.—*Ferric chloride* colours the aqueous solution dark-green, even when very dilute, the colour changing to dark-red when heated. An alcoholic solution of quercetin mixed with alcoholic ferric chloride and evaporated, leaves a dark-green amorphous mass, nearly insoluble in water, but dissolving completely in alcohol and ether, the solutions having the colour of chlorophyll. (Pfaundler.)

Quercetin easily reduces *nitrate of silver* at ordinary temperatures, *chloride of gold* at the boiling heat, and *cupric oxide* in alkaline solution. When heated, or left for some time in contact with aqueous *ammonia*, it forms quercetamide. (Schützenberger and Paraf, p. 2.)

Quercetin heated with *potash* yields quercetic acid and other products, varying according to the duration of the action. When it is heated with 3 pts. potassium-hydrate till a sample dissolved in water exhibits a purple-red colouring on the edges, the product consists chiefly of quercetic acid, phloroglucin, and paradatiscetin,* $C^{15}H^{10}O^{6}$ (formerly called by Hlasiwetz *alpha-quercetin*, and regarded as $C^{29}H^{20}O^{12}$), which separates in yellow flocks on the addition of hydrochloric acid. If the action be further prolonged, protocatechuic and quercimeric acids are produced by the decomposition of the quercetic acid, also a body which has not been obtained in the free state, but remains in the mother-liquor from which the phloroglucin has been deposited, and is characterised by yielding a fine violet colour with carbonate of sodium and indigo-blue with strong sulphuric acid.

Hlasiwetz and Pfaundler regard quercetin as a compound of quercetic acid and morin:

$$\underset{\text{Quercetin.}}{C^{27}H^{18}O^{12}} = \underset{\text{Morin.}}{C^{12}H^{8}O^{5}} + \underset{\text{Quercetic acid.}}{C^{15}H^{10}O^{7}}$$

a view of its composition which explains the formation of quercetic, quercimeric, and protocatechuic acids, but not that of paradatiscetin. The quercimeric and protocatechuic acids are formed as shown by the equation already given (p. 4). The phloroglucin appears to be formed from paradatiscetin, thus:

$$2C^{15}H^{10}O^{6} + 5H^{2}O + O^{4} = 5C^{6}H^{6}O^{3}.$$

The quantity of phloroglucin produced is greater as the action is more prolonged. [The mode of formation of quercetic acid and phloroglucin according to the older formulæ of quercetin has been already given, p. 3.]

When a solution of quercetin in dilute soda-ley is treated with *sodium-amalgam* (containing 3 or 4 per cent. sodium) till the liquid has acquired a light brownish-yellow colour, then neutralised with hydrochloric acid, and shaken up with ether, the ether extracts phloroglucin, together with two other bodies which may be separated by precipitation with acetate of lead. On decomposing the precipitate with sulphydric acid, and evaporating the filtrate in a vacuum, a crystalline powder is first deposited, consisting of a body, A, having the composition $C^{13}H^{12}O^{5}$, while another body B, consisting of $C^{7}H^{8}O^{3}$, separates in granular crystals from the mother-liquid after longer standing and repeated evaporation.

The less soluble body A is a weak acid, which crystallises from hot water in slender prisms, and dissolves easily in alcohol and ether; its alcoholic solution is coloured dark-violet by ferric chloride, and violet changing to brown-yellow by potash. By renewed treatment with sodium-amalgam it is converted into phloroglucin; by fusion with potash, into phloroglucin and protocatechuic acid:

$$C^{13}H^{12}O^{5} + O^{2} = C^{6}H^{6}O^{3} + C^{7}H^{6}O^{4}.$$

The other body B is also a weak acid: it melts at 130°; its aqueous solution is coloured dark yellow-red by a drop of caustic potash, green by ferric chloride, and then purple-violet on addition of sodic carbonate. It reduces silver-solution and alkaline cupric solutions, and is converted by fusion with potash into protocatechuic acid:

$$C^{7}H^{8}O^{3} + H^{2}O = C^{7}H^{6}O^{4} + 2H^{2}.$$

An alcoholic solution of quercetin acidulated with hydrochloric acid is converted by sodium-amalgam into a red body (Stein's *paracarthamin*, iv. 341), which is easily reconverted into quercetin. (Hlasiwetz and Pfaundler.)

QUERCIMERIC ACID. $C^{8}H^{10}O^{5}$.—Produced by the action of melting potash on quercetic acid, or by its prolonged action on quercetin. When quercetin is fused with hydrate of potassium till the mass no longer froths up in large bubbles, and a sample of it dissolves, no longer with golden-yellow, but with tawny-yellow colour, changing to red more quickly on exposure to the air, quercimeric acid is sometimes found in the solution, instead of, or together with, quercetic acid, and separates from the mother-liquor in granular crystals, which may be purified by repeated fractional crystallisation and decolorisation with animal charcoal, or by decomposition of the lead-precipitate with sulphydric acid.

Quercimeric acid in the crystalline state contains $C^{8}H^{6}O^{5}.H^{2}O$. It is colourless, has an acid reaction and astringent taste, dissolves readily in water, alcohol, and ether, and separates therefrom, in granular or small prismatic crystals. The aqueous solution immediately becomes purple-red on addition of a trace of alkali, dark-blue with ferric chloride. Like quercetic acid, it reduces nitrate of silver and alkaline cupric solutions, and is precipitated by acetate of lead. When fused with potash, it yields protocatechuic acid:

---

* To obtain this substance pure, it is dissolved in alcohol; the solution is mixed with acetate of lead, which throws down quercetin; the liquid freed from lead by sulphuric acid, and concentrated to two-thirds, is mixed with water; and the flocks thereby separated are crystallised from very weak spirit. Paradatiscetin is thus obtained in yellowish needles. It is probably isomeric with datiscetin (ii. 306) and luteolin (iii. 736); dissolves easily and with acid reaction in dilute alcohol, less easily in alcohol, and is nearly insoluble in water. The alcoholic solution is coloured violet by ferric chloride, yellow by potash, turning green on exposure to the air, red or red-brown by aqueous bromine or chlorine. It reduces nitrate of silver and alkaline cupric solutions when heated with them. When boiled with alkaline earths, it yields hydrated salts crystallising in long needles. By fusion with hydrate of potassium it yields phloroglucin, but no quercetic or protocatechuic acid. (Hlasiwetz and Pfaundler.)

$$C^8H^6O^5 + O = C^7H^6O^4 + CO^2.$$

QUERCITANNIC ACID. An acid of unknown composition, extracted from oak-bark, and exhibiting with ferric salts the same reactions as gallotannic acid. It differs however from the latter in not being convertible into gallic acid, and not yielding pyrogallic acid by dry distillation. It is precipitated by sulphuric acid in red flocks. (Stenhouse, Ann. Ch. Pharm. xlv. 16.)

According to Rochleder (*ibid.* lxiii. 202), the tannic acid of black tea is the same as that of oak-bark.

QUERCITE. $C^6H^{12}O^5$. *Quercin. Sugar of Acorns.* (Braconnot, Ann. Ch. Phys. [3] xxvii. 392.—Dessaignes, Ann. Ch. Pharm. lxxxi. 103 and 251.)—A saccharine substance contained in acorns. To prepare it, the aqueous extract of bruised acorns is freed from dissolved tannic acid by heating it with lime; the filtrate is left to ferment with yeast, to remove fermentable sugar; the filtered liquid is evaporated to a syrup; and the crystals which separate after a while, are washed with alcohol, and recrystallised from water or weak spirit.

Quercite forms hard monoclinic crystals, grating between the teeth. It is permanent in the air, and does not alter even at 215°, but melts at 235°, with partial sublimation and slight carbonisation. It dissolves in 8 to 10 parts of water, forming a solution which takes up a small quantity of lime; also in hot dilute alcohol.

Quercite triturated with strong *sulphuric acid*, forms a conjugated acid, the calcium-salt of which does not crystallise. By hot *nitric acid* it is converted into oxalic, not into mucic acid. A mixture of *nitric* and *sulphuric acids* converts it into nitroquercite, which is a white amorphous resin, insoluble in water, soluble in hot alcohol, reduced to quercite when its alcoholic solution is treated with sulphydric acid.

With *baryta*, quercite forms a compound containing $C^{12}H^{24}O^{10}.Ba''O.2H^2O$. It forms a white precipitate with a warm solution of *basic lead-acetate* mixed with ammonia.

Benzoquercite, $C^{20}H^{20}O^7 = C^6H^{10}O^5.(C^7H^5O)^2$.—A solid neutral compound produced by heating quercite with benzoic acid to 200° in sealed tubes. It is insoluble in water, soluble in ether and in alcohol. When dissolved in absolute alcohol and treated with hydrochloric acid gas, it is resolved into quercite and ethylic benzoate. (Berthelot, Compt. rend. xliv. 452.)

Stearoquercite, $C^{42}H^{80}O^7 = C^6H^{10}O^5.(C^{18}H^{35}O)^2$, is a white solid mass, which reacts like the preceding, and is obtained in a similar manner. (Berthelot.)

Quercitartaric acid, $C^{22}H^{32}O^{27} = C^6H^{12}O^5 + 4C^4H^6O^6 - 2H^2O$, is obtained like dulcitartaric acid (ii. 348) from quercite and tartaric acid. Its *calcium-salt*, $C^{22}H^{26}Ca^3O^{27}.2H^7O$, gives off 16·1 per cent. water at 110°. (Berthelot, Ann. Ch. Phys. [3] liv. 82.)

QUERCITRIN. *Quercitric Acid. Quercimelin.*—A neutral substance occurring in quercitron-bark, the bark of *Quercus tinctoria.*

Preparation.—1. The bark is boiled with water, the decoction is left to cool, and the impure quercitrin which separates is collected, then rubbed to a pulp with alcohol of 35° B., heated over the water-bath, collected on linen, and pressed, whereby the principal impurities are removed. The residue is dissolved in a larger quantity of boiling alcohol, the solution is filtered hot, and water is added to it till it becomes turbid, so that the greater part of the quercitrin separates before the liquid is quite cold. It is then collected, pressed, and purified by a repetition of the same treatment (Rochleder, J. pr. Chem. lxxvii. 34).[*]—2. The pulverised bark is exhausted with six parts alcohol of specific gravity 0·84 in a percolator, till the liquid is of a bright wine-yellow colour. The tincture is freed from tannic acid by precipitation with washed ox-bladder or isinglass-solution, and filtered; and after adding water, the alcohol is distilled off, when a quantity of brown resinous drops first separates, and afterwards quercitrin crystallises out. The crystals must be collected before remaining too long in the mother-liquor, then washed with cold water, and dissolved in absolute alcohol; and the filtrate, after addition of water, evaporated till it crystallises (Bolley, Ann. Ch. Pharm. xxxvii. 101; lxii. 136.—Rigaud, *ibid.* xc. 283).—3. The bark, in small pieces, is exhausted with boiling alcohol; the alcohol is distilled off; and the residue, while still warm, is mixed with a little acetic acid, and then with neutral acetate of lead; the filtrate, freed from lead by sulphydric acid, is evaporated; and the quercitrin which crystallises is purified by repeated crystallisation from alcohol (**Zwenger** and **Dronke**, Ann. Ch. Pharm. Suppl. i. 266).—**Stein** (J. pr. Chem. lxxxv. 351) apprehends, in this process, a decomposition of the quercitrin by the free acetic acid.

---

[*] The quercitrin remaining in the bark is obtained as quercetin by decomposing a second decoction with hydrochloric acid in the cold, then filtering, and heating to the boiling-point, the quercetin then separating. It is to be filtered whilst hot, as afterwards only a little impure quercetin is deposited from the solution. (Rochleder.)

Properties.—Hydrated quercitrin forms microscopic, partly rectangular, partly rhombic tablets having their obtuse lateral edges truncated; pale-yellow when pulverised. It is neutral, inodorous, tasteless in the solid state, bitter in solution, permanent in the air.

Air-dried quercitrin heated to 100° gives off, on the average, 5·74 per cent. water, and when heated to 165° for some time, a further quantity, amounting altogether to 11·81 per cent. of the air-dried substance. After dehydration, the quercitrin melts at 160° to a dark-yellow resin, which solidifies to an amorphous mass on cooling. (**Zwenger** and **Dronke**.)

Hlasiwetz and **Pfaundler** (Jahresb. 1864, p. 564) give for anhydrous quercitrin the formula $C^{33}H^{30}O^{17}$, and state that it forms three hydrates—$C^{33}H^{30}O^{17}.H^2O$, $C^{33}H^{30}O^{17}.2H^2O$, and $C^{33}H^{30}O^{17}.3H^2O$. Several other formulæ have been proposed for quercitrin. Hlasiwetz at different times assigned to it the formulæ $C^{29}H^{30}O^{17}$ and $C^{35}H^{36}O^{20}$, while Zwenger and Dronke regard it as $C^{19}H^{18}O^{10}$. It is by no means certain that the so-called quercitrins examined by these several chemists are identical with one another (p. 4). [For analyses and calculations, see Gmelin's *Handbook*, xvi. 497.]

Quercitrin is slightly soluble in cold, somewhat more soluble in boiling *water*; much more soluble in *alcohol*, slightly in *ether*. It dissolves also in warm *acetic acid*, in dilute aqueous *ammonia*, and in caustic *soda*; the ammoniacal solution gradually deepens in colour on exposure to the air.

Quercitrin is almost wholly precipitated from its solution by *neutral* or *basic acetate of lead*, the precipitate being readily soluble in acetic acid. Aqueous or alcoholic quercitrin is coloured dark-green by *ferric chloride*, even when diluted to 4,000 or 5,000 times its bulk (**Rigaud**). It is not coloured at first by *ferrous chloride*, but the solution turns greenish on exposure to the air. (**Zwenger** and **Dronke**.)

Decompositions.—1. Quercitrin yields, by dry distillation, empyreumatic products, together with yellow crystals of quercetin, and leaves a light difficultly combustible charcoal.—2. Solutions of quercitrin acquire a brown-red colour by exposure to the air (**Bolley**). Concentrated *nitric acid* produces a violent evolution of nitric oxide and carbonic anhydride, and forms a clear red-brown solution containing oxalic acid (**Rigaud**). Besides a large quantity of oxalic acid, there is produced a trace of picric acid (**Zwenger** and **Dronke**); none according to **Stenhouse** (Ann. Ch. Pharm. xcviii. 179). Dilute nitric acid, when warmed with quercitrin, produces at first the same splitting-up as other acids, afterwards more complete decomposition (**Rigaud**).—4. Quercitrin, heated with *oxide of manganese* and sulphuric acid (**Bolley**), with *chromate of potassium* and sulphuric acid (**Rigaud**), yields formic acid.—5. The dark-brown precipitate produced by *nitrate of silver* in solutions of quercitrin is quickly reduced to the metallic state (**Bolley**). Quercitrin reduces *nitrate of silver* and *trichloride of gold* quickly in the cold, *cuprate of potassium* only after continued boiling or long standing (**Zwenger** and **Dronke**).—6. *Oil of vitriol* forms with it a solution which soon becomes dark and black (**Rigaud**).—7. Quercitrin is decomposed, by boiling with dilute *mineral acids*, into quercetin, which separates, and a saccharine substance, also according to Rigaud by boiling with alum, but not by prolonged heating with acetic acid. The decomposition is not effected by emulsin (**Zwenger** and **Dronke**). According to Hlasiwetz and Pfaundler, the sugar produced is **isodulcite**, $C^6H^{14}O^6$,

$$\underset{\text{Quercitrin.}}{C^{33}H^{30}O^{17}} + H^2O = \underset{\text{Quercetin.}}{C^{27}H^{18}O^{12}} + \underset{\text{Isodulcite.}}{C^6H^{14}O^6}.$$

100 pts. of anhydrous quercetin were found to yield 25·5 pts. isodulcite; calculation requires 26·4 pts. Hlasiwetz formerly found 27·87 per cent. sugar, which he regarded as isomeric with glucose, representing its formation by the equation,

$$\underset{\text{Quercitrin.}}{C^{29}H^{30}O^{17}} = \underset{\text{Quercetin.}}{C^{23}H^{16}O^{10}} + \underset{\text{Sugar.}}{C^6H^{12}O^6} + H^2O,$$

which requires 27·4 per cent. Rigaud, on the other hand, found that 100 pts. of quercitrin yielded on the average 44·35 pts. sugar and 61·44 quercetin, and Stein obtained 62·9 pts. quercetin. These numbers agree approximately with the equation given by Zwenger and Dronke:

$$\underset{\text{Quercitrin.}}{C^{19}H^{18}O^{10}} + 2H^2O = \underset{\text{Quercetin.}}{C^{13}H^{10}O^6} + \underset{\text{Sugar.}}{C^6H^{12}O^6},$$

which requires 60·50 per cent. quercetin and 41·57 sugar. The great divergences in these results seem to indicate that substances differing from one another in constitution have been confounded together under the name of quercitrin.

QUERCITRON. A yellow dye-stuff consisting of the shavings and powder of the bark and alburnum of *Quercus tinctoria*, *Q. nigra*, or *Q. citrina*, a kind of oak indigenous in North America, especially in Carolina, Georgia, and Pennsylvania. It is used in America for tanning, in Europe for dyeing only. For the latter purpose, the aqueous decoction (which contains quercitrin) mordanted with alum or stannic chloride is employed. According to Leesching (Rep. of Patent Inventions, Jan. 1856, p. 55), a product of greater colouring power may be obtained by boiling the bark with dilute sulphuric acid or hydrochloric acid. This result is probably due to the conversion of the quercitrin into quercetin, which, according to Rigaud, produces much purer and brighter colours on tissues than quercitrin.

QUERCUS. *Oak.*—The wood of *Quercus sessiliflora*[*] has a specific gravity of 0·65, and in the air-dried state contains 48·8 per cent. carbon, 6·1 hydrogen, and 45·1 oxygen (Schadler and Petersen, Ann. Chem. Pharm. xvii. 139). Vogel (N. Jahresb. Pharm. vii. 367) found 49·5 C to 5·3 H, 43·7 O, and 1·5 ash; in the mould of oak-wood 52·5 C to 5·0 H, 40·6 O, and 1·9 ash. Sprengel (J. Techn. Chem. xiii. 383) found in the air-dried wood only 0·20 per cent. ash.

The leaves of the oak contain, according to Sprengel, 48 pts. water and 52 pts. dry substance, 25 pts. of which are soluble in water, and 57 pts. in dilute potash-ley. According to Boussingault (Ann. Ch. Phys. [2] lxvii. 408), 100 pts. of the dried leaves contain 2·1 per cent. nitrogen, and according to Sprengel, 100 pts. of the air-dried leaves yield 5·06 per cent. ash.

Oak-bark contains, besides quercitannic acid (p. 6), a small quantity of gallic acid, red tannin-deposit (oak-red), wax, pectin, and other vegetable constituents; it also yields 2 per cent. ash, consisting of lime, magnesia, oxides of iron and manganese, phosphoric, silicic, and carbonic acid. The proportion of soluble constituents in general and of tannin in particular, is less in old than in young bark, less also in the outer than in the inner bark. Davy (Gehl. N. Chem. J. iv. 343) found in 100 pts. of oak-bark,

	Extractive matter.	Tannin.
Inner white bark of old oaks	22·5	15·0
Inner white bark of young oaks	23·5	16·0
Entire bark in spring	12·7	6·0
Entire bark in autumn	—	4·4
Bark of oak underwood	—	6·6
Middle coloured bark	9·0	4·0

Fehling (Wurtemb. Gewerbebl. 1856, p. 77) found in old oak-bark about 9 per cent., in bark of better quality from 13 to 16 per cent., and in the best inner bark 19 to 21 per cent. tannin. Müller (Arch. Pharm. xxxviii. 266) obtained from the bark of stems two or three years old, about 11 per cent., and from that of older stems 5 per cent. tannin.

The barks of *Quercus sessiliflora*, *Q. pedunculata*, and *Q. Ilex* are extensively used in tannin. Oak-bark has also been used for the preparation of inks, and in medicine for its styptic and astringent qualities.

Acorns, *Glandus quercus*, the fruit of the oak, have been examined by several chemists. The shell or cup constitutes about one-fourth of the entire fruit. Shelled acorns contain, according to Brande, 20·3 per cent. starch, 2·9 tannin, 51·7 extractive matter and water, 7·1 wood-fibre, and 18·0 per cent. gluten. The results of analyses by other chemists are as follows:

Composition of shelled acorns.

	Löwig.	Braconnot.	v. Bibra.
Starch	38·0	37·0	34·9
Uncrystallisable sugar	—	7·0	8·1
Gum and extractive matter	6·4	5·0	—
Nitrogenous substances	—	15·0	7·3
Tannic acid	9·0	—	7·0
Fixed oil	4·3	3·3	3·8
Woody fibre	1·9	31·9	—
Water	—	31·8	
Vegetable mucilage, gum, woody fibre, &c.	—	—	44·0

---

[*] This is the common oak in Germany and the South of Europe, and is known as *Quercus Robur*. In England the latter term is applied to *Q. pedunculata*, which is the most common at the present day; but in former times, the sessile-fruited oak, which is a larger and finer tree and produces more durable *timber* than the pedunculated species, was the most abundant (see *Penny Cyclopædia*, article QUERCUS).

Braconnot also found citric acid and quercite in acorns. According to v. Bibra, they also contain a small quantity of volatile oil.

An infusion of roasted acorns (*acorn coffee*) is sometimes recommended as a tonic and astringent. The roasting converts part of the starch into dextrin, and forms bitter matter and empyreumatic oil.

The ash of acorns has been analysed:—*a.* By Graham, Stenhouse, and Campbell (Chem. Soc. Q. J. ix. 33); *b.* by Kleinschmidt (Ann. Ch. Pharm. l. 117), with the following results:—

	K^2O.	Na^2O.	CaO.	MgO.	Fe^2O^3.	P^2O^5.	SiO^2.	SO^3.	Cl.	CO^2.	
a.	54·9	0·6	6·1	4·3	0·5	11·1	1·0	4·8	2·5	13·7	= 99·5
b.	64·6	0·5	6·9	5·6	1·4	17 0	1·0	2·7	0·6	—	= 100·3

The cups of the acorns of *Quercus Ægilops* are imported from Smyrna, Cyprus, and other places in the Levant as *Valoniæ;* they are very rich in tannin, and are therefore used in place of gall-nuts; they likewise contain gallic acid. The tannin contained in them differs, however, from gallo-tannic acid, in not yielding pyrogallic acid by dry distillation. (Stenhouse.)

The cups of various kinds of oak, when distorted by the punctures of the gall-wasp, form the so-called oak-apples. These are also used in tanning, but they contain only a small proportion of tannic acid. The true gall-nuts or nut-galls are excresences produced on the leaves and leafstalks of the dyer's oak (*Quercus infectoria*), by the punctures of the same insect (ii. 762).

QUICKSILVER. Syn. with MERCURY.

QUILLAYA. The bark of *Quillaya saponaria*, a tree growing in Mexico, yields a soapy infusion, which is used for washing. It contains a considerable quantity of saponin; also deposits of crystalline oxalate and tartrate of calcium, formerly mistaken for sulphate. (Flückiger, Jahresb. 1862, p. 524; 1863, p. 610.)

QUILLAYIN. A name applied to saponin from quillaya-bark, before its identity with saponin from other sources was recognised.

QUINANILIDE, or *Phenyl-quinamide.* $C^{13}H^{17}NO^5 = N.C^7H^{11}O^5.C^6H^5.H.$ (O. Hesse, Ann. Ch. Pharm. cx. 335.)—This compound is produced by heating quinic acid with excess of aniline to 180°, freeing the product from unaltered aniline by means of ether, and dissolving the residue in ether-alcohol. The solution on cooling deposits quinanilide in small white silky needles, containing 1 at. water, which they give off at 90°. It melts at 174° (corrected), and decomposes without subliming when heated above 240°. It dissolves easily in water and in alcohol, sparingly in ether.

QUINCE. *Cydonia vulgaris.*—The juice of quinces contains malic acid. Lancaster (Am. J. Pharm. xxxi. 198) obtained 1·6 grm. crystallised malate of lead from the acid contained in 453 grms. of the fruit. The seeds contain a large quantity of mucilage (ii. 953).

QUINCITE. A hydrated silicate of magnesium, occurring near the village of Quincey in France, in light carmine-red particles disseminated through a limestone deposit. Contains, according to Berthier, 64 per cent. silica, 19 magnesia, 8 ferrous oxide, and 17 water (= 98). Strong concentrated acids dissolve out the magnesia and iron, leaving gelatinous silica. (Dana, ii. 281.)

QUINETIN. The name given by Marchand (J. Pharm. xiv. 247) to a product which he obtained by oxidising quinine with peroxide of lead and sulphuric acid. It was not, however, a definite compound, as it was separable by water into a red bitter substance, soluble therein, and another substance insoluble in water but crystallisable from alcohol.

QUINHYDRONE. Green Hydroquinone (iii. 213).

QUINIC ACID. $C^7H^{12}O^6$. *Kinic acid. Chinasäure. Acide quinique.* (Hofmann, Crell. Ann. ii. 314.—Vauquelin, Ann. Chim. lix. 162.—Pelletier and Caventou, Ann. Ch. Phys. [2] xv. 340.—Liebig, Pogg. Ann. xxi. 1; xxix. 70.—Baup, Ann. Ch. Phys. [2] li. 5.—Woskresensky, Ann. Ch. Pharm. xxiv. 257.—Hesse, Ann. Ch. Pharm. cx. 194, 333; cxii. 52; cxiv. 292; *Untersuchungen über die Chinongruppe*, Göttingen, 1860.—Clemm, Ann. Ch. Pharm. cx. 345.—Zwenger and Siebert, *ibid.* cxv. 108; Suppl. i. 77.—Zwenger and Himmelmann, *ibid.* cxxix. 203.—Gm. xvi. 222).

This acid was first isolated in 1785 by Hofmann, an apothecary of Leer, from the calcium-salt of cinchona-barks, already known by the researches of Hermbstädt, Deschamp, and others; afterwards, in 1806, by Vauquelin.

Occurrence.—In the true cinchona-barks, in the bilberry plant (*Vaccinium Myrtillus*), and in coffee-beans; also in the leaves of the coffee-plant, and of the common holly (*Ilex Aquifolium*), of *Ilex paraguayensis*, privet (*Ligustrum vulgare*), ivy (*Hedera Helix*), the common oak (*Quercus Robur*), the evergreen oak (*Q. Ilex*), the common elm (*Ulmus campestris*), the ash (*Fraxinus excelsior*), and *Cyclopia latifolia*, inasmuch as Stenhouse (Phil. Mag. [4] vii. 21) found that all these leaves, as well as coffee-beans, when distilled with sulphuric acid and manganic peroxide, yield quinone, which is a product of the decomposition of quinic acid. The ericaceous plants, *Calluna vulgaris*, *Pyrola umbellata*, *Rhododendron ferrugineum*, and *Arbutus Uva Ursi*, yield by dry distillation hydroquinone,* also derived from quinic acid, or, in the case of the arbutus, probably from arbutin.

Preparation of the calcium-salt.—a. From Cinchona-bark: 1. The liquid obtained by precipitating the sulphuric acid extract with milk of lime in the preparation of quinine (p. 16), is evaporated to a syrup, decanted from sulphate of calcium, and evaporated over the water-bath to a soft extract; this is boiled two or three times with alcohol; and the residue is dissolved in a small quantity of water. The solution, after standing for some days, solidifies to a crystalline mass, which is strongly pressed and purified by recrystallisation. The mother-liquor yields a further quantity of the salt (Henry and Plisson).—2. A decoction of cinchona-bark, in water containing sulphuric acid, is filtered whilst hot, and to the filtrate freshly precipitated oxide of lead is gradually added, until the liquid becomes neutral, and exhibits no longer a red but a pale-yellow colour. (If too little oxide be added, colouring-matter remains in solution; if too much, basic quinate of lead is thrown down). The filtrate is freed from lead by sulphydric acid and filtered; milk of lime is then added, to precipitate the quinine and cinchonine; and the filtered liquid is evaporated to a syrup, which yields, on cooling, a crystalline mass of calcic quinate (Henry and Plisson).—The deposit frequently found in extract of cinchona is impure quinate of calcium; it may be obtained in crystals by precipitating an aqueous solution with neutral acetate of lead, removing the excess of lead by sulphydric acid, and evaporating. (Oenicke, Pharm. Centr. 1838, p. 158.)

β. From the Bilberry plant.—The fresh plant, collected in May, is boiled in water with addition of lime; the decoction is evaporated, and the quinate of calcium thrown down by alcohol. The glutinous precipitate, dissolved in water containing acetic acid, is freed from colouring-matter by addition of neutral acetate of lead, then filtered; and the filtrate (freed from lead) is evaporated to a syrup, from which the quinate of calcium crystallises after some days. (Zwenger.)

γ. From Coffee-beans.—The thoroughly-dried (or roasted) and coarsely-powdered beans are boiled repeatedly in water; the decoction, after being mixed with milk of lime, is concentrated, first over an open fire, and later, after filtration, on a water-bath, to a syrup; twice its volume of alcohol is then added; and the precipitate thereby formed is separated, after 24 hours, from the solution, which contains caffeine. The precipitate is washed with alcohol, pressed, and dissolved in hot water. The filtered solution is slightly acidified with acetic acid, and precipitated with neutral acetate of lead, whereby tannate of lead and other substances are thrown down; and after separating these by filtration, the quinic acid is precipitated by basic acetate of lead. The lead-salt thus obtained, after being washed and decomposed under water with sulphydric acid, yields aqueous quinic acid, which is converted into the calcium-salt by neutralisation with carbonate of calcium. (Zwenger and Siebert.)

The quinate of calcium is purified by repeated crystallisation, or by precipitating it with alcohol of sp. gr. 0·849, and dissolving in alcohol of sp. gr. 0·948.

Separation of the acid from the calcium-salt.—1. A solution of the calcium-salt in water is decomposed by an exactly equivalent quantity of oxalic acid, filtered from the oxalate of calcium, and evaporated to crystallisation (Vauquelin). Hesse employs a slight excess of oxalic acid, which he removes from the filtrate by means of neutral acetate of lead; the excess of lead is then removed by sulphydric acid.—2. An aqueous solution of the salt is precipitated by basic acetate of lead; the washed precipitate, suspended in water, is then decomposed by sulphydric acid; and the solution is filtered and evaporated (Berzelius).—3. The calcium-salt is decomposed by an aqueous or alcoholic solution of sulphuric acid.

Properties—Quinic acid crystallises in monoclinic prisms, $\infty P . oP$, with $nP\infty$ and $[nP\infty]$ subordinate; sometimes oP predominates so far as to give the crystals a tabular form. Angle $\infty P : \infty P = 146° 48'$; $\propto P : oP = 125° 45'$. Specific gravity $= 1·637$ at 8·5°. The acid does not lose weight at 100°, but melts, with loss of water, at 161·6° corrected (Hesse; Zwenger and Siebert); at 155° (Woskresensky), and solidifies on cooling to a hard amorphous mass. It exerts a left-handed action on polarised light, the molecular rotatory power being greater in a solution prepared with cold than in one prepared with hot water, least of all in a solution of the fused acid. (Hesse.)

---

* The hydroquinone thus produced was regarded by Uloth, who first obtained it from ericaceous plants, as a distinct substance, and called *ericinone*. Hesse, however, suggested its identity with hydroquinone, and the correctness of this view has been demonstrated by Zwenger and Himmelmann.

Quinic acid dissolves slowly in 2½ pts. of cold *water*, and in a much smaller quantity of boiling water. The solution, if quite pure, may be evaporated without turning yellow. The acid is very slightly soluble in *alcohol* of 94 per cent., but dissolves easily in alcohol of ordinary strength; it is nearly insoluble in cold *ether*.

Decompositions.—1. Quinic acid heated to 200°—225° gives off water, and is converted into quinide, $C^7H^{10}O^5 = C^7H^{12}O^6 - H^2O$. Other products are, however, formed at the same time: for the calculated loss of water, according to the preceding equation, is 9·95 per cent, whereas, according to Hesse, 10 per cent. are given off at 165°, and more than 13 per cent. at 220°. Quinic acid which has been heated above 200° contains small quantities of carbohydroquinonic acid (iii. 214), recognisable by its reaction with ferric chloride (Hesse).—2. The acid, when quickly heated in contact with the air, burns with a yellow flame, emitting an odour like that of burnt tartar.

3. Quinic acid subjected to dry distillation in a retort, melts, boils, and at about 280° turns brown, giving off water and a gas which burns with a pale-blue flame. At a higher temperature, it yields a sublimate of yellowish prisms, which melt and condense to an oily distillate containing hydroquinone (iii. 213), benzoic acid, phenol, benzene, and pyrocatechin.* The formation of hydroquinone is represented by the equa-acid:

$$C^7H^{12}O^6 = C^6H^6O^2 + CO + 3H^2O.$$

4. Quinic acid dissolves in strong *sulphuric acid* at a moderate heat, with evolution of carbonic oxide and formation of disulpho-hydroquinonic acid (iii. 217):

$$C^7H^{12}O^6 + 2SO^3 = C^6H^6S^2O^8 + CO + 3H^2O.$$

Sulphuric anhydride and fuming sulphuric acid also produce disulpho-hydroquinonic acid, but carbonise a large quantity of the quinic acid (Hesse).—5. A solution of quinic acid in aqueous *phosphoric acid* gives off a large quantity of gas when concentrated, and forms phospho-hydroquinonic acid (iii. 217):

$$C^7H^{12}O^6 + H^3PO^4 = C^7H^7PO^5 + CO + 4H^2O \text{ (Hesse).}$$

6. *Nitric acid* converts quinic acid into oxalic acid, another acid which has not been examined being also formed at the beginning of the action.—7. The aqueous acid treated with *peroxide of lead* gives off carbonic anhydride and yields hydroquinone (Hesse):

$$C^7H^{12}O^6 + PbO^2 = C^6H^6O^2 + CO^2 + 3H^2O + PbO.$$

8. Quinic acid or its salts distilled with *sulphuric acid* and *peroxide of manganese*, yields a yellow crystalline sublimate of quinone:

$$C^7H^{12}O^6 + O^2 = C^6H^4O^2 + CO^2 + 4H^2O.$$

This reaction is very delicate, and will indicate the presence of quinic acid in a few grammes of cinchona-bark. For this purpose the bark is boiled with milk of lime, and the alkaline filtrate concentrated by evaporation is treated in a small capsule with sulphuric acid and oxide of manganese: the presence of quinic acid is then immediately indicated by the pungent odour of quinone (p. 27), (Stenhouse, Ann. Ch. Pharm. liv. 100).—9. The acid distilled with *peroxide of manganese*, *sulphuric acid*, and *common salt*, yields a distillate containing mono-, di-, tri- and tetrachloroquinone together with pentachloracetone. The same products, together with lower chlorinated acetones, are obtained by boiling quinic acid with hydrochloric acid and chlorate of potassium (Städeler, Ann. Ch. Pharm. lxix. 300; cxi. 293); also carbohydroquinonic acid. (Hesse.)

10. *Bromine* dropped into aqueous quinic acid converts it into carbohydroquinonic acid.

11. Quinic acid heated for several hours to 115°—120° with saturated aqueous *hydriodic acid*, is converted into benzoic acid. The same product is formed when a syrupy solution of quinic acid is distilled with 4 at. diniodide of phosphorus. When quinic acid is heated to 140° with hydriodic acid and phosphorus (the addition of which prevents the action of free iodine), an acid is produced containing 6 at. hydrogen more than benzoic acid. The reduction appears, therefore, to take place as follows:—

$$\underset{\text{Quinic acid.}}{C^7H^{12}O^6} + 8HI = C^7H^{12}O^2 + 4H^2O + 4I^2;$$

and

$$C^7H^{12}O^2 + 4I^2 = \underset{\text{Benzoic acid.}}{C^7H^6O^2} + 6HI + I^2.$$

---

* Wöhler (Ann. Ch. Pharm. xlv. 354) found also salicylous acid; but according to Zwenger and Himmelmann, this body does not occur among the products of distillation of quinic acid.

Quinic acid in the form of calcium-salt is converted in the animal organism into hippuric acid. (Lautemann, Ann. Ch. Pharm. cxxv. 9.)

12. Quinic acid heated with *aniline* is converted into quinanilide. (Hesse, p. 9.)

Quinates. Quinic acid decomposes carbonates. It is monobasic, the general formula of its salts being $C^7H^{11}MO^6$. No acid or double quinates are known, but basic quinates of barium, lead, iron, and copper have been obtained. The quinates are for the most part crystallisable, and have a neutral reaction; with the exception of the basic lead-salt they are soluble in water, but insoluble in alcohol stronger than 32° Bm., and are separated from their solution by strong alcohol in the form of glutinous precipitates. Most of them retain their water of crystallisation at 100°. By dry distillation they yield formic acid and a sublimate of quinone (Woskresensky). Quinic acid acts like tartaric acid in preventing the precipitation of metallic oxides by alkalis. (Hesse.)

Quinate of Ammonium is deliquescent, and gives off part of its ammonia on evaporation.—The *potassium-salt* is bitter and deliquescent.—The *sodium-salt*, $C^7H^{11}NaO^6.5H^2O$, crystallises in six-sided prisms containing 14·5 per cent. water of crystallisation. It dissolves in half its weight of water at 15°.

Quinate of Barium, $C^{14}H^{22}Ba''O^{12}.6H^2O$, obtained by saturating the acid with carbonate of barium, crystallises in dodecahedrons formed by the junction of two acute six-sided pyramids. It contains 17·4 per cent. water of crystallisation, is very soluble in water, slightly soluble in alcohol of 83 per cent.

The *calcium-salt*, $C^{14}H^{22}Ca''O^{12}.10H^2O$, occurs, as already observed, in cinchona-bark, and is precipitated by chloride of calcium from alkaline quinates, after adding alcohol and ammonia, and leaving the mixture to stand. It crystallises in rhomboïdal plates of about 78° and 112°, often becoming hexagonal by truncation of the two acute angles, and easily splitting into shining laminæ. It dissolves in 6 pts. of water at 16°, its solubility varying greatly according to the temperature; nearly insoluble in alcohol. Contains, according to Baup, 29·5 per cent. water of crystallisation, which it loses at 100° (calc. 30·3 per cent.); it suffers no further loss of weight at 120°.

The *strontium-salt*, $C^{14}H^{22}Sr''O^{12}.10H^2O$, crystallises in tables apparently isomorphous with the calcium-salt, but distinguished by their rapid efflorescence, and the nacreous aspect which they assume on exposure to the air. It dissolves in 2 pts. of water at 12°, and in a much smaller quantity of boiling water. Contains 27·95 per cent. water of crystallisation, of which it loses three-tenths by efflorescence.

The *magnesium-salt* is very soluble, and forms crystalline efflorescences like cauliflower-heads.—The *yttrium-salt* dries up to a gummy mass.

Quinate of Cadmium, $C^{14}H^{22}Cd''O^{12}$, forms dirty-white laminæ and small white crystalline needles, permanent at 180°, soluble in about 253 pts. of cold water.—The *cobalt-salt*, $C^{14}H^{22}Co''O^{12}.5H^2O$, separates from the dark-red solution, after it has been left for several days to dry up to a syrup and then diluted with water, in small red nodules, which quickly effloresce and assume a lighter colour. After drying over oil of vitriol, or in the air, it gives off 5 at. water at 150°, and becomes reddish-blue. Does not melt when burnt.

Quinates of Copper.—*α.* The *normal salt*, $C^{14}H^{22}Cu''O^{12}$, is obtained by mixing aqueous quinic acid in excess with hydrate or carbonate of copper, and cooling the resulting solution, or leaving it to evaporate, any portion of green basic salt that may be precipitated at the same time being removed, and the neutral salt crystallised from water containing quinic acid. It forms pale-blue laminæ or needles, which contain 5 at. water of crystallisation, and give off two-thirds of it in contact with the air: dissolves in about 3 pts. of cold water, the solution decomposing on standing, and more quickly when heated, with separation of a basic salt.—*β.* A *basic salt*, $C^{14}H^{22}Cu''O^{12}.Cu''H^2O^2.2H^2O$, or $C^7H^{10}Cu''O^6.2H^2O$, is obtained:—1. By decomposing the barium-salt with somewhat less than the equivalent quantity of cupric sulphate, and adding a few drops of baryta-water to the clear filtrate, which then, on standing or evaporating, deposits regular crystals.—2. By boiling aqueous quinic acid with excess of cupric hydrate, and precipitating the filtrate with ether-alcohol. In this mode of preparation, however, it is difficult to separate the sparingly soluble salt from the excess of cupric hydrate.—3. The salt is likewise formed in small quantity, with evolution of acetic acid, on evaporating a solution of calcic quinate with cupric acetate. Over oil of vitriol it gives off only its adhering water (Kremers), amounting to between 1 and 2·5 per cent. Between 100° and 120°, it gives off all its water of crystallisation (Liebig), and decomposes at a temperature above 140°. Dissolves in 1150 to 1200 pts. water at 18°.

The *ferric salt* is a yellowish-red gummy mass, easily soluble in water.

Lead-salts.—*a.* The *normal salt*, $C^{14}H^{22}Pb''O^{12}.2H^2O$, forms needle-shaped crystals soluble in alcohol and extremely soluble in water.—*β.* A *basic salt*, $C^{14}H^{18}Pb^4O^{12}$ or $C^7H^9Pb^2O^6$, is deposited as a white bulky precipitate on mixing an alkaline quinate with basic acetate of lead, or on adding a little ammonia to the boiling solution of the normal salt. It is insoluble in boiling water, soluble in basic acetate of lead, and quickly attracts carbonic acid from the air.

The *manganese-salt* crystallises in rose-coloured laminæ.—The *mercuric salt* is colourless, uncrystallisable, and yields on desiccation a yellowish-red residue, sparingly soluble in water.—The *nickel-salt* is a green, gummy, very soluble mass.

Silver-salt, $C^7H^{11}AgO^6$.—On adding nitrate of silver to an alkaline quinate, the mixture blackens, and quickly deposits metallic silver. The silver-salt may, however, be obtained by saturating a weak solution of the acid with recently precipitated carbonate of silver. The solution evaporated in a vacuum yields mammellated groups of crystals, which are perfectly white, but easily blacken when exposed to light.

The *zinc-salt*, $C^{14}H^{22}Zn''O^{12}$, resembles the cadmium-salt in appearance, but is very soluble in water.

QUINIC ETHER. *Ethylic Quinate*, $C^9H^{16}O^6 = C^7H^{11}(C^2H^5)O^6$, obtained by heating quinate of silver with ethylic iodide, is a yellow syrup, viscid at mean temperatures, mobile at 50°, having a bitter taste and aromatic odour, easily soluble in water and in alcohol, less soluble in ether. It appears to distil, partly without decomposition, between 240° and 250°, in a stream of carbonic anhydride, but a large portion of it is decomposed with intumescence at a temperature a little above 100°. Heated on platinum-foil, it first volatilises in white smoke, and ultimately burns away with a bright flame. (Hesse, Ann. Ch. Pharm. cx. 335.)

QUINICINE. $C^{20}H^{24}N^2O^2$. (Pasteur, Compt. rend. xxxvii. 111 and 166.)—An alkaloïd isomeric with quinine and quinidine, and produced by the molecular transformation of either of those bases. It is prepared similarly to cinchonicine (i. 971), by heating sulphate of quinine with a small quantity of water and sulphuric acid. The salt remains fused even after all the water has been expelled; and by three or four hours' heating in the oil-bath to 120°—130°, the whole mass is transformed into sulphate of quinicine, mixed with an extremely small quantity of colouring-matter.

Quinicine is insoluble in water, but very soluble in absolute alcohol and in spirit of ordinary strength. It is very bitter, possesses febrifugal properties, and is precipitated from its solutions by alkalis as a fluid resin. It turns the plane of polarisation to the right. It unites easily with carbonic acid, and expels ammonia from its compounds at ordinary temperatures. A solution of quinicine in aqueous racemic acid deposits at first chiefly the dextrotartrate, whilst the lævotartrate remains in the mother-liquor. Quinicine is coloured green by chlorine-water and ammonia, though less strongly than quinine. (Herapath.)

QUINIDE or *Quinic Anhydride*, $C^7H^{10}O^5 = C^7H^{12}O^6 - H^2O$.—Prepared by heating quinic acid to 220°—250°, dissolving the residue in boiling alcohol, and leaving the clarified solution to evaporate. When recrystallised from water, it forms small crystals resembling sal-ammoniac. It has an acid reaction, dissolves easily in water, sparingly in dilute alcohol, and in presence of certain bases is reconverted into quinic acid. (Hesse, Ann. Ch. Pharm. cx. 335.)

QUINIDINE. $C^{20}H^{24}N^2O^2$.—This base, isomeric with quinine, exists in certain cinchona-barks together with quinine and cinchonine. It was first observed in 1833, by Henry and Delondre (J. Pharm. xix. 633), in the quinoïdine of commerce, in which it exists, together with smaller quantities of quinine, cinchonine, and resin. Van Heijningen, however (Ann. Ch. Pharm. lxxii. 302), first separated it from this mixture in the pure state, and showed that it is isomeric with quinine. Its action on polarised light has been studied by Pasteur (Compt. rend. xxxvi. 26). Several of its double salts have been prepared and examined by Stenhouse (Proc. Roy. Soc. xii. 491).

Occurrence.—In cinchona-barks, especially in some of the yellow barks (Henry and Delondre). According to Howard (Pharm. J. Trans. v. 368), it occurs in certain varieties of *Cinchona condaminea*, more especially var. *pitayensis*; according to Henkel (N. Repert. Pharm. xiii. 200), in *Cinchona nitida*, together with cinchonine and a little quinine. The root-bark of *C. Calisaya* contains quinidine and a small quantity of quinine. The red bark of *C. officinalis*, *C. micrantha*, and *C. succirubra*, grown in the East Indies, and taken at the age of eighteen months or less, was found to contain 6 per cent. of alkaloïds, of which about 4 per cent. consisted of quinidine, cinchonidine, and quinine, and 0·9 per cent. of cinchonicine with traces of cinchonine (Howard). According to Pasteur, the quinidine of commerce is for the most part a mixture of true quinidine with a second base.

Preparation.—Commercial quinoïdine is dissolved in the smallest possible quantity of ether; the filtrate is freed from ether by distillation; the residue is dissolved in dilute sulphuric acid; the solution is decolorised by animal charcoal, and precipitated by ammonia; the washed precipitate is dissolved in ether; and the ethereal solution, mixed with one-tenth of its volume of alcohol of 90 per cent., is left to evaporate. It then deposits crystals of quinidine, which are purified by washing with alcohol. The mother-liquors saturated with sulphuric acid yield, first crystals of sulphate of quinidine, and afterwards of sulphate of quinine. Quinoïdine thus treated yields from 50 to 60 per cent. of quinidine. (van Heijningen.)

De Vrij (J. Pharm. [3] xxxi. 183, 369) dissolves commercial quinoïdine in the smallest possible quantity of alcohol, and neutralises the solution with aqueous hydriodic acid; whereupon crystals of hydriodate of quinidine, amounting to 23 per cent. of the quinoïdine employed, soon make their appearance.

Properties.—Quinidine separates from its hot ethereal or alcoholic solution in large transparent monoclinic prisms, which effloresce and become opaque when exposed to the air. They contain 2 at. = 10·8 per cent. water of crystallisation, which they give off between 110° and 130°. The anhydrous base melts at 160°, and solidifies in a resinous mass on cooling.

The composition of anhydrous quinidine is as follows:—

	Calculated.		Henry and Delondre.	van Heijningen. *mean.*	Stenhouse.
C^{20}	240	74·07	74·44	74·08	74·04
H^{24}	24	7·41	7·10	7·44	7·71
N^2	28	8·64	8·68	8·55	
O^4	32	9·88	9·78	9·93	
$C^{20}H^{24}N^2O^4$	324	100·00	100·00	100·00	

Quinidine (? crystallised) dissolves in 1500 pts. of cold and 750 pts. of boiling *water*; in 3·7 pts. of hot *alcohol* of ordinary strength; in 45 pts. of absolute alcohol, and 90 pts. of cold *ether* (van Heijningen). Its solution in absolute alcohol turns the plane of polarisation strongly to the right; [α] = 250·75° for the transition tint (Pasteur). This property distinguishes quinidine from quinine, which is lævorotatory.

According to Kerner (Zeitschr. Anal. Chem. i. 152), there are three varieties of quinidine—viz.: α. Slightly soluble in lukewarm ether, crystallising from alcohol in large slowly efflorescent prisms, forming a sulphate which dissolves in 180 to 300 pts. of cold water.—β. Much more soluble in ether; crystallises from alcohol in small needles; sulphate soluble in 10 to 110 pts. water, the solution yielding a pulverulent precipitate with iodide of potassium, whereas the sulphates of all other cinchona-bases, except quinine, yield oleo-resinous precipitates with iodide of potassium.—γ. Still more soluble in ether; the sulphate has the same solubility as that of the α modification.

Decompositions.—1. Quinidine *burns* on platinum-foil with an aromatic odour like that of melilot, and partly volatilises.—2. Quinidine-salts, when *heated*, are converted into salts of quinicine (p. 13). *Chlorine-water* and *ammonia* colour quinidine green, even in solutions containing only $\frac{1}{5000}$th of the alkaloïd (Pasteur; Herapath). In concentrated solutions a precipitate is formed, which is not the case with quinine (Herapath). *Chlorine-water, ferricyanide of potassium,* and *ammonia,* added in succession to salts of quinidine, produce a permanent bulky precipitate; whilst the same reagents produce, with salts of quinine, only a red coloration, which quickly disappears (Schwarzer, N. Jahrb. Pharm. xxiii. 348).—Quinidine forms with *iodine* and *sulphuric acid* a compound corresponding to sulphate of iodoquinine (p. 25).—Quinidine heated for half an hour with *iodide of ethyl,* forms hydriodate of ethylquinidine. (Stenhouse.)

Salts of Quinidine.—Quinidine forms mono- and di-acid salts, which resemble the salts of quinine, but are, for the most part, more easily crystallisable. The sulphates, the mono-acid hydrochlorate, and the oxalate exert a powerful action on polarised light (Herapath). These salts are in some cases more soluble than the corresponding salts of quinine, so that oxalic, acetic, and tartaric acids do not precipitate soluble quinidine-salts. The hydrochlorate and nitrate are more difficultly soluble. With excess of acid the salts are as highly fluorescent as those of quinine. The precipitate thrown down by ammonia in their solutions dissolves far less easily than quinine, but more easily than cinchonidine, in excess of ammonia. (Riegel.)

Acetate of Quinidine crystallises from its syrupy solution in fine transparent crystals.

The *hydrobromate* precipitated by bromide of potassium from the sulphate or hydrochlorate is soluble in 200 pts. water at 14°.

Hydrochlorates.—The *mono-acid* or *neutral salt*, $C^{20}H^{24}N^{2}O^{2}.HCl$, is obtained by dissolving the base in hydrochloric acid, or by precipitating a cold saturated solution of the sulphate with chloride of sodium, in crystals containing 1 at. water, which they give off at 120°. It dissolves easily in water and in alcohol (van Heijningen). The acid salt, $C^{20}H^{24}N^{2}O^{2}.2HCl$, is produced by exposing quinidine to the action of hydrochloric acid gas, 100 pts. of the base taking up 22·52 pts. of the acid (calc. = 21·91 pts.). Its aqueous solution yields large fine crystals. (van Heijningen.)

Chloro-aurate, $C^{20}H^{24}N^{2}O^{2}.2HCl.2AuCl^{3}$.—Pale-yellow precipitate, melting and turning brown when heated to 115°, or boiled with water. (Stenhouse.)

Chloromercurate, $C^{20}H^{24}N^{2}O^{2}.2HCl.Hg''Cl^{2}$.—White precipitate, separating from a solution in boiling alcohol in pearly laminæ. It melts under boiling water; dissolves slightly in cold, more easily in hot water, and especially in water containing hydrochloric acid, from which last solution it is occasionally deposited in the form of a resin. (Stenhouse.)

Chloroplatinate, $C^{20}H^{24}N^{2}O^{2}.2HCl.Pt^{iv}Cl^{4}.2H^{2}O$.—Precipitated immediately from cold concentrated solutions, in crystals after a while from hot or dilute solutions; decomposes at 200°, with an odour of white-thorn; dissolves with difficulty in water, either cold or boiling; gives off 4·86 per cent. water at 100°.

Chlorozincates.—Slightly acid solutions of chloride of zinc throw down from alcoholic quinidine a granular powder, slightly soluble in cold and in boiling water, easily soluble in dilute hydrochloric acid. The easily formed solution of the precipitate in alcohol of 50 per cent. yields crystals resembling calc-spar, and containing 26·7 per cent. of chlorine ($C^{20}H^{24}N^{2}O^{2}.2HCl.Zn''Cl^{2}$ = 26·65 per cent. Cl); when recrystallised, the compound gives up hydrochloric acid and chloride of zinc, and is ultimately transformed into large hexagonal tables and prisms. The latter contain 7·44 per cent. of zinc at 100°, and are, therefore, $2(C^{20}H^{24}N^{2}O^{2}.HCl).Zn''Cl^{2}$ (calc. = 7·58 per cent. zinc. (Stenhouse.)

Hydriodates.—The *mono-acid* or *neutral salt* is thrown down by iodide of potassium from sulphate or hydrobromate of quinidine, as a white granular precipitate, which dissolves in 1250 pts. water at 15°, and separates from a boiling saturated solution in small, white, very hard crystals (De Vrij). The *diacid salt* has a pale-yellow colour, and dissolves in 90 pts. water at 15°. (De Vrij.)

Nitrate.—Large, flat, shining crystals. (van Heijningen.)

Argento-nitrate, $C^{20}H^{24}N^{2}O^{2}.AgNO^{3}$.—An alcoholic solution of quinidine mixed with nitrate of silver solidifies to a mass of fine needles, which may be recrystallised from boiling water containing nitric acid. It then forms fine silky needles, having a silvery lustre when dry. When recrystallised from alcohol, it decomposes with separation of silver. (Stenhouse.)

Oleate.—Quinidine behaves like quinine (p. 21), with oleic acid and olive oil. (Attfield.)

Oxalates.—By neutralising oxalic acid with quinidine, a *neutral salt*, $2C^{20}H^{24}N^{2}O^{2}.C^{2}H^{2}O^{4}.H^{2}O$, is obtained in small brittle crystals, nearly insoluble in cold but freely soluble in boiling water (Stenhouse). According to van Heijningen, on the other hand, the salt thus obtained is an *acid salt* containing $C^{20}H^{24}N^{2}O^{2}.C^{2}H^{2}O^{4}.H^{2}O$.

Picrate.—A solution of quinidine in boiling picric acid deposits on cooling a resin, which does not crystallise by evaporation from solution in alcohol. (Stenhouse.)

The *succinate* forms pearly prisms. (Henry and Delondre.)

Sulphates.—The *neutral salt*, $2C^{20}H^{24}N^{2}O^{2}.H^{2}SO^{4}.6H^{2}O$, is very much like the corresponding quinine-salt, but more woolly. It dissolves at 10° in 350 pts. water, and in 32 pts. absolute alcohol. Gives off 12·6 per cent. water at 130° (calc. for 6 at. = 12·84 per cent.).

The *acid sulphate* is crystallisable and very soluble in water. (van Heijningen.)

Sulphate of Iodoquinidine.—When a dilute solution of di-acid sulphate of quinidine is heated to 70° or 80° with one-third or half its volume of alcohol, and a little tincture of iodine is added, long four-sided prisms of a deep garnet-red colour crystallise out. The crystals are purple-red by reflected and dark brown-red by transmitted light, and polarise light like the corresponding quinine-salt (p. 25). They dissolve in 121 pts. of cold and 31 pts. of boiling alcohol, from which they are precipitated by water in the form of a cinnamon-brown powder. They contain 32·76 per cent. C, 4·44 N, 3·98 H, 6·34 SO^{3}, and 39·73 I, corresponding, according to Herapath, to the formula $C^{38}N^{2}H^{19}O^{4}I^{3}.SO^{3}.HO$ + 5 aq.—Other and optically different crystals are obtained when tincture of iodine is dropped into a strong solution of di-acid sulphate of quinidine mixed with 30 or 40 volumes of alcohol at a temperature below 70°. (Herapath, Chem. Soc. Qu. J. xi. 139.)

Tannate of Quinidine.—Aqueous quinidine forms a white precipitate with tannic acid.

Tartrate of Quinidine.—Pearly crystals, obtained in the same way as the oxalate (van Heijningen). The dextro- and lævo-tartrates undergo the same transformation as the quinine-salts when heated. (Pasteur.)

Tartrate of Quinidine and Potassium.—Quinidine and cream of tartar yield crystals soluble in alcohol. (Henry and Delondre.)

Tartrate of Quinidine and Antimony, $C^{20}H^{24}N^2O^2.C^4H^5(SbO)O^6 = \left.\begin{matrix}(C^4H^4O^4)''\\ C^{20}H^{25}N^2O^2\\ SbO\end{matrix}\right\}O^2$. —1. Mono-acid tartrate of quinidine is boiled for some hours with freshly precipitated oxide of antimony, and the filtrate is left to evaporate.—2. Powdered quinidine is added to a cold saturated aqueous solution of tartar-emetic; the liquid is heated to boiling; and the excess of quinidine, together with the precipitated oxide of antimony, is separated by filtration from the solution of the double salt and neutral tartrate of potassium. Long slender needles, which, after drying in a vacuum, lose ½ to 1 per cent. of water at 100°. Dissolves slightly in cold, easily in hot water, and easily also in boiling alcohol, from which it crystallises. (Stenhouse.)

Ethylquinidine, $C^{22}H^{28}N^2O^2 = C^{20}H^{23}(C^2H^5)N^2O^2$.—Not known in the free state. The *hydriodate,* $C^{22}H^{28}N^2O^2.HI$, is obtained by heating quinidine with excess of ethylic iodide, and crystallises from boiling dilute alcohol in long silky needles, nearly insoluble in water. On removing the iodine by oxide of silver, and filtering, a bitter alkaline solution is obtained, which absorbs carbonic acid but yields no crystals. On decomposing the hydriodate with chloride of silver, and treating the filtrate with platinic chloride, *chloroplatinate of ethylquinidine,* $C^{22}H^{28}N^2O^2.2HCl.Pt^{iv}Cl^4$, is precipitated as a pale-yellow powder, which dissolves very slightly in water either hot or cold, more freely in hot dilute hydrochloric acid. (Stenhouse, Ann. Ch. Pharm. cxxix. 20.)

Sulphate of Iodethylquinidine is obtained in the same manner as the corresponding quinine-compound. (Herapath, p. 25.)

QUININE. $C^{20}H^{24}N^2O^2$. *Chinin.* The *cinchona resin* of the older chemists.—The memoirs cited under CINCHONINE (i. 973) relate also to quinine; see also Pasteur (Compt. rend. xxxvi. 26; xxxvii. 110, 162; Jahresb. 1853, p. 419; Schützenberger (Ann. Ch. Pharm. cviii. 347, 350; Jahresb. 1858, p. 369).—On quinine alone: Robiquet (Ann. Ch. Phys. [2], xvii. 316); Stratingh (Repert. Pharm. xv. 139); Pelletier (J. Pharm. xi. 249); Duflos (Berz. Jahresb. xxvii. 1, 110); Strecker (Ann. Ch. Pharm. xci. 155; Jahresb. 1854, p. 505).

This alkaloïd, the most important constituent of the true cinchona-barks, on account of its tonic and antifebrile properties, was first obtained, but in an impure state, by Gomez of Lisbon, and by Pfaff in 1811; Pelletier and Caventou, in 1820, succeeded in separating it from the other constituents of the bark, and examined many of its properties; and its composition was established by Liebig in 1838.

The proportions of quinine and of the other alkaloïds in various kinds of cinchona-barks, as determined by different analysts, have already been given in the article CINCHONA-BARKS (i. 970). The following table exhibits the average results of the several determinations of the quantities of quinine and cinchonine:—

1. Brown or Grey barks:		
Huanoco . .	0·4 per cent. quinine,	1·7 per cent. cinchonine.
Loxa . . .	0·35 „	0·34 „
Pseudoloxa . .	0·35 „	0·66 „
Huamalies . .	0·3 „	0·8 „
Jaen pallida .	0·56 „	0·60 „
2. Yellow or Orange barks:		
Royal or Calisaya bark.		
a. *plana* . .	2·2 per cent. quinine,	0·28 per cent. cinchonine.
b. *convoluta* .	1·1 „	0·42 „
Cinchona flava fibrosa	1·05 „	0·83 „
Cinchona flava dura	0·54 „	0·48 „
Pitaya . .	1·68 „	0·90 „
3. Red bark:		
Cinchona rubra .	0·91 per cent. quinine,	1·05 per cent. cinchonine.

According to M'Ivor, a covering of moss on the bark during its growth increases the percentage of the alkaloïds; and this observation has been confirmed by De Vrij, who found in a young bark covered with moss, 8·4 per cent. of alkaloïds.

The extraction of quinine and cinchonine from cinchona-barks, by treating the bark with a dilute acid, and precipitating with lime or carbonate of sodium, has been already described under CINCHONINE (i. 973); also the usual methods of separating the two, depending: *a.* On the greater solubility of sulphate of cinchonine in water, and the greater facility of crystallisation of the quinine-salt.—β. On the greater solubility of quinine in cold alcohol, and in ether. Thiboumery (J. Pharm. [3] xvi. 369) extracts the alkaloïds from the lime-precipitate with oil of turpentine or coal-oil, instead of alcohol; Herring uses benzene for the same purpose. These liquids dissolve the quinine, with very little cinchonine, and give it up again to dilute acids: they have the advantage of taking up less of the colouring-matter than alcohol does. When the alkaloïds have been precipitated by carbonate of sodium, hot fatty oils may also be used for the extraction. [For other methods, see *Gmelin's Handbook*, xvii. 266. For the quantitative estimation of the alkaloïds, in cinchona-barks, see the same work, xvii. 268; also this Dictionary, i. 968.]

Properties.—Quinine is precipitated by an alkali from the solutions of its salts, as a white curdy hydrate, porous and friable when dry, agglutinating when heated. By fusion in a vacuum, or by prolonged heating to 120°, it may be deprived of its combined water, leaving a white opaque mass, which has a crystalline surface and concentric radiated fracture, becomes strongly negatively electric when rubbed, and melts to a transparent liquid at a higher temperature.

Quinine is permanent in the air, inodorous, very bitter, and antifebrile. According to Robin (Compt. rend. xxxii. 650), it prevents putrefaction. It restores the blue colour of reddened litmus. In alcoholic solution it exerts a left-handed action on polarised light: $[\alpha] = -141{\cdot}33°$ at 25° for the red ray (De Vrij and Alluard, J. Pharm. [3] xlvi. 192); $= -121{\cdot}5°$ at 22·5° and $-129{\cdot}56°$ at 16°, weaker therefore in warm than in cold solutions. Acids increase the rotatory power; ammonia restores it to its original amount (Bouchardat, Ann. Ch. Phys. [3] ix. 213). For solutions of quinine in acetic or sulphuric acid, $[\alpha] = 287{\cdot}16°$ at 24° for the transition-tint; therefore 220·15° for the red ray. (De Vrij and Alluard.)

The composition of anhydrous quinine is as follows:

	Calculation.		Pelletier and Dumas.	Regnault.	Liebig.	Laurent.	Strecker.
C^{20} . .	240	74·07	75·02	73·38	74·09	73·41	74·05
H^{24} . .	24	7·41	6·66	7·65	7·57	7·10	7·50
N^{2} . .	28	8·64	8·45	8·55			
O^{2} . .	32	9·88	9·87	10·42			
$C^{20}H^{24}N^{2}O^{2}$	324	100·00	100·00	100·00			

Pelletier and Dumas gave the formula $C^{20}H^{10}NO^{2}$; Regnault $C^{11}H^{23}N^{2}O^{4}$; Laurent $C^{38}H^{22}N^{2}O^{4}$ or $C^{19}H^{22}N^{2}O^{2}$. The correct formula was deduced from Liebig's analyses.

Quinine forms two hydrates, containing respectively one and three atoms of water.

a. *Trihydrate*, $C^{20}H^{24}N^{2}O^{2}.3H^{2}O$.—This is the ordinary hydrate obtained by precipitation. When a dilute solution of quinine-sulphate mixed with excess of ammonia is left to evaporate, slender needles, consisting of the same hydrate, gradually form on the surface; when dried, however, they present the appearance of an amorphous powder. A solution of quinine in absolute alcohol leaves on spontaneous evaporation a resinous mass, containing a few needles of the trihydrate, but it does not crystallise readily from alcohol; the ethereal solution of quinine leaves nothing but a resinous mass.

β. *Mono-hydrate*, $C^{20}H^{24}N^{2}O^{2}.H^{2}O$.—When the amorphous trihydrate freshly precipitated and washed is exposed to the air and frequently moistened, it is slowly transformed into crystals of the mono-hydrate, which dissolve in warm alcohol, crystallise again on cooling, and give up their water at 130° (Van Heijningen, Jahresb. 1849, p. 374). This hydrate constitutes Van Heijningen's *γ-quinine*. It dissolves less easily than ordinary quinine in alcohol, and is said to form a neutral sulphate different from the ordinary salt. De Vrij (N. Jahrb. Pharm. xiv. 268) did not succeed in preparing it.

Quinine dissolves in 364 pts. of cold *water* (Duflos); in 480 pts. *water* at 18·75° (Abl); in 200 pts. of boiling water (Pelletier and Caventou); 267 pts. (Duflos). It is very soluble in *alcohol*, and dissolves in *ether*, much more easily than cinchonine. It dissolves also in *volatile oils, fixed oils*, and *chloroform*. It is not quite insoluble in aqueous *alkalis*, especially when recently precipitated from its salts. According to Duflos, however, it is precipitated from aqueous solution by alkalis and alkaline carbonates, so that the presence of acids probably influences its solubility. It dissolves in 2,146 pts. of *lime-water*. (Calvert.)

Decompositions.—1. Quinine when strongly heated in the air turns brown, burns with flame, evolving an aromatic odour, and leaves a bulky easily combustible charcoal. —2. Solutions of quinine-salts turn brown in *sunshine*.—3. They are violently acted upon by the *electric current* (Hlasiwetz and Rochleder).—4. With aqueous *nitrite of potassium*, sulphate of quinine evolves nitrogen, and is converted into oxyquinine

(Schützenberger, iv. 320).—5. A solution of quinine in strong *nitric acid* becomes coloured on heating (Riegel), without forming picric acid (Liebig).—6. A solution in oil of vitriol immediately colours *chromate of potassium* dark-green, with evolution of gas (Riegel and Eboli).—7. *Permanganate of potassium* acts upon quinine in the cold, and more completely at boiling heat, forming carbonate and nitrate of potassium, and a peculiar acid (Cloez and Guignet, Compt. rend. xlvii. 710).—8. *Peroxide of lead* colours a solution of quinine in sulphuric acid grey-brown (Riegel). When a solution of quinine-sulphate is boiled with peroxide of lead, and dilute sulphuric acid is gradually dropt into it, a red substance called quinetin, partly soluble in water, is produced. (Marchand, p. 9.)

9. In contact with *zinc* and dilute *sulphuric acid*, quinine takes up 1 at. of water, and is converted into hydroquinine, $C^{20}H^{26}N^2O^3$ (Schützenberger).—10. When heated to 240° or 260° with *water* in a sealed tube, it forms chinoline. (Reynoso, Compt. rend. xxiv. 795.)

11. The solution of quinine in *oil of vitriol* acquires a yellowish-brown colour when heated (Riegel); *fuming sulphuric acid* colours quinine yellowish-green (Schliekenkamp), forming quinine-sulphuric acid (Schützenberger).—Salts of quinine heated alone, or with sulphuric acid and water, are converted into salts of quinicine (p. 13; Pasteur).

12. Quinine assumes a dirty-yellow colour in vapour of *iodine* (Donne). When triturated with iodine, it forms a brown compound, which appears to be identical with the precipitate formed on adding a solution of iodine in iodide of potassium to a quinine-salt. Quinine is decomposed by aqueous *periodic acid*, with liberation of iodine (Bödeker). When quinine, or its sulphate, is warmed with an equal quantity of *iodic acid*, an explosive evolution of gas takes place. (Brett, J. Pharm. [3] xxvii. 116.)

13. Quinine, *sulphuric acid*, and *iodine* together yield sulphate of iodoquinine (p. 25).

14. Quinine exposed to a current of dry *chlorine*, takes up a large quantity of the gas; according to André, it assumes a carmine-red colour in a few seconds, and becomes soluble in water; but according to Pasteur, it turns greenish, and then gives up to boiling or cold water only a small quantity of a substance having an acid reaction, whilst the remainder behaves like the body formed by the action of chlorine on quinine suspended in water. Quinine suspended in water is reddened by chlorine (André and Pelletier). A solution of quinine in 400 pts. of water, acidulated with sulphuric acid, is not coloured or rendered turbid on passing chlorine into it for ten minutes. (Lepage, J. Pharm. xxvi. 140.)

When *chlorine-water* and then *ammonia* are added to a solution of a quinine-salt, a green precipitate is produced, which is dissolved by more ammonia to a fine emerald-green liquid. Exact neutralisation of the liquid colours it a sky-blue, changing to violet or fiery-red on further addition of acid; ammonia restores the green colour (André, J. Pharm. xxii. 132). In this way [especially by employing an ethereal solution (Leers)] mere traces of quinine may be recognised; quinidine, however, exhibits the same reaction.

The green colour is not produced by other alkalis instead of ammonia. It is not produced when the chlorine-water is allowed to act too long, nor with all proportions of chlorine-water and ammonia; since with too little chlorine-water, ammonia throws down a greenish-white precipitate, and with too much it produces a yellow coloration (Brandes). Reddish-green or brown colours may also be produced. (André.)

When 200 grains of sulphate of quinine are dissolved in 80 ounces of chlorine-water, and the solution is mixed at once with 10 ounces of ammonia-water, a green precipitate is produced, amounting to about 60 grains, whilst the liquid remains of a deep-green colour. The precipitate is Brandes and Leber's *dalleiochine:* the colouring-matter of the solution is not removed by agitation with ether, nor in an unchanged state by other means, but splits up on evaporation into red *rusiochine*, soluble in alcohol, and dark-brown *melanochine*, insoluble in water and alcohol. (See *Gmelin's Handbook*, xvii. 272.)

15. When strong chlorine-water free from hydrochloric acid is poured into a concentrated solution of sulphate of quinine, till the liquid exhibits a faint yellowish colour, and finely pulverised *ferrocyanide of potassium* is then added till the colour changes to light rose-red, this tint gradually changes to dark-red, especially on addition of a larger quantity of the ferrocyanide. The red colour is not due to the formation of any cyanogen-compound, for it may be equally well-produced by means of baryta or lime-water, or of sodic borate or phosphate. (A. Vogel.)

16. When quinine is heated with strong *potash-ley*, hydrogen is evolved, chinoline (i. 869) distils over, and the residue appears to contain formic acid. (Gerhardt and Wertheim.)

17. With *iodide of methyl* and *iodide of ethyl*, quinine forms hydriodate of methyl- or

ethyl quinine (p. 25). With *chloride of acetyl* and *chloride of benzoyl* it yields the hydrochlorates of acetyl and benzoyl-quinine (p. 26).

Quinine-salts.—Quinine neutralises acids completely, forming *mono-acid* or *neutral* and *di-acid* salts. The salts are, for the most part, more easily crystallisable and less soluble in water than the salts of cinchonine. They have a strong bitter taste, and frequently exhibit a pearly or silky lustre. They are precipitated by *alkalis* and their *carbonates*, by the *hydrates of calcium* and *magnesium*, and by *ammonia* and *carbonate of ammonia*, hydrate of quinine being thrown down in white flocks. The precipitate produced by potash, ammonia, or carbonate of potassium is pulverulent, and not crystalline or soluble, to any great extent, even in excess of the precipitant; the sulphate alone yields a precipitate easily soluble in excess of ammonia (v. Planta). *Cyanide of potassium* colours quinine-salts carmine-red (Schwabe). *Lime-water* added in excess to quinine-salts redissolves the precipitate formed at first. Solutions of quinine-salts containing excess of acid are highly fluorescent.

Acetate of Quinine, $C^{20}H^{24}N^2O^2.C^2H^4O^2$, crystallises in long needles, which melt to a colourless glass. It gives off acetic acid at the heat of the water-bath, is slightly soluble in cold, very soluble in boiling water. (Regnault.)

The *arsenate* forms needle-shaped prisms resembling the phosphate, but less pearly.

The *aspartate* forms indistinct crystals, easily soluble in water.

Borate.—A hot solution of quinine in aqueous boric acid yields crystalline granules on cooling; by spontaneous evaporation with an excess of boric acid, a varnish is obtained.

Carbonate, $C^{20}H^{24}N^2O^2.H^2CO^3.H^2O$.—This salt is not formed by precipitation; but when quinine precipitated from the sulphate by ammonia is suspended in water, and carbonic acid is passed into the solution till the quinine dissolves completely, an alkaline liquid is obtained, from which crystals of carbonate of quinine are deposited on exposure to the air for twenty-four hours. By spontaneous evaporation of the mother-liquor, quinine is obtained free from carbonic acid. The carbonate forms translucent needles, having an alkaline reaction, efflorescing rapidly in the air, and decomposing at 110°, with liberation of carbonic acid; they are soluble in alcohol, but insoluble in ether. (Langlois, Ann. Ch. Phys. [3] xli. 89.)

The *chlorate*, formed by dissolving quinine in warm aqueous chloric acid, crystallises in tufts of slender needles, melting to a colourless liquid, which solidifies to a transparent varnish; it explodes when strongly heated. (Serullas, Ann. Ch. Phys. [2] xlv. 279.)

Chromates.—The *neutral salt*, $2C^{20}N^2H^{24}O^2.CrO^3$, is precipitated from an aqueous solution of neutral or acid sulphate of quinine by neutral chromate of potassium, in the absence of free acids, and is slowly deposited in tufts of shining golden-yellow needles, not affected by light, but assuming a green colour when heated above 92°. It dissolves in 2,400 pts. of water at 15°, in 160 pts. of boiling water; in alcohol, but not in ether. (André.)

The *acid chromate*, $C^{20}H^{24}N^2O^2.CrO^3.8H^2O$, is thrown down by acid chromate of potassium from a cold aqueous solution of sulphate of quinine containing sulphuric acid, as an orange-yellow precipitate, consisting of microscopic needles. It decomposes rapidly in the light, turns brown at 60° or 65°, or when boiled with water, evolving oxygen. More soluble than the neutral salt. (André, J. Pharm. [3] xli. 341.)

The *citrate*, $2C^{20}H^{24}N^2O^2.C^6H^8O^7$, is a sparingly soluble salt, crystallising in delicate needles.

Croconate and *Rhodizonate of Quinine* are deep yellow or red amorphous masses, soluble in water and alcohol (Heller).—The *cyanurate* is a white amorphous mass (Elderhorst).—The *formate* crystallises easily in needles resembling the sulphate. (L. L. Bonaparte, J. Chim. méd. xviii. 680.)

Gallate.—Gallic acid and alkaline gallates form precipitates with all salts of quinine, provided the solutions are not too dilute. The precipitate dissolves in boiling water, the liquid becoming milky and yielding an opaque deposit on cooling. Gallate of quinine is soluble in alcohol and in excess of acid (Pelletier and Caventou). According to Pfaff and Henry, gallic acid and alkaline gallates, when free from tannin, do not precipitate quinine-salts.

Hydriodate of Quinine, $C^{20}H^{24}N^2O^2.HI$, is obtained by direct union of the acid and base, or by double decomposition, in nodular groups of delicate crystals (Pelletier), lemon-yellow prisms (Herapath). A solution of sulphate of quinine in boiling water, mixed with an equivalent quantity of iodide of potassium, yields on cooling nothing but crystals of sulphate of quinine; but when 240 pts. of hydrochlorate of quinine are mixed with 460 pts. of iodide of potassium, in hot aqueous solution, a colourless turpentine-like mass is deposited as the liquid cools (Winckler). Iodide of potassium throws down from acetate or hydrochlorate of quinine, a heavy white powder, which runs into drops (v. Planta). The hydriodate melts to a resin over the water-bath. It dissolves in water more freely than the sulphate; in nearly all proportions in alcohol, and in ether (Winckler, Jahrb. pr. Pharm. xx. 321). From a solution containing excess of hydriodic acid, an *acid hydriodate*, $C^{20}H^{24}N^2O^2.2HI.5H^2O$, separates, according to Regnault, in large laminæ having a fine yellow colour and strong acid reaction.

By mixing acid sulphate of quinine with solution of iodide of potassium, Righini (J. Chim. méd. xiii. 116), obtained a red powder, containing, according to his analysis, 50 per cent. of quinine, 30 of hydriodic acid, and 20 of iodine, being a mixture of hydriodate of quinine and iodoquinine. According to Reignier (*ibid.* 119), on dissolving this precipitate in alcohol, and evaporating the solution, transparent four-sided prisms are obtained, which turn dull and brown-red in the air.

Hydrochlorates.—The *neutral salt*, $2(C^{20}H^{24}N^2O^2.HCl).3H^2O$, is easily obtained by dissolving quinine in a slight excess of warm dilute hydrochloric acid, and separates on cooling in long silky fibres. It may also be prepared by precipitating sulphate of quinine with chloride of barium, but the salt thus formed soon turns resinous in presence of an excess of hydrochloric acid (Winckler). At 140° in a current of dry air it gives off 7·105 per cent. water of crystallisation. An *acid hydrochlorate* separates from a solution of quinine in a large excess of hydrochloric acid; but on redissolving it in water, the solution deposits the greater part of the quinine as neutral hydrochlorate.

The neutral hydrochlorate forms yellow precipitates with *auric* and *iridic chlorides*.—The *chloromercurate*, $C^{20}H^{24}N^2O^2.2HCl.Hg''Cl^2$, is obtained as a granulo-crystalline precipitate, by dissolving equal parts of quinine and mercuric chloride in strong alcohol, and mixing the liquids after adding a little hydrochloric acid to the quinine-solution. If weak alcohol is used, the precipitate forms more quickly, but is less crystalline. It is very slightly soluble in water, cold alcohol, and ether.—The *chloroplatinate*, $C^{20}H^{24}N^2O^2.2HCl.Pt^{iv}Cl^4.H^2O$, is obtained by adding platinic chloride to a solution of quinine in a slight excess of hydrochloric acid, as a yellowish flocculent precipitate which on agitation becomes orange-coloured and crystalline, sinking to the bottom of the vessel and attaching itself to the sides. It does not give off any water at 100°, but the whole, equal to 2·37 per cent. (1 at.), at 140°. (Gerhardt.)

Hydrocyanate.—Quinine triturated and agitated with aqueous hydrocyanic acid dissolves to a yellow liquid.

Cyanoplatinates.—A solution of quinine-sulphate precipitated with platinocyanide of potassium yields the salt $C^{20}H^{24}N^2O^2.2HCy.Pt''Cy^2.H^2O$, and with platinidcyanide of potassium, the salt $C^{20}H^{24}N^2O^2.2HCy.Pt^{iv}Cy^4$ (Wertheim, Ann. Ch. Pharm. lxxiii. 210).—According to Schwarzenbach (Pharm. Viertelj. viii. 210), platinocyanide of potassium throws down:—*α*. From a solution of quinine in aqueous acetic acid, a white precipitate of the salt, $3C^{20}H^{24}N^2O^2.2HCy.Pt''Cy^2$, partly converted into needles on standing.—*β*. From a solution of quinine in a moderate excess of sulphuric acid, a bulky white precipitate, which when left at rest is transformed into tabular crystals containing $2(C^{20}H^{24}N^2O^2.2HCy.Pt''Cy^2)H^2O$, warty groups of needles consisting of $C^{20}H^{24}N^2O^2.2HCyPt''Cy^2.H^2O$, and a resin having the same composition.

Hydroferricyanate of Quinine, $2(C^{20}H^{24}N^2O^2.H^3Fe'''Cy^3)3H^2O$, is precipitated by a concentrated aqueous solution of ferricyanide of potassium from a strong aqueous solution of hydrochlorate of quinine containing a little free hydrochloric acid in golden-yellow crystalline laminæ, which after drying resembles mosaic gold. The salt does not lose weight at 100°; dissolves easily in water, and deposits a blue powder on evaporating the solution (Dollfus, Ann. Ch. Pharm. lxv. 224).—The *hydroferrocyanate*, $C^{20}H^{24}N^2O^2.H^4Fe''Cy^6.2H^2O$, is an orange-yellow crystalline precipitate, obtained on mixing the alcoholic solutions of quinine and hydroferrocyanic acid.

Hypophosphite, $C^{20}H^{24}N^2O^2.H^3PO^2$.—To prepare this salt, 100 pts. of sulphate of quinine are heated to 94° with 6,000 pts. of water and 38·7 pts. of hypophosphorous acid; a quantity of hypophosphite of barium, barely sufficient for the complete decomposition of the sulphate, is then added, and the liquid is filtered and left to crystallise. The mother-liquor and wash-water yield colourless crystals only when cautiously evaporated.—It is a light very loose mass, having a pure bitter taste; melts and turns brown at 150°, with loss of water; dissolves in 60 pts. of water at 15·5°, and more easily in boiling water. (L. Smith, Zeitschr. Ch. Pharm. i. 159.)

Hyposulphite of Quinine, $C^{20}H^{24}N^2O^2.H^2S^2O^3$ (at 100°), is obtained by adding hyposulphite of sodium to a solution of hydrochlorate of quinine, as a flocculent precipitate sparingly soluble in cold water. It crystallises from hot alcohol in fine needles containing 1 at. water, which they give off at 100°, yielding a powder, strongly electric when hot.—*Hyposulphate.*—Deposited in crystals from a hot solution of sulphate of quinine mixed with hyposulphate of barium. (Wetherill, Ann. Ch. Pharm. lxvi. 150; How, Ed. N. Phil. J. [2], i. 47.)

Iodates.—The *neutral salt* crystallises in moderately soluble silky needles; the *acid salt* is a sparingly soluble precipitate. (Serullas.)

Lactate of Quinine crystallises by spontaneous evaporation, in flat silky needles resembling the neutral sulphate, but more soluble. It is said to be efficacious in the treatment of intermittent fever. (L. L. Bonaparte.)

Mellitate.—Alcoholic quinine produces, with solution of mellitic acid, an abundant white precipitate, which becomes pearly and crystalline when washed with weak alcohol. It does not lose water at 100°, but evolves a little water and ammonia at 130°, turning sulphur-yellow; dissolves very slightly in cold, and somewhat more freely in hot water, from which it is deposited as a crystalline powder on cooling. (Karmrodt, Ann. Ch. Pharm. lxxxi. 170.)

Morintannate.—Pale-yellow precipitate, slightly soluble in water, easily in alcohol.

Nitrate, $C^{20}H^{24}N^2O^2.HNO^3$.—An aqueous solution deposits on evaporation oily drops, which turn waxy, and when kept under water for many days are transformed into very oblique rhombic prisms (Pelletier and Caventou). Crystals are obtained only by evaporating the excess of acid, and dissolving the residue in water (van Heijningen).—When neutral sulphate of quinine is decomposed by nitrate of barium, and the filtrate is allowed to evaporate spontaneously, large transparent prisms separate, which give off 4·2 per cent. of water at 100° (1 at. = 4·4 per cent.) (Strecker).—*Argento-nitrate.* Alcoholic nitrate of silver throws down, from alcoholic solution of quinine, a crystalline precipitate containing 1 at. silver-oxide to 1 at. quinine. (Strecker.)

Oleate.—Quinine is nearly insoluble in olive-oil, and does not saponify when heated with it. When 1 pt. of quinine is digested with 2 pts. of oleic acid for one to two hours at 100°, a solution miscible with fat oil is obtained (Attfield, Pharm. J. Trans. 1863, pp. 4, 388). By the action of quinine on olive-oil or *margaric acid*, Tripier (J. Pharm. [3], xlvi. 234) obtained soaps miscible in all proportions with oils and fats. The very viscid "*Oleomargarate de Quinine*" thus formed ultimately crystallises by slow cooling in shining globules.

Oxalates.—The *neutral salt*, $2C^{20}H^{24}N^2O^2.C^2H^2O^4$ (at 125°), is obtained by precipitating a cold solution of the acetate with oxalate of ammonium, washing the precipitate with a little cold water, and recrystallising from boiling alcohol, which deposits it on cooling in very fine needles.—The *acid salt* forms needles very soluble in water.

Perchlorate, $C^{20}H^{24}N^2O^2.HClO^4.7H^2O$.—When sulphate of quinine is precipitated by perchlorate of barium, and the filtrate is evaporated, yellowish oily drops are deposited, which redissolve on gently warming the liquid, and afterwards separate in crystals on cooling. By concentration, the mother-liquor yields a further quantity of oil, which solidifies in contact with a crystal.—According to Bödeker, the salt forms striated prisms, exhibiting a faint dichroïsm of blue and yellow; according to Dauber (Ann. Ch. Pharm. lxxi. 65), it forms truncated rhombic octahedrons, cleavable parallel to the end-face. P : P basal = 149° 46′; macrodiagonal = 80° 30′; brachydiagonal = 107° 32′. The crystals melts at 45°, and likewise at a moderate temperature over oil of vitriol; and the fused salt solidifies on cooling to a clear brittle mass, which loses 14·3 per cent. of water at 110°, puffs up strongly at 150°, and solidifies again at 160°, having then lost 18·63 per cent. of water. On further heating, a violent explosion occurs, accompanied by flame.—Aqueous solutions of a certain strength yield highly lustrous, dichroïc, rhombic tables, which melt to an oil under water, but only at 210° when heated alone, losing 6·5 per cent. of water (2 at. = 6·4 per cent.). (Bödeker.)

Periodate, $C^{20}H^{24}N^2O^2.HIO^4$.—Freshly precipitated quinine neutralises aqueous periodic acid but incompletely in the cold, and on warming the liquid, iodic acid is formed. When the acid solution is evaporated over oil of vitriol, it becomes covered with oily drops, which are converted into crystals as the evaporation proceeds. The periodic acid contained in the crystals is reduced on keeping for a short time, the crystals acquiring a yellow colour. On neutralising the alcoholic solution, and evaporating at 30° to 40°, roundish masses of needles are obtained. They dissolve easily in water containing nitric acid, but with difficulty in pure water, and after drying at 40° retain 9 at., and at 100°, 6 at. water. (Langlois, Ann. Ch. Phys. [3], xxxi. 274.)

Phosphates.—Quinine dissolves easily in warm aqueous phosphoric acid, and the solution on cooling yields a pulpy mass of needle-shaped crystals. A more dilute solution deposits radiated groups of very thin silky needles, perfectly neutral to test-paper. They give off 7·57 to 7·85 per cent. water at 120°, and probably consist of

$3C^{20}H^{24}N^2O^2.2PH^3O^4$ (Anderson, Ann. Ch. Pharm. lxvi. 59), or, according to Gerhardt (*Traité*, iv. 118), of $2C^{20}H^{24}N^2O^2.PH^3O^4.2H^2O$.—A hot solution of sulphate or hydrochlorate of quinine mixed with a slight excess of sodic phosphate, deposits on cooling a white crystalline mass, very slightly soluble in water. (Winckler.)

A *pyrophosphate of quinine* is obtained by precipitating the hydrochlorate with sodic pyrophosphate.

Picrate.—Obtained by precipitation as a yellow powder, very slightly soluble in water, freely in alcohol. When boiled in water, it melts and floats on the surface in oily drops (L. L. Bonaparte). According to Carey Lea (Sill. Am. J. [2] xxvi. 379), it crystallises from the alcoholic solution in yellow needles; according to L. Bonaparte, the alcoholic solution does not yield any crystals.

Quinate of Quinine occurs in cinchona-barks (Henry and Plisson). A solution of sulphate of quinine mixed with quinate of barium deposits the salt usually in mammellated crusts, having a horny appearance at the edges, sometimes, however, in needles. It dissolves in 3·5 pts. water at 110°, and in 8 pts. of alcohol of 88 per cent. (Baup.)

Succinate of Quinine forms pearly prisms.

Sulphates of Quinine.—*a. Neutral salt,* $2C^{20}H^{24}N^2O^2.H^2SO^4$, commonly but improperly called *Basic sulphate of quinine.* This salt is produced by neutralising quinine with dilute sulphuric acid, a few drops of alkali added to the solution quickly determining the crystallisation (see also p. 16). It crystallises in scales, or in long slightly flexible needles, having a nacreous aspect The crystals are monoclinic, exhibiting the combination $oP\ .\ \infty P\infty\ .\ [\infty P\infty]$. Angle $oP\ .\ [\infty P\infty] = 95°\ 50'$; $\infty P\infty : [\infty P\infty] = 90°$. They are often hemitropic. Cleavage distinct, parallel to oP and ∞P. The salt is as light as magnesia, has a bitter taste, and effloresces quickly on exposure to the air.

The sulphate dried in the air at 8° to 15°, or over oil of vitrol diluted with 3·2 to 3·5 its volume of water, has the composition $2(2C^{20}H^{24}N^2O^2.H^2SO^4).15H^2O$; the moist salt loses its excess of water when placed over acid of this strength, whilst the air-dried salt does not alter in weight. When heated to 110° to 120°, it loses the whole of its water of crystallisation, but rapidly absorbs 4·87 to 5·1 per cent. again on exposure to moist air (4 at. = 4·82 per cent.) (Jobst and Hesse); the same quantity of water is retained by the salt dried over oil of vitriol [or in dry air (Baup)]. A solution of 1 pt. of the air-dried salt in 40 pts. or more of alcohol of specific gravity 0·852, deposits on evaporation white needles, containing 4 at. water. (Jobst and Hesse, Ann. Ch. Pharm. cxix. 361.)

Commercial sulphate of quinine contains quantities of water varying between 5·1 and 13·3 per cent. (Millon and Comaille). It usually appears half-effloresced, but still contains 15·6 per cent. of water. (Guibourt.)

The anhydrous salt dissolves in 793 pts. water at 6°, and in 788 pts. at 9·5 (Jobst and Hesse). One part of the salt [crystallised or dry?] dissolves in 265 pts. of cold, and in 24 pts. of boiling water (Bussy and Guibourt); in 335 pts. cold, and 33 5 pts. boiling (Howard); in 720° pts. at 18·75° (Abl); in 740 pts. at 13°, and in 30 pts. at 100° (Baup); in 740 pts. at 10° (van Heijningen; Cap and Garot). The commercial salt dissolves in 738 to 770 pts. of water at 12° to 15° (Kerner). It dissolves very sparingly in a cold saturated solution of Glauber's salt, and scarcely at all in Rochelle salt, so that the solution is scarcely clouded by ammonia, or coloured by chlorine-water and ammonia (Mann). The solubility of sulphate of quinine in water is reduced by sulphate of sodium and sulphate of magnesium, but increased by sal-ammoniac, saltpetre, and chlorate of potassium. (Calloud.)

One part of anhydrous sulphate of quinine dissolves in 100 to 115 pts. of alcohol of specific gravity 0·852; the strength of the alcohol, however, is altered by the salt dissolved in it (Jobst and Hesse). One part of the salt [crystallised or dry?] dissolves in 60 pts. of cold alcohol of specific gravity 0·85 (Baup); in 60 pts. of cold alcohol of 21° (Delondre and Henry); in 40 pts. of alcohol (Cap and Garot); in 7·5 pts. of boiling alcohol of 90 per cent. (Bussy and Guibourt), from which it is deposited almost entirely on cooling. Sulphate of quinine dissolves in 40 pts. of glycerin, but not in fatty oils (Cap and Garot; Attfield). It dissolves abundantly in creosote at 20°, and slowly in cold picamar (Reichenbach). It is insoluble in chloroform. (Schlimpert.)

The solution of quinine-sulphate in water acidulated with sulphuric acid turns the plane of polarisation of a ray of light strongly to the left. For the transition-tint $[\alpha] = 255·6$ for the anhydrous sulphate, and 210·87° for the sulphate with 15·72 per cent. water (De Vrij and Alluard, Compt. rend. lix. 201). The same solution exhibits a powerful blue fluorescence. (See LIGHT, iii. 633.)

Sulphate of quinine becomes luminous at 100°; the phosphorescence is likewise produced by friction, the rubbing body becoming charged at the same time with negative electricity very sensible to the electroscope. The salt melts easily, forming a liquid like melted wax. At a higher temperature it assumes a fine red colour, and ultimately burns and carbonises.

Impurities and Adulterations of Sulphate of Quinine.—Sulphate of quinine may be intentionally adulterated, either with inorganic substances (such as sulphate or carbonate of calcium or magnesium), the presence of which is detected on heating, or with organic substances. Of the latter class of bodies, starch-powder and stearin are recognised by their insolubility in acidulated water, and gum by its insolubility in alcohol; salicin, phlorizin, and cane-sugar assume a red or brown colour with oil of vitriol; the other varieties of sugar, as well as other substances soluble in water, remain in solution on boiling the sulphate with baryta-water, passing carbonic acid into the liquid, and filtering, and may be recognised on evaporating the solution. The pure sulphate thus treated leaves only a slight residue, corresponding to the solubility of the salt in water.

Since cinchonine and cinchonidine exist, together with quinine, in cinchona-barks, the sulphates of those bases may occur as impurities in sulphate of quinine. They may be recognised by the following *quinine-test* of Liebig:—10 grains of the sulphate to be tested are warmed with 10 drops of dilute sulphuric acid and 15 drops of water in a test-tube; the solution is cooled; 60 drops of commercial ether and 20 drops of ammonia-water are added; the whole is shaken; and the tube stopped. If the quinine is free from cinchonine, and does not contain more than 10 per cent. of quinidine, the whole remains in solution; but if cinchonine is present, it is deposited as a white pulverulent layer between the ether and the water, as is also the case with cinchonidine when present in large quantity. Smaller portions of cinchonidine crystallise from the ether on standing for a short time, and still smaller quantities when ether saturated with cinchonidine is employed in the first instance. As it sometimes happens that the upper ethereal layer solidifies to a jelly, even with pure sulphate of quinine, it is more convenient to employ ether containing alcohol, or to take a somewhat larger proportion of ether than is directed above. Guibourt evaporates the ammonia before adding the ether (J. Pharm. [3] xxi. 47).—Instead of ether, Riegel (Jahrb. pr. Pharm. xxv. 340) employs 100 drops of chloroform, whereby the cinchonidine also is dissolved. To separate this last substance, he dissolves 10 grains of the sulphate in water, with addition of tartaric acid, and adds acid carbonate of sodium to the solution. The resulting precipitate consists of cinchonine and cinchonidine, whilst quinine remains in solution. The cinchonine and cinchonidine may then be separated by chloroform. O. Henry (J. Pharm. [3] xiii. 107) likewise separates quinine and cinchonine by means of ether or cold alcohol, but first removes the greater part of the quinine by converting it into acetate (by precipitating with caustic soda and dissolving the precipitate in acetic acid), and crystallising out as far as possible.—Delondre and O. Henry (J. Pharm. [3] xxi. 281) triturate 10 grms. of the sulphate and 4 grms. of acetate of barium with 60 grms. of water and a little acetic acid, separate the crystals which form after a few minutes, and dilute the filtrate with twice its volume of alcohol of 36°. After adding a little sulphuric acid and again filtering, the liquid is boiled with excess of ammonia, and after standing for 24 hours, the cinchonine crystallises in needles. The cinchonine may also be obtained in crystals by dissolving 5 grms. of the sulphate in 120 grms. of warm acidulated alcohol, boiling the solution with excess of ammonia, and setting it aside for 24 hours. (For references to other methods see *Gmelin's Handbook*, xvii. 280.)

β. Acid sulphate, $C^{20}H^{24}H^2O^2.H^2SO^4.15H^2O$, improperly called *neutral sulphate.*—This salt, which always separates from a solution of quinine in excess of sulphuric acid, is distinguished from the neutral sulphate by its much greater solubility. It usually crystallises on cooling in small needles, but by evaporation in a hot-air chamber, it may be obtained in rectangular prisms terminated by a truncation, or by two, three, or four facets resting on the faces of the prism.

It melts in its water of crystallisation at 100°, dissolves in 11 pts. of water at 13°, and in 8 pts. at 22°; and in dilute or absolute alcohol, much more freely in the hot liquids than in the cold. From a solution in absolute alcohol it is deposited in crystals, which immediately fall to powder on exposure to the air. (Baup.)

Sulphate of Quinine and Iron.—A mixture of sulphate of quinine and ferric sulphate, left for some months in a partially-covered vessel, deposits this salt in small, perfectly regular, colourless octahedrons. (Will, Ann. Ch. Pharm. xlii. 111.)

Sulphate of Iodoquinine (see p. 25).

Sulphite of Quinine.—Dry quinine absorbs sulphurous anhydride with considerable evolution of heat, forming an anhydrous salt. (Liebig and Pelouze.)

Sulphocyanate of Quinine, $C^{20}H^{24}N^2O^2.2CyHS$, obtained by precipitating a solution of quinine-sulphate with sulphocyanate of potassium, forms fine lemon-yellow monoclinic crystals (Wertheim). Quinine treated with sulphocyanic acid yields two salts crystallising together, the one white, the other yellow and resinous (Dollfus). By precipitating sulphocyanate of quinine with *mercuric chloride* and *cyanide*, two double salts are formed, containing respectively $3(C^{20}H^{24}N^2O^2.2CyHS).4Hg''Cl^2$ and $2(C^{20}H^{24}N^2O^2.2CyHS).Hg''Cy^2$. (Wertheim.)

Tannates.—Quinotannic acid occurs in cinchona-bark (Henry and Plisson). Gallotannic acid forms with dilute quinine-solutions a yellowish-white, amorphous, slightly bitter precipitate, sparingly soluble in boiling water, very soluble in alcohol. This salt is used in the treatment of fever, and is said to exert less action than the sulphate on the digestive organs and on the nervous system. (See *Report of MM. Orfila, Bussy, and Bouvier on a Memoir by M. Barreswil on the Therapeutic Properties of Tannate of Quinine*, J. Pharm. [3] xxi. 206.)

Tartrates.—*a. Dextrotartrates.* The *neutral salt*, $2C^{20}H^{24}N^2O^2.C^4H^6O^6$, is precipitated on mixing sulphate of quinine with neutral dextrotartrate of potassium, as a crystalline powder, neutral, fusible, and having a bitter taste (Arppe, J. pr. Chem. liii. 334). The *acid salt*, $C^{20}H^{24}N^2O^2.C^4H^6O^6.H^2O$, is obtained by mixing equivalent quantities of the acid and base, and leaving the liquid to crystallise. It gives off 1·4 per cent. water at 100°, and the remainder, 4·4 per cent. in all, at 160°, decomposing when heated for some time to that temperature (Pasteur).—*Tartrate of quinine and potassium* forms crystals soluble in alcohol (Delondre and Henry). Quinine boiled with solution of tartar-emetic does not form a double salt analogous to that of quinidine. (Stenhouse.)

β. Lævotartrate.—Obtained like the dextrotartrate, and has the same composition; it differs however in crystalline form, gives off nearly all its water of crystallisation at 100°, and is much more soluble in water than the dextrotartrate. (Pasteur.)

Urate of Quinine, $C^{20}H^{24}N^2O^2.C^5H^4N^2O^3$?—Prepared by boiling uric acid for some time with quinine and a large quantity of water, and filtering the liquid while hot; it is a white, amorphous, laminated mass (Elderhorst), or a dull white powder composed of microscopic prisms. It has a bitter taste; burns without melting when heated; dissolves in 855 pts. cold and 36·2 pts. boiling water; in 1580 pts. cold and 45·3 pts. boiling alcohol; still less freely in ether. (Andrea, Pharm. Viertelj. x. 382.)

Valerate of Quinine, $C^{20}H^{24}N^2O^2.C^5H^{10}O^2.\frac{3}{2}H^2O$.—On neutralising alcoholic quinine with a slight excess of valerianic acid, and allowing a mixture of 1 vol. of the liquid with 2 vols. of water to evaporate at ordinary temperatures, or not above 50°, hard rectangular octahedrons or cubes, permanent in the air, and by rapid evaporation also, needles are obtained (L. Bonaparte). The salt may also be prepared by adding carbonate of sodium to a mixture of 1 pt. of valerianic acid and 2 pts. of water in sufficient quantity to render the liquid slightly alkaline, and pouring the mixture, at a temperature of 48°, into a solution of 2 pts. of sulphate of quinine in water containing sulphuric acid: the solution, on standing for 24 hours, deposits crystals, which are washed with water at 36° (Chatin, J. Pharm. [4] i. 268). It smells of valerianic acid: tastes very bitter, and afterwards of the acid, melts at 90° to a transparent liquid, giving off 3½ per cent. of water, and solidifies to a glass on cooling. When more strongly heated, it gives off valerianic acid. The salt, fused at 90°, dissolves easily in alcohol, and remains on evaporation as an amorphous mass when the alcohol is strong, or in the form of crystals when weaker alcohol is employed. (Bonaparte.)

The crystals dissolve in 110 pts. of cold [96 pts. at 18·75° (Abl)], and in 40 pts. of boiling water (Wittstein). The solution on boiling deposits resinous drops of the anhydrous salt, which do not become crystalline on cooling or standing in water, but crystallise from dilute alcohol. The same anhydrous salt is precipitated by valerianic acid from an aqueous solution of the crystals (Bonaparte, J. Chim. méd. xviii. 680; xix. 330). Dissolves in 6 pts. of cold, and in 1 pt. of boiling alcohol of 80 per cent. (Wittstein, Repert. lxxxvii. 295). The salt prepared with natural, but not that made with artificial, valerianic acid, becomes phosphorescent when rubbed, especially after it has effloresced. The two salts also exhibit different crystalline forms. (Landerer, N. Br. Arch. cxix. 240.)

DERIVATIVES OF QUININE.

1. *By Addition.*

Hydroquinine, $C^{20}H^{26}N^2O^3 = C^{20}H^{24}N^2O^2.H^2O$ (at 150°) (Schützenberger, Ann. Ch. Pharm. cviii. 347).—This compound, which contains the elements of 1 at. water more than quinine, is obtained by the action of zinc and sulphuric acid on quinine. It is an amorphous resin nearly as bitter as quinine. When dried at 120°, It retains 1 at. water, forming the mono-hydrate $C^{20}H^{26}N^{2}O^{2}.H^{2}O$, which slowly gives off half its water at 140°, leaving the compound $2C^{20}H^{26}N^{2}O^{2}.H^{2}O$. The mono-hydrate softens at 35° and melts at 100°. Hydroquinine dissolves in alcohol and ether, and exhibits with chlorine-water and ammonia the same green coloration as quinine. Its salts are more soluble than the corresponding salts of quinine. The *sulphate* crystallises with difficulty. The *chloroplatinate* dried at 100° contains 26·2 per cent. platinum, agreeing exactly with the formula $C^{20}H^{26}N^{2}O^{2}.2HCl.Pt^{iv}Cl^{4}$.

Iodoquinine, $2C^{20}H^{24}N^{2}O^{2}.I^{3}$?.—By triturating quinine with iodine, a brown substance is obtained, exactly resembling iodocinchonine (i. 979), and containing 28·0 per cent. iodine (calc. = 30·3). (Pasteur, Compt. rend. xxxvii. 110.)

Sulphate of Iodoquinine, or *Sulphato-iodide of Quinine.* This salt, discovered by Herapath, is obtained by dissolving acid sulphate of quinine in strong acetic acid, and gradually dropping into it an alcoholic solution of iodine. The mixture, if left at rest for a few hours, deposits the salts in large plates, generally rectangular, sometimes rhombic, octagonal, or hexagonal. These crystals, when viewed by reflected light, exhibit an emerald-green colour, with an almost metallic lustre like the wing-cases of cantharides or the crystals of murexide; by transmitted light they are nearly colourless, having only a faint olive-green tint; but when two of them are placed across one another, so that their longest dimensions shall intersect at right angles, the superposed portions are quite impervious to light, just like two crossed tourmalines. This effect is produced even with crystals not thicker than $\frac{1}{20}$th of a millimetre. In polarised light, the crossed plates exhibit complementary colours, one for example being green and the other rose-coloured, and the superposed portions are of a dark chocolate-brown colour. In short, these crystals possess all the optical properties of tourmalines, and may be substituted for them, presenting moreover the advantage of transmitting a greater proportion of the incident light; but they are somewhat difficult to manipulate with, on account of their brittleness.

The composition of this salt has not yet been ascertained with certainty. Herapath originally assigned to it the improbable formula $C^{57}H^{33}N^{4}O^{5}I^{3}.2HSO^{4}.3HO$. His latest analysis, however, agrees better with the formula $2C^{20}H^{24}N^{2}O^{2}.3H^{2}SO^{4}.I^{6}$. Von Hauer's analysis, made in Kraut's laboratory, agrees nearly with same formula + $3H^{2}O$:

		Calc.	Herapath.			Calc.	v. Hauer.
C^{80}	960·0	40·81	41·35	C^{80}	960·0	39·89	39·39
H^{102}	102·0	4·34	4·70	H^{108}	108·0	4·48	4·67
N^{8}	112·0	4·76	3·54	N^{8}	112·0	4·64

$3SO^{3}$	240·0	10·19	9·77	$3SO^{3}$	240·0	9·96	9·98
	2352·6	100·00	100·00		2406·6	100·00	

—Herapath, Phil. Mag. [4], iii. 161; iv. 186: vi. 171, 346; vii. 352; ix. 366; xiv. 224; complete Chem. Soc. Qu. J. xi. 130; Chem. Gaz. 1858, p. 437; Jahresb. 1858, p. 364.—Haidinger and Stokes, Wien. Akad. Ber. x. 106; Jahresb. 1853, p. 198.—Gm. xvii. 312.

Sulphate of Iodethylquinine, prepared in like manner, forms either thin needles perfectly opaque, or thick plates, transparent and purple in thin films, and of a shining metallic green colour by reflected light, or dark-red or orange-red laminæ, transparent and orange-yellow by transmitted light.

Oxyquinine, $C^{20}H^{24}N^{2}O^{3}$.—Produced by boiling sulphate of quinine with nitrate of potassium, and precipitating by ammonia. Already described (iii. 320).

2. *By Substitution.*

Methylquinine, $C^{21}H^{26}N^{2}O^{2}$ = $C^{20}H^{23}(CH^{3})N^{2}O^{2}$. (Strecker, Ann. Ch. Pharm. xci. 164.)

When iodide of methyl is added to an ethereal solution of quinine, crystals of *hydriodate of methylquinine*, $C^{21}H^{26}N^{2}O^{2}.HI$, are formed in the liquid after standing for a while. The compound resembles hydriodate of ethylquinine in its behaviour with ammonia and caustic potash.

Ethylquinine, $C^{22}H^{28}N^{2}O^{2}$ = $C^{20}H^{23}(C^{2}H^{5})N^{2}O^{2}$. (Strecker, *loc cit.*)—Iodide of ethyl in contact with alcoholic or ethereal solution of quinine, forms, after some hours, yellow needles of hydriodate of ethylquinine, an aqueous solution of which is converted by oxide of silver into iodide of silver and a strongly alkaline solution of ethylquinine. When the latter is evaporated, and the amorphous residue is dissolved in alcohol and mixed with ether, a syrup is precipitated which is gradually converted into colourless needles, probably of hydrate of ethylquinine. The base tastes caustic and bitter in aqueous solution.—When heated to 120°, it evolves an odour of chinoline and decomposes. A strong alcoholic solution is not altered by iodide of ethyl.

Ethylquinine dissolves easily in *water* and in *alcohol*. It forms with *acids* mono- and di-acid salts. Aqueous ethylquinine absorbs carbonic acid from the air, and is converted into an uncrystallisable, alkaline salt.

Hydrochlorate of Ethylquinine, $C^{22}H^{28}N^2O^2.HCl$, or $C^{22}H^{24}N^2O^2.C^2H^5Cl$, crystallises in slender needles united in hemispherical groups.—The *chloroplatinate*, $C^{22}H^{28}N^2O^2.2HCl.Pt^{iv}Cl^4$, is a yellow precipitate, soluble in boiling water, and separating in indistinct crystals on cooling.

The *hydriodate*, $C^{22}H^{28}N^2O^2.HI$, or $C^{20}H^{24}N^2O^2.C^2H^5I$, when purified by washing with water, and recrystallising from ether, forms very light, colourless, silky needles, neutral, unchangeable at 110°, melting at a higher temperature, without loss of weight, and solidifying to a vitreous mass on cooling. Tastes very bitter. Dissolves freely in water, and is not precipitated by ammonia, but is thrown down in an unaltered state by a large quantity of caustic potash after standing for some time. Dissolves in alcohol, but not in ether.

The *neutral sulphate*, $2C^{22}H^{28}N^2O^2.H^2SO^4$, obtained by decomposing the hydriodate with sulphate of silver, is slightly soluble in water, more soluble in alcohol than the acid salt.

The *acid sulphate*, $C^{22}H^{28}N^2O^2.H^2SO^4$, crystallises in needles, which have an acid reaction, and after drying over oil of vitriol, give off 8·2 per cent. water (= 2 at.) at 120°. It is very soluble in water, less soluble in alcohol than the neutral sulphate. Potash added to the concentrated aqueous solution throws down a precipitate of the neutral sulphate, which dissolves in water.

Benzoyl-quinine, $C^{27}H^{28}N^2O^3 = C^{20}H^{23}(C^7H^5O)N^2O^2$. (Schützenberger, Compt. rend. xlvii. 334).—When chloride of benzoyl is poured upon quinine dried at 130°, an evolution of heat occurs, and the quinine deliquesces to a thick syrup, composed of hydrochlorate of benzoyl-quinine and excess of chloride of benzoyl. The syrup is dissolved in water; the base is precipitated by ammonia; and the white resinous mass is dried at 140°, at which temperature it gives off a large quantity of water.

Benzoyl-quinine is coloured green by *chlorine-water* and *ammonia*. The *platinum-salt* contains 23·2 per cent. of platinum (calc. for $C^{27}H^{28}N^2O^3.2HCl.Pt^{iv}Cl^4$ requires 23·5 per cent. Pt).

QUININE-SULPHURIC ACID, $C^{40}H^{48}N^4SO^7 = 2C^{20}H^{24}N^2O^2.SO^3$.—*Sulphoquinic acid.* Obtained by dissolving quinine in fuming sulphuric acid, neutralising with baryta, and decomposing the barium-salt with sulphuric acid. It is a solid amorphous acid mass, easily soluble in water and in alcohol.—The *barium-salt*, $C^{40}H^{46}Ba''N^4SO^7$, is a transparent friable vitreous mass having a bitter taste. (Schützenberger, Ann. Ch. Pharm. cviii. 353.)

Cinchonine forms a similar acid, containing $C^{40}H^{48}N^4SO^5$. (Schützenberger.)

QUINOA-SEEDS. See Chenopodium (i. 868).

QUINOÏDINE. This name is applied to the brown resinous mass obtained in the manufacture of quinine and cinchonine, by precipitating the brown uncrystallisable mother-liquor with ammonia or potash, or by evaporating the mother-liquors of sulphate of quinine to dryness. There appear to be two kinds of quinoïdine—the one freely soluble in ether, and containing quinidine, with smaller quantities of quinine, cinchonine, and resin; the other, which is only partially soluble in ether, consisting chiefly of uncrystallisable transformation-products of the cinchona-bases. The former is obtained from inferior kinds of cinchona-bark, but not from *Cinchona regia* or *C. flava dura*. (Winckler; see *Gmelin's Handbook*, xvii. 303.)

Animal quinoïdine.—This name is applied by Bence Jones and Dupré (Proc. Roy. Soc. xv. 73),to a fluorescent substance resembling quinine in optical and chemical properties, which may be extracted from every texture of man and of some animals, and is identical with the fluorescent substance existing in the crystalline lens.

QUINOÏL. An old name of Quinine.

QUINOLEINE. Syn. with Chinoline (i. 869).

QUINONAMIC ACID. Syn. with Quinoylamic Acid.

QUINONAMIDE. C^6H^5NO. (Woskresensky, J. pr. Chem. xxxiv. 251.)—A product intermediate in composition between quinone ($C^6H^4O^2$) and diphenine ($C^6H^6N^2$), formed by the action of dry ammonia or quinone:—

$$C^6H^4O^2 + NH^3 = C^6H^5NO + H^2O.$$

It is a crystalline mass of a fine emerald-green colour, soluble in water, but quickly decomposing, and yielding a nearly black solution.

QUINONE, $C^6H^4O^2$. (Woskresensky, Ann. Ch. Pharm. xxxvii. 168.—Wöhler, *ibid.*, li. 148.—Laurent, Compt. chim. 1849, p. 190.—Hesse, Ann. Ch. Pharm. xiv. 299.)—A compound produced: 1. By the oxidation of quinic acid. When quinic acid or a quinate is heated with about 4 pts. peroxide of manganese and 1 pt. strong sulphuric acid diluted with half its weight of water, the mass froths up, and gives off thick white vapours, which condense in the receiver to shining golden-yellow needles of quinone; the reaction is:

$$\underset{\text{Quinic acid.}}{C^7H^{12}O^6} + O^2 = \underset{\text{Quinone.}}{C^6H^4O^2} + CO^2 + 4H^2O.$$

The product is pressed between paper, and purified by sublimation. In like manner quinone may be obtained from coffee and other vegetable substances containing quinic acid (p. 9).—2. By the dry distillation of quinates.—3. From hydroquinone, by the action of heat (iii. 213).—4. From benzidine, aniline, and phenylene-damine, especially the β-modification (iv. 481), by oxidation with manganic peroxide and sulphuric acid. Benzidine thus treated yields a large quantity of quinone:

$$C^{12}H^{12}N^2 + H^2O + O^3 = 2C^6H^4O^2 + 2NH^3.$$

Aniline yields but a small quantity: $C^6H^7N + O^2 = C^6H^4O^2 + NH^3$, the greater part suffering more complete decomposition. (Hofmann, Proc. Roy. Soc. xiii. 4.)

Properties.—Quinone when sublimed forms long, transparent, golden-yellow, shining needles (Woskresensky); after crystallisation from hot water it is of a darker and dingier colour, and less transparent (Wöhler); from solution in hot ethylic iodide, it crystallises in beautiful laminæ (Hesse). It is heavier than water, melts at 100° (Woskresensky), at 115·7° (Hesse), to a yellow liquid, which crystallises on cooling (Wöhler), at 115·2° (Hesse). It volatilises without alteration, and sublimes, even at ordinary temperatures, from one part of the containing vessel to another. It has a pungent irritating odour. It is very slightly soluble in cold *water*, more soluble in *alcohol* and *ether*; the solutions have no effect on vegetable colours, but the aqueous solution colours the skin brown. It dissolves with yellow colour in dilute *hydrochloric* and *nitric acids*. The aqueous solution forms a pale-yellow gelatinous precipitate with *basic acetate of lead*, but does not precipitate the neutral salts of lead, copper, or silver.

Decompositions.—1. The aqueous solution of quinone acquires, by exposure to the air, a continually deeper yellowish-red colour, and ultimately deposits a black-brown mouldy substance (Wöhler). The aqueous solution mixed with ammonia or potash absorbs oxygen, and assumes a black-brown colour on exposure to the air, and then forms with acids a black mouldy precipitate, resembling melanic acid (iii. 867; Laurent, Compt. rend. xxvi. 35).—2. With dry *chlorine gas*, quinone forms trichloroquinone, the action being attended with great rise of temperature and evolution of hydrochloric acid (Woskresensky):

$$C^6H^4O^2 + Cl^6 = C^6HCl^3O^2 + 3HCl.$$

—3. Heated with hydrochloric acid and chlorate of potassium, it is quickly converted into tetrachloroquinone (Hofmann, Ann. Ch. Pharm. lxii. 65).—4. *Oil of vitriol* carbonises quinone (Woskresensky).—5. Strong *hydrochloric acid* colours quinone brownish-black, and then dissolves it, forming a red-brown afterwards colourless liquid, which no longer smells of quinone, but contains chlorohydroquinone, $C^6H^5ClO^2$. (Wöhler). The first products are probably quinhydrone and chloroquinhydrone (iii. 213, 217), the presence of both of which in the black magma formed at the begininng of the action was pointed out by Städeler (Ann. Ch. Pharm. lxix. 308):

$$4C^6H^4O^2 + 2HCl = C^{12}H^{10}O^4 + C^{12}H^8Cl^2O^4;$$

and these compounds, by the further action of the hydrochloric acid, are converted into chlorhydroquinone, being at the same time dissolved and decolorised:

$$C^{12}H^{10}O^4 + C^{12}H^8Cl^2O^4 + 2HCl = 4C^6H^5ClO^2.$$

Chlorhydroquinone is likewise formed by the action of hydrochloric acid gas upon dry quinone (Wöhler).—6. Quinone heated with *nitric acid* yields oxalic and picric acids. On treating it with nitric and strong sulphuric acids, and immersing metallic zinc in the diluted solution, a base is produced resembling aricine or cinchovatine (Schoonbroodt, Bull. Soc. Chim. 1861, p. 107).—7. *Ammoniacal gas* passed over quinone, quickly converts it, with separation of water, into quinonamide (p. 26).—8. *Sulphydric acid gas* has no action upon dry quinone, but when passed through the cold aqueous solution, first reddens it, and then throws down flakes of brown sulphohydroquinone, which, if the passage of the gas be still continued, and especially if the action be aided by heat, is converted into yellow sulphohydroquinone. The same compound is formed when sulphydrate of ammonium is poured upon quinone (Wöhler).—9. Quinone dissolved in water is converted into hydroquinone by excess of *hydriodic* or *hydrotelluric acid*, with precipitation of iodine or tellurium; and by *sulphurous acid*, with formation of sulphuric acid (Wöhler). *Sulphurous anhydride* has no action upon dry quinone; and even phosphuretted hydrogen, arsenetted hydrogen, and hydrocyanic acid are without action upon it (Wöhler).—10. *Quicklime*, or *hydrate of potassium*, in contact with moist crystals of quinone, acquires a fine indigo-blue colour; and on trituration a blue powder is formed, having a coppery lustre, and yielding a blackish-green solution with water (Hesse).—11. Quinone heated with hydrate of potassium is converted into quinonic acid, $C^{12}H^{8}O^{6}$ (Schoonbroodt, p. 30).—12. Quinone heated for a long time to 118° with *iodide of ethyl* in sealed tubes, yields long white crystals (Hesse).—13. With *aniline* in boiling alcoholic solution, it forms diphenyl-quinoyl-diamide. (Hofmann, iv. 430.)

Chloroquinones. When quinic acid or a quinate is heated with a mixture of peroxide of manganese, sulphuric acid, and common salt, a yellow crystalline sublimate is obtained, consisting of several chlorinated derivatives of quinone, which may be separated by their different degrees of solubility in alcohol. These compounds are more like quinone in proportion as they contain less chlorine, mono- and di-chloroquinone still crystallising in prisms, whereas tri- and tetra-chloroquinone crystallise in laminæ. By reducing agents, and especially by sulphurous acid, they are converted into the corresponding chlorhydroquinones (iii. 216).

Monochloroquinone, $C^{6}H^{3}ClO^{2}$ (Städeler, Ann. Ch. Pharm. lxix. 300). *Preparation.*—One pt. of quinate of copper, or any other quinate (25 grammes at most), is distilled with 4 pts. of a mixture of 3 pts. common salt, 2 pts. peroxide of manganese, and 4 pts. oil of vitriol (diluted with three times its bulk of water), in a flask provided with a descending tube six feet long, and kept cool at the upper part by a wet cloth, but not so much as to cause the liquid which distils over to crystallise. At first the mixture froths up considerably, giving off carbonic anhydride with a small quantity of chlorine; but when the liquid begins to boil, the evolution of chlorine ceases. The rapid ebullition must be kept up, as long as any oil passes into the receiver from the tube, in which, if it be moderately cooled, all the tetrachloroquinone is deposited. This oil, which solidifies on cooling, is collected on a filter, repeatedly washed with cold water, dried, pulverised, and exhausted with successive small quantities of cold alcohol of 85 per cent., as long as the alcohol acquires a yellow colour and gives a precipitate with water. Dichloroquinone then remains undissolved, together with a small quantity of tri- and tetra-chloroquinone, whilst the alcohol retains in solution the quinone and trichloroquinone, which colour it yellow. These compounds are precipitated from the solution, by addition of a triple volume of water, in slender needles and laminæ, and dissolved in a small quantity of hot moderately strong alcohol; the solution is cooled, till the large yellow laminæ of trichloroquinone, which separate out, begin to be associated with needles of monochloroquinone; the liquid is then immediately filtered and mixed with water; and the precipitate, consisting of monochloroquinone and a small quantity of trichloroquinone, is freed from the latter by repeatedly treating it as above with alcohol, which however cannot be effected completely, and is attended with great loss.

Monochloroquinone crystallises in long yellow needles, very soluble in *ether*, moderately soluble in *alcohol* and *acetic acid*. It dissolves also in boiling *water*, and separates on cooling; but if the boiling be prolonged, the solution becomes dark-red and opaque, with formation of brown chloroquinhydrone (iii. 217). Chloroquinone melts at 160° to a deep yellow oil, having an aromatic odour and biting taste. It colours the epidermis purple, like gold-salts. It dissolves in cold aqueous *sulphurous acid*, and is reduced thereby to chlorohydroquinone (iii. 216).

Dichloroquinone, $C^{6}H^{2}Cl^{2}O^{2}$.—This compound forms the portion of the oily product obtained in the preparation of monochloroquinone, which is but slightly soluble in alcohol. When purified by repeated crystallisation from hot alcohol, it forms shining, deep yellow, well-defined monoclinic prisms, melting at 160°, insoluble in *water*, nearly insoluble in cold *alcohol*, soluble in hot *alcohol*, very soluble in *ether*. It dissolves in weak *potash*, forming a red-brown solution, from which hydrochloric acid throws down prisms consisting of a peculiar acid.—Dichloroquinone dissolves slightly in *ammonia*, forming a yellow solution gradually changing to red and brownish-black. *Sulphuric, hydrochloric, nitric*, and *acetic acids* dissolve dichloroquinone, especially when hot, and deposit it in crystals on cooling. Sulphurous acid at the boiling heat converts it into dichlorohydroquinone or dichloroquinhydrone. (Städeler, *loc cit.*)

Trichloroquinone, $C^{6}HCl^{3}O^{2}$. (Woskresensky, J. pr. Chem. xviii. 419.—Städeler, Ann. Ch. Pharm. lxix. 318.)—Produced by the direct action of chlorine on quinone; also, together with the other chloroquinones, by the action above-mentioned. The action of chlorine on quinone is so violent at first, that the vessel requires to be kept cool at the beginning, but towards the end of the process it must be surrounded with boiling water. The product then volatilises with the vapours of hydrochloric acid, and is deposited in crystals on the cold parts of the apparatus; it may be purified by crystallisation from hot alcohol.

Trichloroquinone forms small yellow prisms melting at 160° and subliming at a lower temperature. It does not colour the skin, is quite insoluble in *water*, very soluble in *ether*, soluble in hot *alcohol*. Aqueous *potash* colours it green, and forms a brown solution, which gradually deposits long needles of a red salt, the acid of which is precipitated by hydrochloric acid in red needles.

Trichloroquinone is coloured green by strong aqueous *ammonia*, but the solution gradually assumes a brown-red colour, and yields by spontaneous evaporation hard dark-brown crystals.—*Sulphuric* and *nitric acids* dissolve trichloroquinone without alteration; *sulphurous acid* converts it into trichloroquinone.

The alcoholic solution of trichloroquinone does not precipitate acetate of lead or nitrate of silver.

Tetrachloroquinone, *Perchloroquinone*, or *Chloranil*, $C^6Cl^4O^2$. (Erdmann, J. pr. Chem. xxiii. 273 and 279; Hofmann, Ann. Ch. Pharm. lii. 55; Hesse, *ibid*. cxiv. 303.)—This compound is formed by the action of a mixture of hydrochloric acid and chlorate of potassium on quinone, aniline, phenol, trichlorophenol, dinitrophenol, trinitrophenol, salicin, salicylous acid, salicylic acid, nitrosalicylic acid, isatin, chlorisatin, dichlorisatin, and, according to Wagner (J. pr. Chem. lxvii. 441), on pyrocatechin; also, together with the other chloroquinones, when quinone is heated with peroxide of manganese, sulphuric acid, and common salt. (p. 28).

Preparation.—1. From *Phenol:* Strong hydrochloric acid is poured upon phenol in a basin; chlorate of potassium added in small crystals; and the mixture heated as soon as the first violent action is over, the heating being continued for some time, till in fact the phenol, which at first becomes thick and red-brown, is converted into a light yellow crystalline mass, which, after washing with water, may be crystallised from boiling alcohol. The transformation takes place more quickly when the phenol is dissolved in boiling water or in alcohol; but if alcohol be used, it is necessary, on account of the readiness with which explosion takes place, to use more dilute hydrochloric acid, and to add the chlorate gradually (Hofmann).—2. From *Salicin:* This substance is dissolved, together with chlorate of potassium, in boiling water; and small quantities of hydrochloric acid are added, whereupon the solution immediately acquires a deep orange-yellow colour, and becomes covered with a crust of small crystals of perchloroquinone, amounting to 30·27 per cent. of the salicin. If the salicin be first heated with hydrochloric acid alone, saliretin is formed, which, when afterwards heated with chlorate of potassium, does not yield any perchloroquinone (Hofmann).—3. *Quinone*, or the wash-water obtained in its preparation (p. 27), may also be boiled with hydrochloric acid and chlorate of potassium.

Properties.—Perchloroquinone forms pale-yellow scales, having a nacreous and metallic lustre. When gently heated, it sublimes completely without melting, but if suddenly heated, it melts, and suffers partial decomposition. It is insoluble in *water*, and nearly insoluble in cold *alcohol;* but dissolves in boiling alcohol, forming a pale-yellow solution, from which it crystallises on cooling in iridescent scales resembling iodide of lead. Ether dissolves it somewhat more readily than alcohol.

Perchloroquinone is not acted upon by hydrochloric, nitric, or ordinary sulphuric acid, even at the boiling heat (Erdmann), but dissolves without alteration in *fuming sulphuric acid*, and in a mixture of sulphuric and nitric acids (Hesse). *Sulphurous acid* converts it into tetrachlor-hydroquinone or chlorhydranil (Städeler). *Sulphurous anhydride* passed through a warm mixture of tetrachloroquinone and strong alcohol, forms octochlorinated ethyl-dihydroquinone (iii. 217), probably thus:

$$2C^6Cl^4O^2 + C^2H^6O + 3H^2O + 2SO^2 = C^{12}H^3(C^2H^5)Cl^8O^4 + 2H^2SO^4.$$

In like manner with *sulphurous anhydride* and *glacial acetic acid*, it yields octochlorinated acetyl-dihydroquinone (Hesse). A hot filtered solution of perchloroquinone in concentrated aqueous *acid sulphite of potassium* deposits crystals of thiochronate of potassium, $C^5H^4K^4S^4O^{14}$ (Hesse), thus:

$$C^6Cl^4O^2 + 4SHKO^3 + 2H^2O = C^5H^4K^4S^4O^{14} + 4HCl + CO^2.$$

A solution of tetrachloroquinone in concentrated *acid sulphite of ammonium* yields on cooling colourless crystals, consisting of the ammonium-salt of dichloro-disulphosalicylic acid, $C^6H^4Cl^2S^2O^7$, an acid which may be regarded as derived from sulphosalicylic acid ($C^6H^6O.CO^2.SO^3$), by the substitution of Cl^2 for H^2 and of SO^3 for CO^2 (Hesse). The maion of the ammonium-salt takes place as shown by the equation:

$$C^6Cl^4O^2 + 2SH(NH^4)O^3 + 2SO^2 + 3H^2O = C^6H^2(NH^4)^2Cl^2S^2O^7 + 2HCl + 2H^2SO^4.$$

Perchloroquinone heated to 100° in a glass tube, with dry *acetate of silver* and a little ether, yields chloride of silver and dichloroquinoylic acid; probably thus:

$$\underset{\substack{\text{Perchloro-}\\\text{quinone.}}}{C^6Cl^4O^2} + \underset{\substack{\text{Acetate of}\\\text{silver.}}}{2C^2H^3AgO^2} = 2AgCl + \underset{\substack{\text{Acetic an-}\\\text{hydride.}}}{C^4H^6O^3} + \underset{\substack{\text{Dichloroquinoylic}\\\text{anhydride.}}}{C^6Cl^2O^3}\ \text{(Hesse.)}$$

Perchloroquinone dissolves easily in hot dilute *potash* or *soda*, forming a purple liquid, which on cooling deposits dichloroquinoylate (chloranilate) of potassium or sodium (p. 34):

$$C^4Cl^4O^2 + 2H^2O = C^6H^2Cl^2O^4 + 2HCl.$$

It dissolves easily also in aqueous monosulphide of potassium, forming a yellow liquid, which in contact with the air quickly turns brown and finally black, and deposits a black granular powder. The recently prepared yellow solution yields, with hydrochloric acid, a yellowish-white precipitate, soluble in alcohol, ether, and caustic potash.

Perchloroquinone heated with aqueous ammonia is converted into dichloroquinoylamate of ammonium; with alcoholic ammonia it yields the same salt, together with dichloroquinoylamide (Laurent):

$$\underset{\substack{\text{Perchloro-}\\\text{quinone.}}}{C^6Cl^4O^2} + NH^3 + H^2O = \underset{\substack{\text{Dichloroquinoy-}\\\text{lamic acid.}}}{C^6H^3Cl^2NO^3} + 2HCl.$$

$$\underset{\substack{\text{Perchloro-}\\\text{quinone.}}}{C^6Cl^4O^2} + 2NH^3 = \underset{\substack{\text{Dichloroquinoyl-}\\\text{diamide.}}}{C^6H^4Cl^2N^2O^2} + 2HCl.$$

With *aniline* in presence of alcohol, perchloroquinone yields diphenyl-dichloroquinoyl-diamide. (Hofmann, iv. 426.)

QUINONIC ACID. $C^{12}H^8O^6$?—An acid obtained by Schoonbroodt (Bull. Soc. Chim. 1861, p. 107), by heating quinone with potash, but very imperfectly described. When heated with excess of potash, it is said to yield a brown empyreumatic oil, $C^{10}H^8O^2$, insoluble in water, and solidifying in the cold to brown crystalline laminæ. With the vapour of fuming nitric acid, this oil forms a nitro-compound insoluble in water; and from this, by the action of zinc and sulphuric acid, a colourless base is said to be obtained, soluble in alcohol, insoluble in ether, slightly soluble in water, and forming uncrystallisable salts, which have a sharp bitter taste, and yield with potash or ammonia a precipitate insoluble in excess of the reagent.

The name quinonic acid is also used as synonymous with quinoylic acid (p. 34).

QUINOTANNIC ACID, or *Cinchonatannic acid.* (Berzelius, *Lehrbuch*, 3 Aufl. vi. 246.—Pelletier and Caventou, Ann. Ch. Phys. [3] xv. 337.—R. Schwarz, J. pr. Chem. lvi. 76.)—Cinchona-barks contain a tannic acid different from gallotannic acid, which imparts to them the property of precipitating tartar-emetic greyish-yellow, colouring ferric salts green, and precipitating a solution of gelatin (Berzelius). The tannin, both from brown and from red cinchona-bark, precipitates ferric salts dark-green; that from yellow cinchona-bark forms a lighter green precipitate with ferric salts. (Pelletier and Caventou.)

Preparation.—The decoction of cinchona-bark is mixed with a small quantity of calcined magnesia, which precipitates cinchona-red; the filtrate is precipitated with neutral acetate of lead; the precipitate is decomposed under water by sulphydric acid; the liquid filtered from the sulphide of lead is precipitated with basic acetate of lead; the precipitate separated by filtration is dissolved in dilute acetic acid (which leaves cinchona-red undissolved); and the filtrate is precipitated by ammonia. The light-yellow precipitate is washed and decomposed by sulphydric acid, and the liquid filtered from the sulphide of lead is again precipitated by an alcoholic solution of neutral acetate of lead. If the quinotannate of lead thus obtained, be decomposed under water by sulphydric acid, and the liquid, filtered from the sulphide of lead, be evaporated in vacuo over oil of vitriol and a mixture of ferrous sulphate and lumps of potash, quinotannic acid remains behind, but already somewhat altered. (Schwarz.)

Quinotannic acid is a light-yellow, friable, very hygroscopic mass, which becomes electric by friction. Its taste is slightly sour and somewhat astringent, but not at all bitter. It dissolves in *water*, *alcohol*, and *ether*; the ethereal solution is nearly colourless. [The acid cannot be extracted from the bark by means of ether, because it is in combination with an alkali.] Schwarz found it to contain 44·75 per cent. carbon, 5·49 hydrogen, and 49·76 oxygen, whence he deduces the formula $C^{42}H^{30}O^{35}$.

Quinotannic acid subjected to dry distillation gives off an odour of phenol. Its aqueous solution rapidly absorbs oxygen from the air, especially in presence of fixed alkalis, acquiring a brown-red colour, and yielding cinchona-red (i. 969). A concentrated solution of the acid, boiled with a little hydrochloric acid, deposits red flocks, which dissolve with green colour in alkaline liquids (Schwarz). From the concentrated aqueous solution, hydrochloric and sulphuric acids throw down compounds of quinotannic acid with those acids, but less easily than from aqueous gallotannic acid.

Quinotannic acid unites with bases, forming salts which decompose in contact with the air, much more easily than the gallotannates, yielding cinchona-red and a carbonate. (Berzelius.)

With *starch, gelatin*, and *white of egg*, quinotannic acid reacts like gallotannic acid. It colours *ferric salts* green, and produces an abundant yellowish-grey precipitate with *tartar-emetic.* Its aqueous solution mixed with gallotannic acid dries up to a transparent varnish.

QUINOVA-BITTER. See QUINOVIN.

QUINOVA-SUGAR. $C^6H^{12}O^5$. (Hlasiwetz and Gilm, Ann. Ch. Pharm. cxi. 182; Jahresb. 1859, p. 581.)—A saccharine substance produced, together with quinovic acid, by the action of hydrochloric acid gas on quinovin in alcoholic solution (p. 32). It remains in the acid mother-liquor from which the quinovic acid has crystallised out, and may be separated by quickly neutralising the liquid with anhydrous carbonate of sodium or carbonate of lead, filtering, washing the precipitate with a small quantity of absolute alcohol, then distilling off the alcohol, evaporating to dryness at 100°, treating the residue with water, evaporating again, and exhausting the residue with absolute alcohol. The alcoholic solution thus obtained leaves the quinova-sugar, on evaporation, as an uncrystallisable hygroscopic mass, having a faint and slightly bitter taste. It emits an odour of caramel when heated, gives off a little water when exposed for some time to a temperature of 100°, reduces an alkaline cupric solution only when concentrated. It resembles mannitan more than any other kind of sugar.

QUINOVATANNIC ACID. A tannic acid obtained by Hlasiwetz (Ann. Ch. Pharm. lxxix. 130; Gm. xv. 484), from the bark of *Cinchona nova* or *C. surinamensis.* It is very much like quinotannic acid, but differs from the latter in having a somewhat bitter taste, and in not giving a precipitate with gelatin or tartar-emetic. It yielded by analysis 51·8 per cent. carbon and 5·8 hydrogen, whence Hlasiwetz deduces the formula $C^{28}H^{19}O^{17}$, requiring 52·01 C, 5·9 H, and 42·1 O.

QUINOVATIC ACID. See QUINOVIN.

QUINOVIC ACID. $C^{24}H^{38}O^4$. (Hlasiwetz and Gilm, Ann. Ch. Pharm. cxi. 1829; Jahresb. 1859, p. 579.)—This term was originally used as a synonym for quinovin or quinova-bitter, but is now applied by Hlasiwetz to an acid produced, together with quinova-sugar, by the decomposition of quinovin.

When dry hydrochloric acid gas is passed into a solution of quinovin in strong alcohol, the liquid becomes hot, and deposits quinovic acid as a white crystalline powder, while quinova-sugar remains in solution. The quinovin may be obtained pure by washing it with alcohol, then boiling it with a large quantity of strong alcohol, concentrating the solution by distillation, and leaving it to cool. The quinovin is then deposited as a white sandy powder composed of six-sided laminæ, belonging to the trimetric system. It is tasteless, insoluble in *water*, very slightly soluble in cold, and not very freely in boiling *alcohol*, sparingly soluble in *ether*. It has the properties of a weak acid, and dissolves easily in *alkalis;* but is precipitated from the ammoniacal solution by strong acids as a bulky gelatinous mass, which becomes pulverulent when left for some time under the liquid. The alcoholic solution is not coloured by ferric chloride.

Quinovic acid does not lose weight at 140°. When somewhat strongly heated on platinum-foil, it melts and solidifies to a fissured mass; at a higher temperature it gives off a vapour smelling like incense, and burns with flame, leaving no residue. By dry distillation it first gives off an oil smelling like oil of turpentine, then vapours having an odour of incense, and a thickish amber-yellow liquid, which condenses in the neck of the retort. It is scarcely affected by hydrochloric or even by boiling nitric acid; it dissolves in *sulphuric acid*, and is precipitated therefrom by water. When triturated, or warmed with *phosphoric chloride*, it liquefies, evolving hydrochloric acid, and on distillation, gives off phosphoric oxychloride, leaving a blackened residue.

Quinovates.—Quinovic acid is dibasic, the general formula of its salts being $C^{24}H^{36}M^2O^4$. It dissolves in alkalis and decomposes alkaline carbonates, but its ammoniacal solution gives off ammonia on evaporation. The same solution gives precipitates with salts of the heavy metals.—The *potassium-salt*, $2C^{24}H^{36}K^2O^4.3H^2O$ (at 160°), is obtained as a bulky pasty precipitate, on adding strong caustic potash to a concentrated ammoniacal solution of the acid, also by concentrating a solution of the acid in potash. —The *sodium-salt* resembles it, and is obtained in like manner.—The *barium-, strontium-*, and *calcium-salts* separate as gelatinous precipitates, on adding the corresponding chlorides to the ammoniacal solution of the acid.—The *copper-salt* is a light-blue precipitate, whose composition (at 120°) is approximately represented by the formula $C^{24}H^{36}Cu''O^4.5H^2O$.—The *silver-salt* is a bulky precipitate, quickly changing on exposure to light, and exhibiting when dried in a vacuum, and then at 120°, the composition $C^{24}H^{36}Ag^2O^4$.

QUINOVIN. $C^{30}H^{48}O^8$. *Quinova-bitter;* formerly also called *Quinovic, Quinovatic,* or *Chiococcic acid.* (Pelletier and Caventou, J. Pharm. vii. 112.—Winckler, Répert. Pharm. li. 193.—Buchner, jun. Ann. Ch. Pharm. xvii. 161.—Peterson, *ibid.* xvii. 165.—Schnedermann, *ibid.* xlv. 277.—Rochleder and Hlasiwetz, *ibid.* lxxvi. 238.—Hlasiwetz, *ibid.* lxxix. 129.—Schwarz, *ibid.* lxxx. 330.—Hlasiwetz and Gilm, *ibid.* cxi. 182; Jahresb. 1859, p. 578).—A substance discovered by Pelletier and Caventou in the false cinchona-bark of commerce (*Cinchona nova*), found also by Schwarz and by De Vrij (J. Pharm. [3] xxxvii. 256) in the true cinchona-barks. According to Rochleder and Hlasiwetz, quinovin (or perhaps rather quinovic acid) is formed by the action of acids and alkalis on caïncic acid (i. 710). It may be extracted from false cinchona-bark by boiling with milk of lime, precipitating the extract with hydrochloric acid, and purified by dissolving the precipitate in alcohol, reprecipitating with water, and repeating this operation till a perfectly colourless product is obtained. (Schnedermann.)

According to De Vrij, the crude quinova-bitter extracted from cinchona-bark may be separated by chloroform into quinovin, soluble in that liquid, and easily soluble in alcohol; and quinovic acid, insoluble in chloroform and only sparingly soluble in alcohol. He obtained quinova-bitter from all parts of *Cinchona Calisaya*, cultivated in Java: from the woody parts of the roots, 2·57 per cent.; from the root-bark, 1·08; from the wood of the stem, 1·80; from the bark of the stem, 0·36; from the bark of the woody branches, 0·68; from the herbaceous stalks, 0·85; and from the dried leaves, 0·23 per cent. The amount of quinova-bitter in the several organs (excepting the leaves, which contain no alkaloïds) is inversely proportional to the quantity of alkaloïds present.

Quinovin when dry forms amorphous fragments resembling gum. It has a very bitter taste, is nearly insoluble in *water*, moderately soluble in *ether*, very soluble in *alcohol*, and is not deposited from its solutions in the crystalline state (Schnedermann). It is soluble in *chloroform*, and turns the plane of polarisation of a luminous ray to the right, but less strongly than quinovic acid. (De Vrij.)

The analyses of quinovin (or quinova-bitter) by different chemists do not exhibit very close agreement, probably because some of the products examined consisted of crude quinova-bitter, containing quinovic acid as well as quinovin. Schnedermann found 67·2 per cent. carbon, 9·05 hydrogen; Hlasiwetz, 66·6 carbon and 8·9 hydrogen—numbers agreeing nearly with the formula $C^{30}H^{48}O^8$, which requires 67·2 carbon, 9·0 hydrogen, and 11·9 oxygen.

Quinovin yields by dry distillation a thick oil, having a strong odour of incense and petroleum, together with a small quantity of shining crystals. With *nitrous acid* it gives off red vapours; and on adding water to the solution, white amorphous flocks are precipitated, together with a resinous matter; no oxalic acid is produced.

When dry *hydrochloric acid gas* is passed into the alcoholic solution of quinovin, the latter is resolved into quinovic acid and quinova-sugar (Hlasiwetz):

$$C^{30}H^{48}O^8 + H^2O = C^{24}H^{38}O^4 + C^6H^{12}O^5.$$

QUINOYL. A diatomic radicle, which may be supposed to exist in quinone and its derivatives, quinone itself being regarded as the hydride $(C^6H^2O^2)''H^2$, dichloroquinone as the chloride of quinoyl $(C^6H^2O^2)''Cl^2$, a view which is in accordance with its reactions with alkalis (p. 28), and perchloroquinone in like manner as the chloride of dichloroquinoyl $(C^6Cl^2O^2)''Cl^2$.

QUINOYLAMIC ACID, $\left.\begin{array}{c}H^2\\(C^6H^2O^2)''\\H\end{array}\right\}\begin{array}{l}N\\O\end{array}$, is not known; but dichloroquinoylamic acid, $C^6H^3Cl^2NO^3 = \left.\begin{array}{c}H^2\\(C^6Cl^2O^2)''\\H\end{array}\right\}\begin{array}{l}N\\O\end{array}$, also called *dichloroquinonamic acid, chloranilam,* and *chloranilamic acid*, was discovered by Erdmann (J. pr. Chem. xxii. 287), and further examined by Laurent (Ann. Ch. Phys. [3] iii. 493). It is produced by the action of aqueous ammonia on perchloroquinone (chloranil):

$$C^6Cl^4O^2 + NH^3 + H^2O = C^6H^3Cl^2NO^3 + 2HCl.$$

The resulting red liquid, when concentrated, deposits crystals of dichloroquinoylamate of ammonium; and on mixing a saturated solution of this salt with hydrochloric or sulphuric acid, dichloroquinoylamic acid is deposited on cooling in black needles containing $2C^6H^3Cl^2NO^3.5H^2O$, having a fine adamantine lustre and often several inches long: it may be purified by crystallisation from boiling water.

Dichloroquinoylamic acid is slightly soluble in water, forming a violet solution, which precipitates metallic salts. Caustic potash decomposes it, eliminating ammonia, and forming dichloroquinoylate of potassium (p. 34). It is not altered by hydrochloric or sulphuric acid in the cold, but at the boiling heat these acids convert it into dichloroquinoylic acid.

Dichloroquinoylamate of Ammonium (or *Chloranilammon*) $C^6H^2(NH^4)Cl^2NO^3.2H^2O$, forms flattened chestnut-coloured shining needles, soluble with purple colour in water, especially when warm. The solution precipitates metallic salts.—The *barium-salt* is a light-brown precipitate, soluble with purple colour in hot water.—The *copper-salt* is a greenish-brown precipitate, obtained by mixing the ammonium-salt with cupric acetate.—The *lead-salt* is a red-brown precipitate; the *mercurous salt* a dark-brown precipitate. Mercuric chloride does not form a precipitate with the ammonium-salt.—The *silver-salt*, $C^6H^2AgCl^2NO^3$, is precipitated in brown flocks, often crystalline, and apparently easily decomposible.

QUINOYLAMIDES. 1. *Quinoyl-diamide*, $\left.\begin{matrix}(C^6H^2O^2)''\\ H^4\end{matrix}\right\}N^2$, is not actually known, but would probably be obtained by the action of ammonia on quinone in presence of alcohol, in the same manner as its derivatives, described below. Quinone treated with dry ammonia gas takes up 2 at. ammonia, and forms quinonamide, C^6H^5NO (p. 26).

Dichloroquinoyl-diamide, $\left.\begin{matrix}(C^6Cl^2O^2)''\\ H^4\end{matrix}\right\}N^2$. *Dichloroquinonamide, Chloranilamide* (Laurent, Rev. Scient. xix. 141).—This compound is formed by the action of ammonia on perchloroquinone (chloranil) in presence of alcohol:

$$(C^6Cl^2O^2)''Cl^2 + 4NH^3 = \left.\begin{matrix}(C^6Cl^2O^2)''\\ H^4\end{matrix}\right\}N^2 + 2NH^4Cl.$$

When a mixture of perchloroquinone, alcohol, and ammonia is gently heated, the liquid becomes red-brown, part of the solid substance dissolves (the solution containing dichloroquinoylate of ammonium), whilst another portion remains in the form of a brown-red precipitate. This precipitate is washed with alcohol, then redissolved in the liquid with addition of potash, and gentle heating; the liquid is filtered if necessary; and the potash is neutralised by an acid, while the liquid is still warm. Dichloroquinoyl-diamide is then separated almost immediately, as a red-brown precipitate, the colour of which is finer in proportion as the quantity of alcohol used is larger, and the temperature of the liquid higher. Too great a heat must however be avoided, as above a certain temperature the product would be decomposed by the potash.

Dichloroquinoyl-diamide in the dry state, is a crystalline powder composed of microscopic needles of a deep crimson colour and almost metallic lustre. It is insoluble in water, and nearly insoluble in alcohol and ether. When cautiously heated on a glass plate, it partly sublimes, partly decomposes. It is not attacked by hydrochloric acid, even at the boiling heat. It dissolves in strong sulphuric acid, forming a violet solution, from which it is almost wholly precipitated by water. Boiling potash eliminates ammonia, and converts the amide into dichloroquinoylate of potassium.

Diphenyl-quinoyl-diamide, $C^{18}H^{14}N^2O^2 = \left.\begin{matrix}(C^6H^5)^2\\ (C^6H^2O^2)''\\ H^2\end{matrix}\right\}N^2$, is produced by the action of quinone on aniline, in presence of a large quantity of boiling alcohol:

$$\underset{\text{Quinone.}}{3(C^6H^2O^2)''H^2} + \underset{\text{Aniline.}}{2(C^6H^5)H^2N} = \underset{\text{Diphenylquinoyl-diamide.}}{\left.\begin{matrix}(C^6H^5)^2\\ (C^6H^2O^2)''\\ H^2\end{matrix}\right\}N^2} + \underset{\text{Hydroquinone.}}{2C^6H^6O^2}.$$

The resulting brown solution deposits the diamide on cooling, in red-brown scales having an almost metallic lustre, and the mother-liquor evaporated with hydrochloric acid, yields a mixture of hydrochlorate of aniline and hydroquinone. (Hofmann, Proc. Roy. Soc. xiii. 4.)

Diphenyl-dichloroquinoyl-diamide, $C^{18}H^{12}Cl^2N^2O^2 = \left.\begin{matrix}(C^6H^5)^2\\ (C^6Cl^2O^2)''\\ H^2\end{matrix}\right\}N^2$.—This compound is produced by the action of aniline on perchloroquinone, according to the equation:

$$C^6Cl^4O^2 + 4C^6H^7N = C^{18}H^{12}Cl^2N^2O^2 + 2(C^6H^7N.HCl).$$

It was first obtained by Hesse (Ann. Ch. Pharm. cxiv. 292; Jahresb. 1860, p. 283), who regarded it as *dichloro-quinoyl-pentaphenyl-pentamide*; but Hofmann (*loc. cit.*) has shown that its true formula is that above given. It forms brown-black crystals, sublimable, insoluble in water and in cold alcohol, ether, hydrochloric acid, and alkalis, but soluble in benzene, by which it may be separated from another substance, formed in the same reaction. (Hesse.)

QUINOYLIC ACID, or *Quinonic acid,* $\left.\begin{matrix}(C^6H^2O^2)''\\H^2\end{matrix}\right\}O^2$, is not known, but its dichlorinated derivative has been obtained.

Dichloroquinoylic acid, $C^6H^2Cl^2O^4 = \left.\begin{matrix}(C^6Cl^2O^2)''\\H^2\end{matrix}\right\}O^2$.—*Dichloroquinonic acid, Chloranilic acid* (Erdmann, J. pr. Chem. xxii. 281).—Produced by the action of potash on perchloroquinone, dichloroquinoylamide, or dichloroquinoylamic acid. On adding hydrochloric acid to a solution of perchloroquinone in warm potash-ley, the liquid turns red, and deposits dichloroquinoylic acid in yellowish-white nacreous scales, which, when collected on a filter and viewed in mass, exhibit the colour of minium.

The crystallised acid contains 7·1 per cent. (= 1 at.) water of crystallisation, which it gives off at 115°; when heated in a test-tube it partly sublimes unaltered, but a considerable portion turns brown and decomposes. It dissolves in water, forming a violet solution, from which it is precipitated by sulphuric or hydrochloric acid.

Dichloroquinoylic acid is dibasic.

The *potassium-salt,* $C^6K^2Cl^2O^4.H^2O$, is deposited in crystals from a solution of perchloroquinone in warm caustic potash on cooling, and so completely that the mother-liquor retains only a very faint reddish or brownish tint. It is purified by recrystallisation from water. The crystals do not give off their water at 100°. The salt heated on platinum-foil burns with slight detonation, giving off purple vapours. It dissolves in water and alcohol, with purple colour, inclining to violet; less freely in potash. Its aqueous solution precipitates several metallic salts.—The *neutral ammonium-salt,* produced by the action of aqueous ammonia on perchloroquinone, crystallises like the potassium-salt.

The *barium-salt* is obtained by precipitation with chloride of barium, in red-brown micaceous scales, slightly soluble in boiling water. *Cobalt-salts, nickel-salts,* and *ferrous salts* are not precipitated by dichloroquinoylate of potassium.

Ferric dichloroquinoylate is a blackish precipitate, obtained with ferric nitrate. The *cupric salt* is a greenish-brown, the *lead-salt* a brown precipitate. The *mercurous salt* is a yellowish-brown precipitate obtained with mercurous nitrate. Mercuric chloride gives no precipitate.—The *silver-salt,* $C^6Ag^2Cl^2O^4$, is a brown-red pulverulent precipitate, which dissolves but very slightly in water, forming a reddish solution.

QUINTESSENCE. The alchemists distinguished four essences, answering to the four Aristotelian elements; to these Raimund Lullius added a fifth, namely alcohol, denominated *quinta essentia* on account of its enlivening action. The term is sometimes also used to denote the therapeutic constituents of any substance.

QUINTO. Prefix synonymous with PENTA.

QUIRINUS OIL. A kind of rock-oil or petroleum, of thickish consistence, so called from the Chapel of St. Quirinus, at Tegernsee, near which it issues. It is brownish-yellow, olive-green by reflected light, and has a specific gravity of 0·835.

R

RACEMIC ACID. $C^4H^6O^6 = \left.\begin{matrix}(C^4H^2O^2)^{iv}\\H^4\end{matrix}\right\}O^4$. *Paratartaric acid. Uvic acid. Traubensäure.*—An acid, isomeric with tartaric acid, but distinguished from the latter by several characters, and chiefly by its optical properties,—tartaric acid exhibiting the power of circular polarisation, whereas racemic acid is optically inactive, but may be separated into equal quantities of dextrotartaric and lævotartaric acids, exerting equal and opposite actions on polarised light. There is also a modification of tartaric acid, called *inactive tartaric acid,* likewise optically inactive, but not separable into the two optically opposite acids.

Racemic acid exists ready-formed in certain tartars, and was discovered in 1822 by Kestner, a manufacturer of tartaric acid at Thann, in the Vosges, who obtained it in large quantity from the tartars produced in the vintages of 1822–1824. It has since been found by Kestner and others in the crude tartars of Austria, Hungary, Saintonge, and especially of Italy, but never in such quantity as from those in which it was first discovered.

It is formed artificially by several processes:—1. By the direct combination of equal weights of dextrotartaric and lævotartaric acid.—2. By the action of heat on tartaric ether, and on the dextrotartrate or lævotartrate of quinine or cinchonine (Pasteur, Ann. Ch. Pharm. lxxii. 164, lxxxviii. 211).—3. By heating inactive tartaric acid to 200°, or by boiling it with hydrochloric acid (Dessaignes, Bull. Soc. Chim. 1865, i. 34).—4. From cane-sugar and other carbohydrates, and from mannite, dulcite, sorbin, mucic acid, and saccharic acid, by oxidation with nitric acid, sometimes alone, sometimes together with tartaric acid (Carlet, Rép. Chim. pure, ii. 345; iv. 17.—Hornemann, J. pr. Chem. lxxxix. 283; Jahresb. 1853, p. 380). The following are the relative quantities of tartaric and racemic acids produced by oxidation of different carbohydrates and of saccharic and mucic acids (Hornemann):—

	In 100 pts. of acid.	
	Tartaric.	Racemic.
Milk-sugar	55·4	44·6
Gum	63·0	37·0
Cane-sugar	59·7	40·3
Starch	100	. .
Dextroglucose	100	. .
Lævoglucose	. .	100
Saccharic acid	72·6	27·4
Mucic acid	?	100

Hornemann's experiments confirm the supposition of Liebig (Jahresb. 1859, p. 281) and of Heintz (*ibid.* 1860, p. 259), that the formation of tartaric acid from sugars by oxidation is preceded by that of saccharic acid, and the formation of racemic acid by that of mucic acid.

5. By boiling dibromosuccinate of silver with water (Perkin and Duppa, Chem. Soc. Qu. J. xiii. 102):

$$C^4H^2Ag^2Br^2O^4 + 2H^2O = C^4H^6O^6 + 2AgBr.$$

6. By heating an aqueous solution of racemo-carbonic (desoxalic) acid, or a dilute solution of its ethylic ether slightly acidulated with sulphuric acid, to 100° in a sealed tube for a considerable time: $C^5H^6O^8 = CO^2 + C^4H^6O^6$ (Löwig, Jahresb. 1861, p. 605). The acid obtained by the last two processes has not, however, been actually separated into dextro- and lævotartaric acid, so that it may possibly be inactive tartaric acid. The calcium-salt of the acid obtained from dibromosuccinic acid differs, also, in some respects from that of natural racemic acid. (Kekulé, p. 37.)

Preparation.—1. From crude tartar. Racemic acid accumulates in the mother-liquors obtained in the refining of tartar; and when these mother-liquors are treated with chalk, and the insoluble calcium-salt thus produced is decomposed by sulphuric acid, an acid liquid is obtained, which when concentrated yields crystals of racemic and tartaric acids. In most cases the tartaric acid forms the greater part of the product, and is deposited in large transparent crystals, the spaces between which are more or less filled up with small, white, opaque needles of racemic acid. By separating these needles, dissolving them in water, and evaporating, the racemic acid may be obtained in large crystals.

2. From tartrate of cinchonine.—This salt (either the dextro- or the lævotartrate), when subjected to a gradually increasing temperature, is first converted into tartrate of cinchonicine (i. 971); and if the heat be continued, the cinchonicine gives off water, and is transformed into cinchonidine, while the tartaric acid likewise undergoes alteration, and after exposure for five or six hours to a heat of 170°, is partly converted into racemic acid. To extract this acid, the black resinous mass is treated several times with boiling water; the filtered liquid is mixed with excess of chloride of calcium; the racemate of calcium thereby precipitated is decomposed by dilute sulphuric acid; and the filtrate is concentrated to the crystallising-point. (Pasteur.)

Part of the racemic acid formed in the process just described is further converted into inactive tartaric acid, the quantity of the latter increasing as the heating is prolonged; and if the solution obtained as above be filtered immediately after the addition of the calcic chloride, the inactive tartrate of calcium, which is more soluble than the racemate, remains in the mother-liquor, and separates after 24 hours quite free from racemate. By decomposing this salt with sulphuric acid as above, and concentrating the solution, the inactive tartaric acid may be obtained in crystals. Now Dessaignes has lately shown (Bull. Soc. Chim. 1865, i. 34), that this acid in the free state is partially converted by heat into racemic acid, although, when the latter is in combination with certain organic alkaloïds, the opposite transformation takes place. If the inactive tartaric acid, after being dried, be heated in a retort to 200°, till about a third of it has passed off in the form of volatile products, a distillate is obtained, consisting chiefly of pyroracemic acid (iv. 770), and the residue consists partly of racemic, partly of unaltered inactive tartaric acid. On dissolving this residue in water, and half neutralising with ammonia, acid racemate of ammonium crystallises out first, while the more soluble inactive tartrate, constituting about two-thirds of the whole, remains dissolved. Inactive tartaric acid may also be partly converted into racemic acid by boiling with hydrochloric acid.

Properties.—Racemic acid forms hydrated crystals, $C^4H^6O^6.H^2O$, belonging to the triclinic sytem. Dominant combination: $\infty{}'P$. $\infty\bar{P}\infty$. $\infty P{}'$. $\infty\breve{P}\infty$. $,\breve{P}'\infty$. $,\bar{P},\infty$. $'\bar{P},\infty$, sometimes with oP, $P{},$ and $,\breve{P}'\infty$. Angle $'\bar{P},\infty : \infty\breve{P}\infty = 128° 33'$; $'\breve{P}\infty : \infty\bar{P}\infty = 123° 32'$; $\infty{}'P : \infty,\breve{P}\infty = 110° 45'$; $\infty{}'\bar{P} : \bar{P}\infty = 129° 51'$; $\infty\bar{P}\infty : \infty P{},$ = 152° 54'; $\infty\breve{P}{}' : \infty\breve{P}\infty = 146° 30'$; $'\bar{P}'\infty : ,\bar{P}\infty = 111° 57'$; $'\bar{P}\infty : \infty P{}, = 113° 32'$; $\breve{P},\infty : \infty{}'\breve{P} = 107° 28'$; $'\bar{P}'\infty : \infty\breve{P}\infty = 84° 26'$; $'\bar{P}\infty : \infty,P = 120° 32'$. Ratio of axes, $a : b : c = 0·48434 : 1 : 0·80602$. Angle $\alpha = 120°$; $\beta = 96° 19'$; $\gamma = 76° 5'$. (De la Provostaye, Ann. Ch. Phys. [3] iii. 131.)

The crystals have a specific gravity of 1·690 (Buignet, Jahresb. 1861, p. 15): they effloresce slowly on exposure to the air, give off all their water of crystallisation at 100°, dissolve in 5·7 pts. water at 15°, and in 48 pts. cold alcohol of specific gravity 0·809. In these respects racemic acid differs considerably from tartaric acid, which forms anhydrous monoclinic crystals, much more soluble in water than those of racemic acid.

Towards reagents racemic acid behaves for the most part like tartaric acid. Its calcium-salt is, however, less soluble than the tartrate, so that racemic acid precipitates a solution of gypsum, whereas tartaric acid does not. Racemate of calcium is likewise insoluble in acetic acid, whereas the tartrate is soluble. On adding ammonia to a solution of calcic racemate in hydrochloric acid, a crystalline precipitate is formed in a few seconds; whereas with the tartrate, the precipitation does not take place for several hours.

Racemic acid when heated above 100°, remains unaltered up to 200°, and then yields the same products as tartaric acid; being converted, before complete decomposition takes place, into tartrelic acid, tartralic acid, and other products formed by abstraction of water, which, however, have not been completely investigated. (See TARTARIC ACID.)

When a solution of neutral racemate of ammonium is mixed with a small quantity of the soluble portion of beer-yeast, or an albuminous body, a vegetable extract, or any animal liquid, and exposed to a temperature of 30°, fermentation takes place, and the whole of the racemic acid is converted into lævotartaric acid (Pasteur, Jahresb. 1858, p. 248). The same transformation is produced when acid racemate of ammonium is fermented under the influence of *Penicillium glaucum*. (Pasteur, Jahresb. 1860, p. 250.)

Racemates. Racemic acid, like tartaric acid, is tetratomic and dibasic, the formulæ of the racemates containing monatomic metals being:

$$\text{Neutral Racemates } C^4H^4M^2O^6 = \left.\begin{matrix} H^2 \\ (C^4H^2O^2)^{iv} \\ M^2 \end{matrix}\right\}O^4.$$

$$\text{Acid Racemates } C^4H^5MO^6 = \left.\begin{matrix} H^2 \\ (C^4H^2O^2)^{iv} \\ HM \end{matrix}\right\}O^4.$$

With diatomic metals it forms only neutral salts, $C^4H^4M''O^6$.

The racemates are very much like the corresponding tartrates, but their crystalline forms are always holohedral, and their solutions exert no action on polarised light; whereas the tartrates are hemihedral, and exhibit circular polarisation (see LIGHT, iii. 675). Most of the racemates have been analysed by Fresenius (Ann. Ch. Pharm. xli. 1; liii. 230).

Racemates of Ammonium.—The *neutral salt*, $C^4H^4(NH^4)^2O^6$, obtained by spontaneous evaporation of a solution of the acid neutralised with ammonia, crystallises in rhombic prisms exhibiting the dominant combination, ∞P . $\infty\breve{P}2$. $\infty\breve{P}\infty$. P . $\bar{P}\infty$. $\frac{3}{5}\bar{P}\infty$. Angle $\infty P : \infty P = 99° 30'$; $\infty P : \infty\breve{P}2 = 160° 50'$; $\bar{P}\infty : \bar{P}\infty = 118°$; $\bar{P}\infty : \frac{3}{2}\bar{P}\infty = 169°$. Ratio of axes, $a : b : c = 0·5087 : 1 : 0·8466$. The crystals when exposed to the air become dull, and give off ammonia: they are very soluble in water, nearly insoluble in alcohol.—The *acid salt*, $C^4H^5(NH^4)O^6$, is precipitated as a crystalline powder, on neutralising 1 pt. of racemic acid with ammonia, and adding an equal quantity of the acid. It dissolves in 100 pts. water at 20°, and in a much smaller quantity of boiling water. It reddens litmus, and is insoluble in alcohol. From an aqueous solution slowly cooled, it crystallises in monoclinic prisms, often assuming the tabular form from predominance of oP. The decomposition of the racemates of ammonium by fermentation has been already described.

Racemate of Antimony.—White granular precipitate, obtained by adding alcohol to a solution of antimonious oxide in aqueous racemic acid. (Berzelius.)

Potassio-antimonious Racemate, $2C^4H^4(SbO)KO^6.H^2O$, is obtained by saturating a boiling solution of acid racemate of potassium with antimonious oxide, and crystallises on cooling from a saturated solution in monoclinic prisms terminated by the facets of a very obtuse octahedron. Observed combination, $\infty P \, . \, \frac{1}{3}P$. Angle $\infty P : \infty P = 85° \, 20'$; $\infty P : \frac{1}{3}P = 118° \, 2'$; $\frac{1}{3}P : \frac{1}{3}P = 140°$; the same behind $= 142° \, 55'$. Axes, $a : b : c = 1{\cdot}074 : 1 : 0{\cdot}9217$ (De la Provostaye). Like tartar-emetic, after drying at 100°, it loses 5·5 per cent. water at 260°.

Racemates of Arsenic and the Alkali-metals.—These salts are prepared by adding to a boiling solution of a neutral racemate of alkali-metal, first a small quantity of arsenious acid, then racemic acid, and so on alternately till a sufficient quantity of the double salt is produced, while a large excess of acid racemate of the alkali-metal remains in solution. On evaporating the liquid, the double salt and the acid racemate are deposited separately.—The *ammonium-salt*, $2C^4H^4(AsO)(NH^4)O^6.H^2O$, forms small efflorescent crystals, soluble in 10·6 pts. of water at 15°. Its solution is decomposed by evaporation into arsenious acid and acid racemate of ammonium.—The *potassium-salt*, $2C^4H^4(AsO)KO^6.3H^2O$, forms well-defined nacreous crystals, which effloresce and give off 4·23 per cent. water at 100°, the remainder of the crystallisation-water between 155° and 170°.—The *anhydrous salt* may be heated to 250° without alteration, but at 255° it gives off water and empyreumatic products. It dissolves in a very small quantity of hot water, but the solution is partially decomposed by evaporation, acid racemate of potassium being deposited, while arsenious acid remains in solution. The crystals dissolve in 7·96 pts. water at 16°.—The *sodium-salt*, $2C^4H^4(AsO)NaO^6.5H^2O$, forms large non-efflorescent crystals, which dissolve in 14·6 pts. water at 19°, give off $\frac{4}{5}$ths of their crystallisation-water at 100°, and the remainder at 130°. (Werther, J. pr. Chem. xxxii. 385.)

Racemate of Barium, $2C^4H^4Ba''O^6.5H^2O$.—Racemic acid forms with baryta-water, white flocks, which dissolve in excess of the acid; but the solution soon becomes turbid, and deposits the whole of the barium-salt as a crystalline precipitate. The same precipitate is formed on mixing racemate of sodium with chloride of barium.

Racemate of Calcium, $C^4H^4Ca''O^6.4H^2O$.—Obtained in the same manner as the barium-salt. Aqueous racemic acid also gives a precipitate after a while, with sulphate of calcium. Racemate of calcium assumes the form, either of an amorphous precipitate or of fine needles. The crystals give off their water (27·75 per cent.) at 200°. The salt is nearly insoluble in cold water, but dissolves in hydrochloric acid, and is precipitated therefrom by ammonia. It is insoluble in acetic acid, and likewise in excess of racemic acid, after it has become crystalline. The calcium-salt of racemic acid produced from dibromosuccinic acid (p. 35), crystallises from boiling water in cubic crystals containing $C^4H^4Ca''O^6.3H^2O$, whereas that of natural racemic acid separates from boiling water in small white prisms containing 4 at. water. The artificial calcic racemate, when dissolved in hydrochloric acid and precipitated by ammonia, likewise forms prisms with 4 at. water, but on recrystallisation from boiling water it assumes the cubic form with 3 at. water. The calcium-salt of the artificial acid is also somewhat more soluble in water than that of the natural acid. (Kekulé, Jahresb. 1861, p. 364.)

Racemates of Chromium.—The violet solution of chromic hydrate in racemic acid leaves on evaporation a violet crystalline mass soluble in water; alcohol added to this solution throws down a violet basic salt, which blackens in drying, and dissolves in water only on addition of racemic acid.—With *potash*, racemate of chromium forms a solution which leaves a dark-violet mass on evaporation, and is completely precipitated by lime-water.

Racemate of Cobalt.—The solution of recently precipitated cobalt-oxide in racemic acid, yields by evaporation a pale red crystalline crust, soluble in water containing racemic acid; it dissolves also in potash, forming a violet solution, which on dilution deposits a dingy-blue precipitate.

Racemates of Copper.—*a.* The *cuprous salt* is obtained by digesting cuprous oxide with racemic acid in a tightly-closed vessel. It is moderately soluble in water, and is deposited on cooling in colourless rhomboïdal prisms. When exposed to the air it is converted into the cupric salt.

β. Cupric Racemates.—A mixture of the hot solutions of racemic acid and cupric sulphate, deposits, after a while, pale-green tabular crystals. A dilute solution of cupric acetate forms with racemic acid pale-blue needles, containing $C^4H^4Cu''O^6.2H^2O$ This salt gives off its water at 100°, dissolves sparingly in water, easily in hydrochloric acid; the solution when mixed with potash assumes a fine blue colour, and is not decolorised even at the boiling heat. Alkaline racemates form a green precipitate with cupric salts.

Cupric racemate dissolves in caustic alkalis and alkaline carbonates. On adding alcohol to a saturated solution of the salt in caustic soda, dark-blue needle-shaped crystals are deposited on the sides of the vessel, and light-blue tables at the bottom; both consisting of the salt, $C^4H^4Na^2O^6.Cu''O.4H^2O$, sparingly soluble in cold, more soluble in boiling water, and depositing cuprous oxide when boiled with excess of alkali.

Racemates of Iron.—Ferric hydrate dissolves in racemic acid, an insoluble basic salt being formed at the same time. The solution when evaporated leaves a brown amorphous mass, easily pulverised, very soluble in water, not precipitable by alkalis.—With *potash*, ferric racemate forms a dark-brown, granular, deliquescent double salt, soluble in racemic acid.

Racemate of Lead, $C^4H^4Pb''O^6$ (at 100°).—On adding racemic acid drop by drop to a hot solution of lead-acetate as long as the precipitate redissolves, and cooling the filtrate, racemate of lead is deposited in shining grains or delicate needles, soluble in hot aqueous racemic acid.

Racemate of Magnesium, $C^4H^4Mg''O^6.5H^2O$.—A solution of magnesium-carbonate in the boiling aqueous acid deposits this salt on slow cooling in small right rhomboïdal prisms; by quick cooling or prolonged evaporation as a white powder. It effloresces in dry air, gives off 4 at. (27·24 per cent.) water at 100°, the rest without decomposition at 200°. It dissolves in 120 pts. water at 19°, in a small quantity of boiling water, is insoluble in alcohol, dissolves in racemic acid, but the solution deposits nothing but the neutral salt and the free acid.

A saturated solution of magnesium-carbonate in an acid racemate of alkali-metal yields by slow evaporation, a syrupy mass, which gradually changes on cooling to an amorphous double salt, from which water extracts but a small quantity of alkaline racemate, even at the boiling heat.

Racemate of Manganese, $C^4H^4Mn''O^6.H^2O$.—Obtained by evaporating a solution of manganous acetate mixed with racemic acid, in yellowish-white crystals, permanent in the air even at 100°, slightly soluble in water, easily soluble in acids and alkalis.

Racemate of Mercury.—Racemic acid forms with mercurous nitrate, a white heavy precipitate, which becomes coloured on exposure to light, is insoluble in water and in racemic acid, but soluble in nitric acid.

Racemate of Nickel, $C^4H^4Ni''O^6.5H^2O$, is obtained, like the manganous salt, in green needles, which effloresce slowly at ordinary temperatures, rapidly at 100°. It is but slightly soluble in pure water, more soluble in water containing racemic acid. It dissolves with green colour in potash, also in hot aqueous carbonate of sodium, the liquid solidifying to a gelatinous mass on cooling.

Racemates of Potassium.—The *neutral salt*, $C^4H^4K^2O^6.2H^2O$, crystallises by slow evaporation, according to Pasteur, in six-sided tables belonging to the trimetric system, and exhibiting the combination $oP \,.\, \infty\breve{P}\infty \,.\, \infty P$. Angle $\infty\breve{P}\infty : \infty P = 128° 20'$. According to v. Lang, on the other hand (Wien. Akad. Ber. xlvi. [2] 31; Jahresb. 1862, p. 305), the crystals (with the same amount of water) are monoclinic, exhibiting the combination $\infty P\infty \,.\, [\infty P\infty] \,.\, oP \,.\, [P\infty] \,.\, [2P\infty] \,.\, \infty P \,.\, \infty P\frac{5}{3} \,.\, -P \,.\, +P \,.\, +P2$. Axes $a : b : c = 1 : 0·9134 : 0·7586$. Angle of inclined axes $= 92° 35'$. $[P\infty] : [\infty P\infty] = 97° 9'$; $[2P\infty] \,.\, [\infty P\infty] = 146° 35'$; $[2P\infty] : oP = 122° 56'$, $\infty P : \infty P\infty = 137° 57'$; $\infty P : oP = 88° 6'$; $\infty P\frac{5}{3} : oP = 87° 43'$; $-P : oP = 132° 43'$. The crystals dissolve in 0·97 pt. water at 25°, are nearly insoluble in alcohol, and give off all their water at 100°. Mineral acids or racemic acid added to the solution throw down the acid racemate.—The *acid salt*, obtained like the corresponding ammonium-salt, forms crystals soluble in 180 pts. of water at 19°, in 139 pts. at 25°, and in 14·3 pts. of boiling water; it is insoluble in alcohol, but dissolves easily in mineral acids.

Racemate of potassium and ammonium, $C^4H^4K(NH^4)O^6$, is obtained by slow evaporation of a solution of the acid potassium-salt saturated with ammonia, in acicular, longitudinally striated, rhombic prisms, having the angle $\infty\breve{P}\infty : \infty P = 130° 45'$, and not modified at the ends. (Pasteur.)

A *racemoborate of potassium* is obtained, according to Fresenius, by evaporating a solution of 1 at. boric acid and 2 at. acid potassic racemate, at 100°, as a white, acid, almost crystalline, friable mass, very soluble but not deliquescent. Similar products are obtained by evaporating a solution of borax and acid racemate of potassium or sodium. (Fresenius.)

Racemate of Silver, $C^4H^4Ag^2O^6$.—When a warm moderately strong solution of the acid potassium-salt is added to a solution of silver-nitrate heated to 80° or 85°, till the precipitate begins to be permanent, the liquid on cooling deposits racemate of silver in fine shining scales, less soluble in water than the tartrate, soluble in ammonia.

Racemates of Sodium.—The *neutral salt*, $C^4H^4Na^2O^6$, crystallises readily in anhydrous rhombic prisms soluble in 2·63 pts. of water at 25°, insoluble in alcohol.—The *acid salt*, $C^4H^5NaO^6.H^2O$, is precipitated by alcohol from a mixture of equivalent quantities of the neutral salt and racemic acid, and may be obtained, by recrystallisation from water, in monoclinic prisms with striated faces. It has a pleasant acid taste, gives off its water (9·41 per cent.) at 100°, dissolves in 11·3 pts. water at 19°, in a much smaller quantity of boiling water, but is insoluble in alcohol.

Sodio-ammonic and *Sodio-potassic racemates* exist only in solution, being separated by recrystallisation into mixtures of equal quantities of the corresponding dextro- and lævotartrates.

Racemate of Strontium, $C^4H^4Sr''O^6.4H^2O$.—Precipitated by racemic acid, from strontia-water in white flocks, and by the neutral potassium-salt from chloride of strontium, as a crystalline precipitate. It gives off its water (22·87 per cent.) at 100°, is nearly insoluble in cold, and only slightly soluble in boiling water; dissolves easily in hydrochloric acid, but is insoluble in acetic acid.

Racemate of Thallium forms small, closely-aggregated, easily soluble crystals, resembling those of the neutral ammonium-salt. $\infty P : \infty P = 100°$. (De la Provostaye, Ann. Ch. Pharm. cxxvi. 79.)

Racemate of Tin is very soluble and crystallisable.

Racemate of Zinc.—Racemic acid dissolves zinc with evolution of hydrogen, and the solution yields by evaporation colourless needles of racemate of zinc. Racemic acid forms with acetate of zinc, a gelatinous precipitate, nearly insoluble in water and difficult to dry.

Nitroracemic acid. $C^4H^4(NO^2)^2O^6$. (Dessaignes, J. Pharm. [3] xxxii. 46).—Prepared by quickly dissolving perfectly dehydrated and finely pulverised racemic acid in lukewarm nitric acid of specific gravity 1·52, and mixing the decanted solution with half its volume of strong sulphuric acid. The resulting magma dried between bricks under a bell-jar, forms a light white silky mass, the saturated solution of which in lukewarm water yields, when filtered and cooled to 0°, nacreous prisms, thinner and shorter than those of nitrotartaric acid. It has no action on polarised light. In aqueous solution it decomposes, giving off gas and yielding tartronic acid, together with other products. It dissolves without decomposition in absolute alcohol, and crystallises therefrom by spontaneous evaporation, in small plates composed of microscopic crystals. It forms a precipitate with basic acetate of lead, but not with acetate of potassium, calcium or lead, or nitrate of silver. The ammonium-salt decomposed by sulphydric acid, yields racemic and tartaric acid.

RACEMIC ETHERS. The only known compounds of this group are the acid racemates of ethyl and methyl.

Ethyl-racemic acid, or *Racemovinic acid*, $C^6H^{10}O^6 = C^4H^5(C^2H^5)O^6$ (Guérin-Varry, Ann. Ch. Phys. [2] lxii. 77).—Produced by boiling 4 pts. absolute alcohol with 1 pt. of racemic acid, and cohobating the mixture in a retort at a gentle heat till the liquid evaporated to a syrup no longer deposits any solid matter on cooling. It is then diluted with water, and saturated with carbonate of barium; the filtrate is evaporated at 50° or 60°; and the crystallised ethyl-racemate of barium thus obtained is decomposed by sulphuric acid.

Ethyl-racemic acid crystallises in colourless elongated prisms with obliquely inclined bases, deliquescent, very soluble in water and in alcohol, insoluble in ether. The solution has no action on polarised light, and is decomposed by ebullition into alcohol and racemic acid, which crystallises out.

Ethyl-racemic acid is decomposed by dry distillation, yielding alcohol, water, ethylic acetate, acetic acid, ethylene gas, pyroracemic acid, &c.—*Nitric acid* converts it into acetic, carbonic, and oxalic acids. Its solution dissolves *zinc* and *iron*, with evolution of hydrogen; yields with potash a pulverulent precipitate, and with soda an opaline precipitate, which appears just before the liquid becomes neutral, and increases with the quantity of acid added. When added drop by drop to *baryta-water*, it forms a precipitate, which diminishes as the liquid approaches neutrality, but reappears when the acid is added in excess. The precipitate is soluble in nitric acid.—With *lime-water* ethyl-racemic acid forms a precipitate insoluble in water, and in excess of the acid, but soluble in nitric acid. The acid does not produce any turbidity with calcic or sodic sulphate. It forms a white precipitate with *acetate of lead*, and with a concentrated solution of *nitrate of silver*.

Ethyl-racemic acid is monobasic. Its salts crystallise, but not so well as the ethyl-tartrates: some of them contain water of crystallisation, which they give off in a vacuum.—The *barium-salt*, $C^{12}H^{18}Ba''O^{12}.2H^2O$, crystallises in small prisms arranged in nodular groups. It is much more soluble in hot than in cold water, insoluble in absolute alcohol and in ether.—The *potassium-salt*, $C^6H^9HO^6.H^2O$, forms prisms, apparently monoclinic, gives off 7·56 per cent. water in vacuo.—The *silver-salt*, $C^4H^5AgO^6$, crystallises in prisms slightly soluble in cold water, decomposing at 100°.

Methyl-racemic acid, $C^5H^8O^6 = C^4H^5(CH^3)O^6$ (Guérin-Varry, *loc. cit.*)—Prepared by dissolving 1 pt. of racemic acid in 1 pt. of methylic alcohol, at the boiling heat, evaporating to a syrup at a temperature below 100°, leaving the syrup to evaporate freely, and drying the resulting crystals in a vacuum. It forms colourless rectangular prisms truncated on the longitudinal edges, and passing into rhomboïdal prisms. It dissolves easily in *water*, *alcohol*, and *wood-spirit*, slightly in ether. By boiling with water, it is resolved into methylic alcohol and racemic acid. Its aqueous solution decomposes *zinc* and *iron*, with evolution of hydrogen. With *baryta-water*, it forms a precipitate soluble in excess of the acid, and in water; with *lime-water*, it forms a precipitate composed of radiate groups of acicular prisms, insoluble in excess of the acid. Methyl-racemic acid does not precipitate caustic soda or carbonate of sodium.

Methyl-racemate of Barium, $C^{10}H^{14}Ba''O^{12}.4H^2O$, crystallises in monoclinic prisms, which give off part of their crystallisation-water on exposure to the air. When not effloresced, it softens at 60°, and at 100° gives off vapours, which condense in beautiful crystalline laminæ. It is more soluble in hot than in cold water, insoluble in alcohol and ether.—The *lead-salt* is precipitated on pouring methyl-racemic acid into a solution of lead-acetate; the precipitate redissolves in excess of acid.—The *potassium-salt*, $2C^5H^7KO^6.H^2O$, forms rectangular prisms, which are decomposed, by prolonged ebullition with water, into methylic alcohol and acid racemate of potassium. Methyl-racemic acid added to aqueous potash forms a pulverulent precipitate soluble in a large quantity of water.—The *silver-salt*, $C^5H^7AgO^6$, is precipitated on adding methyl-racemic acid to a moderately concentrated solution of silver-nitrate; it is soluble in excess of methyl-racemic acid.

RACEMOCARBONIC ACID. *Desoxalic acid*, $C^5H^6O^8 = \left.\begin{matrix}(C^5H^3O^5)'''\\H^3\end{matrix}\right\}O^3$. (Löwig, J. pr. Chem. lxxix. 455; lxxxiii. 129; lxxxiv. 1; Jahresb. 1860, p. 404; 1861, p. 601.)—This acid, which contains the elements of racemic acid and carbonic anhydride ($C^5H^6O^8 = C^4H^6O^6 + CO^2$), is produced in the form of an ethylic ether, by the action of sodium-amalgam on ethylic oxalate. It is probably formed by the deoxidation of oxalic acid, thus:

$$5C^2H^2O^4 + H^2O - O^5 = 2C^5H^6O^8;$$

whence the name *desoxalic acid;* but the reaction is complicated, yielding a number of products which have not been thoroughly investigated.

Preparation.—An amalgam of 30 grms. sodium and 800 to 2,000 grms. mercury is agitated in a glass cylinder with about an equal part of ethylic oxalate, the mass being kept cool by occasionally plunging the vessel into cold water; the resulting unctuous mass is stirred up with ether, the liquid is decanted from the mercury; the residue is treated several times more with ether; the united ethereal liquids are left at rest for a while; and the clarified solution, decanted from the sediment, is repeatedly and violently agitated with small quantities of water, till a pasty mass no longer separates from it, and the ethereal solution rises to the surface free from colour. This ethereal solution, when freed from the greater part of the ether by distillation, and left to evaporate in a warm place, deposits, after a while, large transparent shining crystals of ethylic racemocarbonate, which increase in quantity on further evaporation, while the uncrystallisable portion thickens to a yellow syrup.

The ethylic racemocarbonate may be converted by heating with carbonate of potassium, or by treatment with caustic potash, into alcohol and racemocarbonate of potassium; the solution of this salt, precipitated by nitrate of lead, yields the corresponding lead-salt; and this, when decomposed by sulphuretted hydrogen, yields racemocarbonic acid, the filtered solution of which may be made to crystallise, by first evaporating it at a gentle heat over the water-bath, and then leaving it under a bell-jar over oil of vitriol.

Properties and Reactions.—Racemocarbonic acid thus obtained is a dry crystalline mass, yielding a dazzling white powder. It is very soluble in water and in alcohol, and deliquesces in the air. It softens at the heat of the water-bath, and at a somewhat high temperature becomes dark-coloured; swells up, giving off an odour like that of burnt tartaric acid; then carbonises, and burns with a faintly luminous flame, leaving no residue. When its dilute aqueous solution is heated for some time to 100° in a sealed tube, it splits up into racemic acid and carbonic anhydride.

Racemocarbonates.—Racemocarbonic acid is tribasic, the formula of its neutral salts being $C^5H^3M^3O^8$. It likewise forms acid and basic salts.—The *neutral potassium-salt*, $C^5H^3K^3O^8$, formed by direct neutralisation, or by decomposing the ethylic ether with caustic potash, or boiling it with potassic carbonate, remains, on leaving its aqueous solution to evaporate, as a gummy mass, which becomes crystalline after standing over oil of vitriol, and dries up at 100° to a white porous mass. The solution yields the barium-, lead-, and silver-salts by double decomposition.—An *acid potassium-salt*, $C^5H^4K^2O^8$, is obtained by decomposing the ethylic ether with a solution of potash in absolute alcohol, as a viscid mass, which dries up to a dazzling white powder, becoming moist on exposure to the air. The same salt is obtained in shining white crystalline crusts, by supersaturating a solution of racemocarbonic acid in potash with acetic acid. It has a slightly sour taste, dissolves in 19·4 pts. water at 16°, and does not decompose till heated above 100°.—The *neutral sodium-salt* is very soluble, and decomposes at 130°.—The *barium-salt*, $C^{10}H^6\overset{''}{Ba}{}^3O^{16}$, and the *calcium-salt*, $C^{10}H^6\overset{''}{Ca}{}^3O^{16}.3H^2O$, are white powders. When racemocarbonic acid is mixed with excess of lime-water, and the bulky precipitate is dissolved in a few drops of hydrochloric acid, the solution instantly yields with ammonia a flocculent precipitate of calcic racemocarbonate, whereas the racemate is precipitated under similar circumstances as a heavy crystalline powder, and only after the lapse of a few seconds.—The *neutral lead-salt*, $C^{10}H^6\overset{''}{Pb}{}^3O^{16}$, is when dry, a dazzling white powder, not quite insoluble in hot water. It appears to retain 1 at. water at 100°.—A *basic lead-salt*, $C^{10}H^6\overset{''}{Pb}{}^3O^{16}.C^{10}H^4\overset{''}{Pb}{}^4O^{16}$, is obtained as a bulky precipitate, by heating the aqueous solution of the ethylic ether with basic acetate of lead.—The *neutral silver-salt*, $C^5H^3Ag^3O^8$, is a white precipitate, soon turning black when moist, slightly soluble in water, easily soluble in dilute nitric and in racemocarbonic acid, the latter solution depositing a mirror of silver on standing.—A somewhat more soluble *acid silver-salt*, $C^5H^4Ag^2O^8$, is obtained by precipitating the corresponding potassium-salt with nitrate of silver.—The precipitates formed in the solution of the neutral potassium-salt by the sulphates of *zinc*, *copper*, and *manganese*, dissolve in excess of the precipitant.

Ethylic Racemocarbonate, $C^{11}H^{18}O^8 = C^5H^3(C^2H^5)^3O^8$, prepared as above described, forms large, transparent, colourless, highly lustrous crystals, which resemble chlorate of sodium, but do not appear to belong to the regular system. They retain their lustre for months, dissolve in 10 pts. water at 16°, also in alcohol and ether, have no odour, but a strong purely bitter taste, melt at 85°, forming a liquid which solidifies again at 85°. When the fused compound is exposed for some time to the heat of boiling water, it remains after cooling as a thick oily liquid, which does not solidify for a considerable time. The ether may be sublimed by careful heating in a glass tube, but if heated for some time to 140°—150°, it yields on cooling (without loss of weight) a perfectly colourless, syrupy, extremely bitter mass, which no longer solidifies. When distilled in a retort, it leaves only a trace of carbonaceous residue; the distillate is oily, has a bitter taste, and does not appear to contain racemocarbonic acid.

Ethylic racemocarbonate heated with baryta-water, caustic alkalis, or alkaline carbonates, is decomposed, yielding alcohol and a racemocarbonate of barium, &c. (p. 40). When a dilute solution of the ether, slightly acidulated with sulphuric or hydrochloric acid, is heated to 100° in a sealed tube, the racemocarbonic acid is resolved into carbonic anhydride and racemic acid. If, on the other hand, a concentrated solution of the ether is used, only partial decomposition takes place; and Löwig thinks it probable that an acid intermediate between racemocarbonic and racemic acid, or perhaps a compound of the two, may be formed. When a dilute solution of ethylic racemocarbonate containing a little sulphuric or hydrochloric acid, is boiled in a platinum dish, scarcely any gas is evolved, so long as the water lost by evaporation is renewed; but on subsequently concentrating the liquid, it becomes darker and gives off gas. The syrupy liquid remaining, after the hydrochloric acid has been completely expelled, solidifies on cooling to a brittle friable mass, easily soluble in water; and if the concentrated solution be left to evaporate, a tolerably abundant crystallisation of racemic acid is obtained; the greater part, however, forms a syrupy acid, which dries up over oil of vitriol to a translucent mass, and yields a silver-salt having the composition of silver-racemate.

The yellow syrup (p. 40), obtained together with the crystals in the preparation of ethylic racemocarbonate, is an uncrystallisable modification of that compound. By heating it with strong hydrochloric acid, and then evaporating off the whole of that acid, a very acid syrup is obtained, which dries up over oil of vitriol to an amorphous transparent mass, easily soluble in water. The acid thus obtained is isomeric with racemic acid, but is distingushed from that acid and from racemocarbonic acid by its reaction with lime-water, yielding therewith a precipitate, which when dissolved in a small quantity of hydrochloric acid is not reprecipitated by ammonia. Moreover, it does not form a sparingly soluble acid salt with potash. (Löwig.)

RADIATION AND CONDUCTION OF HEAT. There are various modes in which heat may be transferred from one place to another. Of all these, the most easily intelligible—in the sense of our being able clearly to conceive and follow the several parts of the process—consists in the bodily movement of heated matter. A very important case of the transference of heat in this manner is presented by the so-called phenomena of *convection*, upon which the distribution of heat in liquid and aëriform bodies almost entirely depends. Another way in which the motion of material bodies may intervene, as the medium of the transference of heat, is exhibited in many cases of the evolution of heat by mechanical means. For instance, if a steam-engine is employed to overcome friction, or to do other work in opposition to molecular forces, and so to develop heat, the process may be correctly described, so far as the general result is concerned, as consisting in the transfer of part of the heat of combustion of the coals, from the furnace to the place where the heat-producing work is performed. In other cases, again, electricity is the medium of the transference of heat from one place to another. But, in addition to all these various ways in which the motion of heat may be brought about by the action of other forms of energy, there are two distinct ways in which it can occur without the intervention of energy in any other form. These are RADIATION, or the spontaneous outflow of heat in all directions which is constantly taking place at the free surface of material bodies; and CONDUCTION, or the propagation of heat by communication through the substance of material bodies, whereby the temperature of every mass of matter tends constantly to become uniform throughout. We shall attempt in this article to state the most important laws and conditions by which the transference of heat in these two ways has been found to be determined.

RADIATION.

The radiation of heat is a phenomenon completely analogous to the radiation of light; in fact, all the known properties of radiant heat and of light point to the conclusion, that there is no difference of a fundamental kind between them. And if, as seems inevitable, we adopt the hypothesis that temperature in material bodies consists in a vibratory or other movement of their particles (HEAT, iii. 131), we must regard radiation, whether of heat or light, as due to vibrations of the luminiferous ether (LIGHT, iii. 589), excited by the heat-vibrations of the particles of ordinary matter, and propagated by the ether in all directions from their source. According to this view, a radiating body may be compared with a vibrating tuning-fork, or other source of sound; and the rays of heat or light which it emits, with the progressive undulations, constituting waves of sound, which the vibrations of the sounding body excite in the air. The cooling of a heated body by radiation would thus answer to the gradual dying-out of the vibrations of the tuning-fork, as it gives up its motion to the air: any circumstance which increases the rate of radiation, that is to say, the quantity of heat given out in a given time, hastening the fall of temperature of the heated body; just as whatever increases the amount of motion imparted to the air in a given time by a vibrating fork, and so augments the loudness of the resulting sound, causes the fork to come to rest more quickly. On the same view, a rise of temperature in a material body, caused by rays of heat absorbed by it, would correspond with the production of sympathetic vibrations in solid bodies under the influence of sound-waves transmitted to them through the air; and just as those conditions, which facilitate most the communication of motion by a vibrating body to the air, are also the conditions most favourable to its being thrown into vibration by undulations of the air, so, as we shall see, the conditions which most promote the loss of heat by radiation are also those which are most favourable to the absorption or gain of heat in the same way. Again, the different refrangibility which characterises rays of light of various colours, as well as rays of heat from various sources, being caused by different rates of vibration, corresponds to the different pitch of various sounds. (On the analogies of heat and sound, comp. Thomas Young, *Lectures on Natural Philosophy*, 2 vols. 4to. Lond. 1807, vol. i. p. 656.)

Radiation, considered as a mode of transference of heat, is obviously a process which can only go on between at least two material bodies, of which one gives out, and the other receives, heat. And, except in the case of radiation through a vacuum, a third body also intervenes in the phenomenon—namely, that *through* which the radiation takes place. Hence the entire process consists of three distinct parts—Emission, Absorption, Transmission—the course of each of which is dependent on the physical properties of the particular material substances concerned. But, before considering radiant heat in relation to the properties of individual substances, we will briefly describe its general properties, and enumerate the most important and decisive of the experiments by which the essential identity of radiant heat and light has been proved, and which therefore justify the conclusion that radiant heat, like light, consists in undulations propagated by the luminiferous ether, in the same way as waves of sound are propagated by the air.

1. *Radiant heat traverses a vacuum, or any homogeneous medium, in straight lines.*

This fact is proved, like the corresponding fact in the case of light, by the effect of opaque screens, which, with the exceptions mentioned at page 46 (parag. 7), prevent the heat of any radiant source from arriving at any point so situated that a straight line drawn from it to the source would cut such a screen.

2. *Radiant heat is emitted in straight lines in all directions from a radiating point.* Hence the quantity of heat which in a given time falls on a given surface from a radiating point is *inversely proportional to the square of the distance* of that surface from the radiating point. The most complete and decisive proof of this law was furnished by Melloni, who showed that when a thermo-electric pile (ELECTRICITY, ii. 413; HEAT, iii. 22), fitted with a non-reflecting cone, is turned towards a large, flat, uniformly heated surface, the heating effect, as shown by the deflection of the needle of a galvanometer connected with the pile, is the same at all distances of the pile from the heated surface. In this case the portion of the flat surface subtended by the face of the pile, or *visible* therefrom, *increases* proportionably to the square of the distance: that is to say, the number of points of the heated surface from which rays can reach the pile is *directly proportional* to the square of the distance; but, since the total heating effect remains the same at all distances, it follows that the effect of each point must be *inversely proportional* to the square of its distance from the pile. (Melloni, *La Thermochrôse*, Naples, 1850, p. 129.)

3. The *velocity of propagation* of radiant heat has not yet been measured directly, in consequence of the time required by it to produce sensible effects being greater than the time of its transmission through such distances as are available for experiment. There is, however, every reason to suppose that, in substances not possessed of dispersive power, it is the same as that of light. Melloni found the time of transmission through 357 feet of air inappreciably short. (*Op. cit.* pp. 121–123.)

4. It follows, from the laws which hold with respect to the propagation of wave-motions, that, whenever a train of waves arrives at a surface, on opposite sides of which the relation between the elasticity and density of the medium of propagation is different, *partial* or *total reflection* must take place; and that this reflection must take place so that the reflected ray lies in the same plane with the incident ray, and the normal to the reflecting surface at the point of incidence, and that the incident and reflected rays make equal angles with the normal. That radiant heat is thus *reflected* on arriving at the surface of separation of two media, may be proved by means of a thermo-multiplier placed in such a position relatively to a source of heat and a plane metallic reflector, that the radiation from the source cannot reach it, except by the rays being reflected in accordance with the above conditions. The equality of the angles of incidence and reflection can be still more decisively demonstrated by means of two parabolic reflectors placed with their concave surfaces towards each other, and their axes coincident: if a source of heat be placed in the focus of one reflector, the rays which strike this reflector will be brought to a focus again at the focus of the other reflector.

But, as in the case of light, this law can only be recognised when reflection takes place at polished surfaces, that is, at surfaces each element of which is situated sensibly at the same plane, or coincides with the same curve. Since, however, even with the most perfect polish that can be obtained, many superficial elements are doubtless inclined in directions which do not coincide with the general form of the surface, the intensity of the heat reflected in such a direction as to make with the normal to the general surface an angle equal to that made by the direction of the incident heat, is always less than the intensity of the incident heat, even allowing for the quantity which may penetrate the reflecting surface. The amount of heat thus irregularly reflected, or *diffused*, necessarily varies with the nature of the reflecting surface, being less, under otherwise similar circumstances, in proportion as the latter is more perfectly polished; it also varies with the absolute value of the angle of incidence.

The fact of the diffusive reflection of heat was first placed beyond doubt by Melloni, whose method of experiment consisted in determining, by means of the thermo-multiplier, the relative quantities of heat radiated obliquely by very thin unpolished screens, upon which rays were incident normally from a source of heat. The screens were so thin that both surfaces might be regarded as having the same temperature; nevertheless, the quantity of heat radiated in a direction making a given oblique angle with the surface turned towards the source of heat, exceeded that radiated in a direction making the same angle with the other surface; showing that the radiation from the former surface did not consist entirely of the heat given out by the screen itself, but also, in part, of heat irregularly reflected. The influence of the absolute value of the angle of incidence on the proportion of heat reflected irregularly, has been investigated by Knoblauch. With solar heat and, in one set of experiments, a glass mirror blackened at the back, and in another set with a metallic mirror, he obtained the following results:—

Angle of Incidence measured from the Mirror.	Deflection of the Galvanometer-needle produced by the Rays regularly reflected—	
	From the Blackened Mirror.	From the Metallic Mirror.
60°	10·0°	56·0°
50	10·0	55·0
40	11·0	54·5
30	15·1	53·0
20	28·1	48·0
10	43·0	43·0

The numbers in the last column show that the quantity of heat reflected regularly by the metallic mirror diminished, and consequently the quantity reflected irregularly increased, as the incident rays made a smaller angle with the surface of the mirror. The increased reflection from the glass mirror at low angles of incidence is to be attributed, not to diminished diffusion, but to diminished absorption.

4. In addition to the portion which is reflected, regularly or irregularly, when radiant heat arrives at the surface of separation of two media, a certain quantity usually—perhaps always—penetrates the second medium. Of the heat which thus passes onwards into the second medium, a greater or less proportion is always *absorbed;* or, in the language of the view we have adopted respecting the nature of radiant heat, the vibratory motion of the particles of the ether is given up to the material particles of the medium. The proportion of heat so absorbed varies, from a barely perceptible amount, even when a considerable thickness of the second medium is traversed, as in the case of rock-salt, to the total quantity which enters the medium, as in the case of the metals, in which the absorption of heat is so complete, within a very short distance from the surface, that it was only by employing exceedingly thin films of metal, deposited on glass by chemical means, that Knoblauch succeeded in proving that the metals are not absolutely impenetrable by radiant heat. The proportion of radiant heat absorbed in its passage through a given thickness of a given medium is not, however, a constant quantity; it varies to a great extent, as we shall presently see, with the temperature of the source from which the heat comes, just as the absorption of light by various media depends on the colour of the light.

5. Another consequence of the general principles of wave-motion, is that, upon the theory we have adopted, when radiant heat passes from one medium into another, in which the elasticity and density of the luminiferous ether are to each other in a different ratio from what they were in the first medium, its velocity of propagation must be different in the two media. Consequently, if the rays of heat are incident upon the separating surface of the media in any other direction than that of the normal to the surface at the point of incidence, their direction will be altered on passing from the first medium into the second, or they will undergo *refraction;* and this refraction will take place according to the same laws as the refraction of light—that is, the refracted ray will be in the same plane with the incident ray and the normal to the surface, and the sine of the angle which the incident ray makes with the normal will be to the sine of the angle which the refracted ray makes with the normal, as the velocity of the ray in the first medium is to its velocity of propagation in the second medium (see Light, iii. 608, 609). A familiar example of the refraction of heat is afforded by the effects of burning-glasses.

The second part of the law of refraction of heat, as above stated, has not hitherto received direct experimental confirmation, for, as has been already said (p. 43), the velocity of propagation of radiant heat has not yet been measured. It is, however, abundantly proved that the *index of refraction* (Light, *loc. cit.*), corresponding to the passage of radiant heat from a given medium into a given second medium, has a constant value. But, just as there are various kinds of light, differing from each other in refrangibility (Light, iii. 618), so there are various kinds of radiant heat which differ from each other in the same way. The indices of refraction of heat of several kinds, corresponding to its passage from air into rock-salt, have been measured by Forbes, by Wollaston's method (iii. 614), depending on the total reflection which takes place when rays traversing one medium are incident very obliquely on the surface of another medium of less refractive power. In the following table (taken from Wüllner's *Lehrbuch der Experimental-physik*, 2 vols. Leipzig, 1863-65, vol. ii. p. 327) the numbers in the last column represent the indices of refraction of the rays present in greatest abundance in the heat of the various kinds specified; but it is to be understood that each kind of heat examined contained, in a smaller proportion, rays of both greater and less refrangibility than those which formed the largest part.

Indices of Refraction of Heat-rays in Rock-salt.

Kind of heat.	Index of Refraction.
Heat from a Locatelli's lamp (an oil-lamp with solid square wick but no chimney)	1·531
The same after passing through a plate of alum	1·558
" " window-glass	1·547
" " black glass	1·553
" " black mica	1·543
Heat from incandescent platinum	1·532
The same after passing through a plate of window-glass	1·548
" " black mica	1·544
Heat from brass at 371° C.	1·528
Luminous rays of mean refrangibility from the lamp	1·552

The index of refraction for crown-glass of the least refrangible solar rays has been deduced by J. Müller, from an examination of the solar spectrum produced by a prism of crown-glass, by means of a linear thermo-electric pile (Müller's *Lehrbuch der Physik*, 6th ed., ii. 743–745). Müller gives the number 1·506, but from a criticism of his experiments by F. Eisenlohr (Pogg. Ann. cix. 240), it appears that 1·516 would be more correct.

We shall have occasion, as we proceed, to return several times to the differences between the kinds of heat emitted by various sources; but we may take this first occasion, upon which such differences call for special mention, to state wherein they probably consist, and also how far there is any real difference between radiant heat and light.

If radiant heat be regarded as consisting in an undulatory motion of the luminiferous ether, all the differences (irrespective of intensity and state of polarisation) which have been observed between various rays of heat may be referred to differences in the rapidity of the vibrations by which they are produced, and consequent differences in the length of the waves of which they consist; the most refrangible rays having the most rapid vibrations and the smallest wave-length, and the least refrangible rays having the slowest vibrations and the greatest wave-length. These, it will be seen, are differences of precisely the same kind as those existing between rays of light of various colours. Hence, unless the vibrations constituting radiant heat have a different direction, or a different form, from those constituting light (of which, however, there is not the slightest evidence, for, as we shall see, *all* the characteristic properties of light, with the single exception of visibility, are shared by radiant heat), we are forced to admit that rays of heat and rays of light of the same wave-length are in all respects identical, and this conclusion is borne out by every test which it has hitherto been possible to apply (comp. iii. 632). But although there is absolutely no known difference between rays of heat and rays of light of the *same* refrangibility (rate of vibration, wave-length), rays of heat exist whose refrangibility is less, and accordingly their rate of vibration slower and wave-length greater, than that of the least refrangible rays of light. The relation between radiant heat and light may therefore be summed up as follows: All luminous rays are rays of heat, but all rays of heat are not luminous; they only become so when their rate of vibration exceeds a certain minimum limit (about 400 millions of millions per second), and their wave-length consequently falls below a certain maximum (about 7 ten-millionths of a millimetre). According to this view, the difference between radiant heat and light is subjective and not objective, being dependent on the structure of our eyes, and not upon any want of similarity between radiant heat and light themselves.

6. Like rays of light, rays of heat *interfere* with and neutralise each other, when two rays from the same source arrive at the same point by paths of very slightly different lengths. This phenomenon was first observed by Fizeau and Foucault (Compt. rend. xxv. 447), by means of Fresnel's interference-mirrors (iii. 599), and a spirit thermometer whose bulb was not more than 1·1 mm. in diameter, and which could be read to $\frac{1}{400}$th of a degree centigrade. When this instrument was gradually moved across the middle of the field, the readings were successively, 20·9, 35·9, *and* 20, the number 35·9 corresponding to the middle of the central fringe.

Knoblauch afterwards (Ann. Ch. Phys. [3] lix. 493) observed the same phenomenon by means of a Pouillet's interference-prism (iii. 600), and a linear thermo-electric pile; and the same philosopher showed, at the same time, that the positions of the alternate maxima and minima of heating effect (corresponding to the light and dark bands in the case of light) suffered a lateral displacement when a slightly wedge-shaped piece of glass was interposed between the prism and the thermo-electric pile, thus proving that the velocity of propagation of radiant heat is not the same in glass as it is in air. (See LIGHT, iii. 601.)

Knoblauch has likewise demonstrated the interference of radiant heat under the same circumstances as those under which the colours of thin plates (iii. 643) are produced by light.

7. *Diffraction* (iii. 601) of radiant heat occurs when rays from a source of sufficiently small extent pass through a small aperture, or by the edge of an opaque screen. Knoblauch ascertained that when heat from a linear source passes through a narrow slit, the thermal effect on the farther side of the slit extends to points which the rays could not reach if they all followed straight paths; and he found that the lateral extension of the heating effect increased (1) with the distance from the slit of the position where the effect was examined, (2) with the narrowness of the slit, and (3) with the distance of the slit from the source of heat.

The diffraction of radiant heat and the simultaneous interference, when it passes the edge of a simple screen, were observed by Fizeau and Foucault; and its diffraction by "gratings" (iii. 605), by Seebeck in 1849 (Pogg. Ann. lxxvii. 574), and subsequently by Knoblauch.

8. The interference and diffraction of radiant heat prove conclusively that it consists in undulations; and that these undulations, like those of light, take place in directions perpendicular to that in which the undulatory movement advances, is proved by the phenomena of the *polarisation* of radiant heat. Like light, radiant heat may be polarised, by reflection, by ordinary refraction, by double refraction, and by absorption in doubly-refracting crystals.

The polarisation of heat by reflection from the surface of glass was distinctly proved in 1812 by Bérard, who showed that when heat was reflected successively by two glass mirrors, the intensity of the beam reflected from the second mirror was decidedly greater when the plane of reflection of the two mirrors coincided, than when they were at right angles to each other. But the accurate investigation of the phenomena of the polarisation of heat is chiefly due to Knoblauch and De la Provostaye and Desains (Ann. Ch. Phys. [3] xxvii. 109; xxx. 159; 267; 276). Knoblauch found that, as in the case of light so in that of radiant heat, the polarisation produced by reflection is most complete when the rays are incident at some particular angle depending on the nature of the reflecting substance. Thus, out of 100 rays reflected from glass at various angles (measured from the normal), he found the proportion of polarised rays to be that stated below:—

Angle of Incidence	20°.	25°.	30°.	35°.	40°.	45°.	50°.	55°.	60°.	65°.	70°.	75°.	80°.
Percentage of polarised heat in the whole quantity reflected	0·0	11·1	40·6	66·6	66·6	69·2	69·2	74·1	44·4	30·5	28·4	25·0	18·8

It will be seen that the maximum of polarisation occurred when the angle of incidence was 55°, which agrees almost exactly with the angle (54° 35′) at which the most complete polarisation takes place in the case of luminous rays (iii. 653). When a steel mirror was used as the polarising apparatus, the maximum of polarisation (34 per cent. of the total heat reflected) occurred with an angle of incidence of about 75°.

De la Provostaye and Desains not only proved that the polarisation of heat takes place under the same conditions as the polarisation of light, but showed that the properties of polarised heat agree precisely with those of polarised light. Fresnel had established that, when polarised light is reflected at the surface of a transparent medium, the intensity of the reflected light may be expressed by the formula $\frac{\sin^2(i-r)}{\sin^2(i+r)}$ when the plane of polarisation is parallel to the plane of reflection, and by the formula $\frac{\tan^2(i-r)}{\tan^2(i+r)}$ when the plane of polarisation is perpendicular to the plane of reflection, i and r denoting the angles of incidence and refraction respectively. Taking the index of refraction of glass as $= 1{\cdot}52$, De la Provostaye and Desains calculated the intensity of the reflected beam for various angles of incidence, for the two cases to which these formulæ correspond, and found the results to agree precisely with those furnished by direct experiments with polarised heat, as shown by the following table:—

Reflection of Polarised Heat.

Heat polarised in plane of incidence.			Heat polarised at right angles to plane of incidence.		
Angle of incidence.	Intensity of reflected beam.		Angle of incidence.	Intensity of reflected beam.	
	Observed.	Calculated.		Observed.	Calculated.
80	55·1	54·6	80°	24·0	23·6
75	40·7	40·8	75	11·0	10·6
70	30·6	30·8	70	4·3	4·15
60	18·0	18·3	28	3·0	2·9
50	11·7	11·7			
40	8·1	8·1			
30	6·1	6·1			
20	5·0	5·0			

De la Provostaye and Desains have likewise observed that rotation of the plane polarisation of heat is caused when polarised heat is transmitted through a piece of heavy glass placed between the poles of a powerful electro-magnet, and also when it is made to pass through certain liquids, such as oil of turpentine and solution of sugar, and have ascertained that in both cases the action is precisely the same as in the analogous phenomena presented by polarised light (see iii. 671 and 676). Some of the numerous other points of agreement which the same observers have detected between the properties of polarised heat and polarised light, are mentioned below in connection with the double refraction of heat.

The polarisation of heat by ordinary refraction was observed by Forbes (Phil. Mag. [3] vi. 209) and Melloni, but this phenomenon also has been more completely investigated by Knoblauch and De la Provostaye and Desains, than by previous observers. It has been shown by their experiments, that when a beam of radiant heat is incident upon a bundle of thin plates of glass at the polarising angle, it is separated into two parts—a reflected beam polarised in the plane of incidence, and a refracted beam polarised at right angles to the plane of incidence; and they have also proved that the intensity with which a beam of polarised light is transmitted through one or more plates of glass can be calculated by precisely the same formulæ as those which apply in the case of light.

9. The same investigators have demonstrated the *double refraction* of heat, and proved that the phenomenon agrees in all respects with the double refraction of light. Knoblauch caused a pencil of solar rays, reflected from a heliostat, to fall upon the natural-cleavage faces of a crystal of calc-spar, and received the transmitted rays upon a thermo-electric pile, the face of which presented only a vertical strip of 0·25 mm. in width. As the pile was placed successively in the path of one of the luminous beams produced by the double refraction of the incident light, in the dark space between the two beams, and in the path of the second luminous beam, the needle of the galvanometer was deflected to 20·5°, then came back to 5°, and was then deflected again to 20·75°, showing that the heat-rays had been completely separated into two pencils of equal intensity. Knoblauch further found that, when the crystal was turned round the incident ray as an axis, one of the transmitted pencils of heat-rays (the extraordinary pencil) rotated round the other (the ordinary pencil), which remained stationary.

Similar results have been obtained by De la Provostaye and Desains. A beam of solar rays was directed, by means of a heliostat, on to an achromatic double-image prism, and, one of the emergent beams being stopped by a screen, the other was received upon a glass mirror placed vertically, whereby it was reflected at an angle of 56° upon the the thermo-electric pile. When the principal section of the prism was horizontal, and the ordinary ray (which was consequently polarised in a horizontal plane, iii. 654) was allowed to fall upon the mirror, the galvanometer-needle was deflected to 75°, whereas it remained completely at rest when the prism was turned round through 90°; thus proving that the two transmitted beams were completely polarised in planes at right angles to each other, a result which was also arrived at by Knoblauch.

De la Provostaye and Desains have also proved that when a beam of polarised heat falls upon a doubly-refracting crystal, so that the plane of polarisation is neither parallel with, nor perpendicular to, the principal section of the crystal, it is broken up into two beams whose relative intensities follow the same law as the intensities of the two beams of light produced under similar circumstances. In the case of light, if the intensity of the incident beam be represented by I, that of the ordinary refracted beam by O, that of the extraordinary refracted beam by E, and the angle which the plane of polarisation makes with the principal section of the crystal by α, **Malus** showed that these quantities are related to each other as follows:—

$$O = I \, . \cos^2\alpha; \qquad E = I \, . \sin^2\alpha.$$

Putting I = 1, De la Provostaye and Desains found the following values for O corresponding to various values of α: namely, for—

$$\begin{array}{ccccccccc} \alpha & = & 30^\circ, & = & 35^\circ, & = & 45^\circ, & = & 52^\circ \\ O & = & 0{\cdot}75, & = & 0{\cdot}67, & = & 0{\cdot}50, & = & 0{\cdot}3 \end{array}$$

results which agree exactly with the above formula.

When a doubly-refracting crystal absorbs one of the two beams produced by double refraction, as is the case to a great extent with tourmaline cut parallel to the principal axis (iii. 655), the beam which is transmitted is necessarily polarised, either in the case of light or heat. The polarisation of heat by tourmaline, observed by **Forbes**, was the earliest discovered instance of the polarisation of heat by double refraction; and it was supposed by him for a time to reveal an essential difference between radiant heat and light, since he found the polarisation of heat from some sources apparently much less complete than that of light. The cause of this apparent anomaly was afterwards ascertained by Melloni to be that, although tourmaline is opaque for luminous rays whose vibrations take place perpendicularly to its principal axis, and therefore completely absorbs one of the two luminous beams, it is not equally opaque for rays whose vibrations are perpendicular to the axis but are as slow as those of the invisible heat-rays.

Having thus briefly stated the most important of the general properties of radiant heat, we have still to consider it in its relation to material bodies, under the three heads of Emission, Absorption, and Transmission.

Emission of Radiant Heat.

It is a matter of universal experience, that, under otherwise similar circumstances, a given body gives out more heat in a given time, the hotter it is. Temperature, therefore, is one condition which determines the emissive power of bodies for heat; but further examination shows that it is not the only condition upon which this phenomenon depends. It was observed as early as 1804, by **Leslie**, that different substances have very different powers of emitting heat, even when their temperatures are exactly the same. He placed in front of a concave metallic mirror a cubical metal vessel filled with boiling water, and put one bulb of a differential thermometer in the focus of the mirror, the other bulb being protected from the radiation. By coating the different sides of the cube with the various substances to be examined, and turning them successively towards the mirror, he was able to compare, by the effect on the thermometer, the relative emissive powers of the several substances, independently of any difference of temperature. **Melloni** subsequently made similar comparative experiments, using his thermo-multiplier instead of Leslie's differential thermometer. Among all the substances examined, both Leslie and Melloni found that lampblack had the greatest emissive power, or at least that the emissive power of no other substance exceeded it, and they accordingly adopted it as a standard of comparison for all the rest. The numerical results given in the following table are, therefore, to be understood as giving the intensity of the radiation at 100° C. from a superficial unit of each of the substances named, the radiation from a unit of surface covered with lampblack being taken at 100:—

Emissive Powers for Radiant Heat at 100° C.

Leslie.				Melloni.	
Lampblack	100	Mica	80	Lampblack	100
Paper	98	Graphite	75	White lead	100
Resin	96	Tarnished Lead	45	Isinglass	91
Sealing-wax	95	Mercury	20	Indian ink	85
Crown-glass	90	Polished Lead	19	Gum-lac	72
Indian ink	88	Polished Iron	15	Polished Metals	12
Ice	85	Tinplate	12		
Red lead	80	Gold, Silver, Copper,	12		

The exact numbers in this table cannot, however, lay claim to any very great degree of accuracy. For it was found both by Leslie and Melloni, that the radiating power of the same substance varied considerably according to the condition of its surface, and the same fact has been repeatedly observed by later investigators. The metals, for instance, when polished, radiate much less than they do when tarnished or roughened. That a tarnished metallic surface should have a different emissive power from a bright metal is not surprising: for the tarnish consists in the formation of a thin film of oxide or sulphide, and it is this film, and not the metal itself, which forms the true surface from which a great part of the radiation proceeds. But even when the chemical nature of the surface undergoes no change, the emissive power is often affected to a considerable extent by the physical state of the surface. This is very distinctly shown in the following experiment of Melloni's (*Thermochrôse*, p. 87, note): he prepared four plates of pure silver, two of which were strongly hammered, and the other two simply cast and not hammered; all four plates were then polished with pumice-stone and charcoal, but without the use of a hammer or burnisher; and lastly, one plate of each pair was scratched by rubbing it in one direction with coarse sandpaper. The four plates so prepared were used to form the vertical sides of a cube which was filled with boiling water, and the radiating power of the four sides was determined. The deflections of the galvanometer-needle which they severally produced were—

	Polished.	*Scratched.*
Hammered plate . . .	10°	18°
Unhammered plate . .	13·7	11·3

The following numbers, obtained by De la Provostaye and Desains (Ann. Ch. Phys. [3] xxii. 372) for the relative radiating powers at 120° C., of several metals in different conditions, compared with the radiating power of lampblack at the same temperature taken as 100, show similar differences, although the absolute values of the numbers are considerably below those found by Melloni and Leslie. The comparisons with lampblack were made in two ways: the first method depended on determining the size of the surface of the substance under examination which caused as great a deflection of the galvanometer as a given surface of lampblack at the same temperature; in the second method the radiating surfaces were equal, and their respective radiating powers were calculated from the excess of temperature of the metals over the lampblack at which they emitted equal quantities of heat.

Emissive powers of Metals at 120° C.

	Emissive power.	
	By first method.	By second method.
Pure silver, rolled, ...	3·0	2·9
„ „ polished.	2·5	2·2
„ „ „ after long heating	2·75	3·0
Silver chemically deposited on silver	. .	2·05
Silver chemically deposited and burnished	2·25	2·2
Silver chemically deposited on copper, dull	5·4	5·3
Platinum, rolled	10·8	10·4
Platinum, polished	9·5	9·0
Gold-leaf	4·3	4·3
Copper-foil	4·9	

The general rule which may be deduced from these and numerous allied observations, is that the denser and more compact the surface of a body is, the smaller is its emissive power, while any treatment which diminishes the density of the surface increases the emissive power. The mere fact of the surface being polished or not polished, if these differences do not involve differences of density, does not affect the emissive power of a substance: thus marble, ivory, agate, quartz, selenite, and other similar substances which are capable of receiving a polish, but in which the polishing process does not alter the density of the superficial stratum, have the same emissive powers whether polished or unpolished. (Melloni, *La Thermochrôse*, p. 83, note.—Compare also Knoblauch, Pogg. Ann. lxx. 343.)

The following table gives the relative emissive power, at 100° C., of several substances in a state of fine powder, according to Tyndall's experiments:—

Emissive powers of Powders at 100° C.

Rock-salt	35·3	Sulphate of calcium	77·7
Mercuric iodide	39·7	Ferric oxide	78·4
Sulphur	40·6	Zinc hydrate	80·4
Chloride of lead	55·4	Ferroso-ferric oxide	81·3
Carbonate of calcium	70·2	Ferrous sulphide	81·7
Red lead	74·2	Lampblack	84·0
Oxide of cobalt	76·7		

Previous experimenters, in particular Masson and Courtépée (Compt. rend. xxv. 936), had concluded that the emissive powers of all substances, in a sufficiently fine state of division, were equal; but, according to Tyndall, this apparent result was due to the powders examined having been mixed with gum in order to attach them to a metallic surface, whereby radiation from the gum took the place, to a great extent, of radiation from the particles of powder enveloped by it.

Another circumstance which exerts an influence on the quantity of heat emitted by a given substance at a given temperature, is the *thickness* of the radiating stratum. The effect of variations of this condition is not however sensible, except in the case of substances which are perceptibly transparent for radiant heat, and therefore allow the particles which lie below the actual surface to take part in the radiation, such as glass and varnishes of various kinds; with metals, on the other hand, which are completely opaque for radiant heat as well as for light in any thickness in which they can be used, the effect of variations of thickness is imperceptible. Thus Melloni found, on applying successive coats of varnish to the metal face of a radiating cube, that the radiating power was increased by each coat of varnish up to the sixteenth; but on coating one of the faces of the cube with gold-leaf of various thicknesses, the radiating power was diminished to the same extent in each case

The intensity of the radiation from a plane surface is not the same in all directions, but is greatest in the direction of the normal to the surface. Leslie, who investigated this point experimentally, believed that the radiation in any direction was proportional to the cosine of the angle which that direction made with the normal; that is to say, if R represents the quantity of heat radiated by a unit of surface in the direction of the normal to the surface, and R′ the quantity of heat radiated by a unit of surface in any direction making an angle α with the normal, Leslie concluded that the relation between these two quantities might be expressed in all cases by the equation

$$R' = R \, . \cos \alpha$$

According to the experiments of De la Provostaye and Desains, however, this relation does not hold good except for a small number of substances, lampblack being one of them. They placed, between a radiating surface of considerable extent and the thermo-electric pile, a screen pierced with a comparatively small aperture, through which alone the rays could reach the pile. Now it is obvious that with this arrangement, the extent of surface from which rays could arrive at the pile was less when the surface was placed so as to radiate normally through the aperture, than when it was placed so as to radiate obliquely, and that the extent of surface from which rays were received by the pile in the latter case, was to the extent of surface from which they were received in the former case, inversely as the cosine of the angle through which the radiating body had been turned. Hence, if the intensity of the radiation from a unit of surface, varied directly as the cosine of the same angle, the total heating effect upon the pile must have remained the same for all positions of the radiating surface; this, however, was not the case except with lampblack, as will be seen from the following table:—

Emissive Powers at various Angles.

Angle of emission. (measured from normal).	Lampblack.	Glass.	White-lead varnish.	Red ochre varnish.	Black varnish.
0°	100	90·0	100	100	100
60°	. .	83·6	94·6		
70°	100	75·0	83·9	91·2	
75°	. .	65·3			
80°	100	54·4	65·9	82·3	76

From these results it appears that the emissive powers of the substances mentioned, for oblique directions, diminish more rapidly than the cosine of the angle of obliquity, except in the case of lampblack.

In considering the *effect of the temperature* of the radiating body on the quantity of heat emitted, it is important to bear in mind that what is measured in the various methods for determining the emissive powers of different bodies, is not the actual quantity of heat given out in a given time by a given extent of surface, but merely the rate of exchange of heat between the radiating body and surrounding objects, including the thermometric apparatus itself. If in a given time a thermo-electric pile gives out to a body placed opposite to it exactly as much heat as it receives back again from that body, its temperature is not altered, and the state of things is the same as though neither the pile nor the radiating body near it had any emissive power whatever. But this stationary condition will be disturbed equally by raising the temperature of the radiating body, so as to make it give out more heat than it receives in return, or by lowering the temperature of the thermo-electric pile, so as to make it give out less heat than it receives; that is to say, the same thermometric effect may be produced upon the thermo-electric pile by lowering its temperature, as by raising that of the radiating body. There is therefore obviously no reason to expect that any simple relation would be apparent between the emissive power of a given body, as measured by the methods above described, and its absolute temperature (HEAT, iii. 52), much less between this property and the temperature of the body on the centigrade or any other arbitrary thermometric scale. We might, however, expect to find the actual quantity of heat which a given body loses in a given time, proportional to the excess of its temperature over that of surrounding bodies.

To ascertain whether this is so, it is needful to examine the rate at which the same body cools in a vacuum, when its initial temperature exceeds that of the surrounding space by different known amounts. A very elaborate investigation of this subject was made by Dulong and Petit (Ann. Ch. Phys. [2] vii. 225, 337). They determined the rate of cooling of a large mercurial thermometer, placed in the middle of an exhausted brass globe kept at a constant known temperature, with various definite differences of temperature between the thermometer and the globe, and at various absolute temperatures of each. Their most important results are given in the following table, where the columns headed "Rate of Cooling" give the number of degrees through which the temperature of the thermometer would sink in *one minute* under the various conditions specified, if it continued during the whole time to lose heat as fast as at the beginning of the interval:—

Excess of temperature of thermometer over globe.	Temp. of globe = 0°. Rate of Cooling = v.	$\frac{v_1}{v}$	Temp. of globe = 20°. Rate of Cooling = v_1.	$\frac{v_2}{v_1}$	Temp. of globe = 40°. Rate of Cooling = v_2.	$\frac{v_3}{v_2}$	Temp. of globe = 60°. Rate of Cooling = v_3.	$\frac{v_4}{v_3}$	Temp. of globe = 80°. Rate of Cooling = v_4.
240° C.	10·69	1·16	12·40	1·16	14·35				
220 "	8·81	1·18	10·41	1·15	11·98				
200 "	7·40	1·16	8·58	1·16	10·01	1·15	11·64	1·15	13·45
180 "	6·10	1·15	7·04	1·16	8·20	1·16	9·55	1·15	11·05
160 "	4·89	1·16	5·67	1·17	6·61	1·16	7·68	1·16	8·95
140 "	3·88	1·17	4·57	1·16	5·32	1·15	6·14	1·17	7·19
120 "	3·02	1·17	3·56	1·17	4·15	1·17	4·84	1·16	5·64
100 "	2·30	1·18	2·74	1·15	3·16	1·16	3·68	1·17	4·29
80 "	1·74	1·15	1·99	1·16	2·30	1·18	2·73	1·17	3·18
60 "	. .	. .	1·40	1·16	1·62	1·16	1·88	1·15	2·17

From this table it appears that the rate of cooling, or quantity of heat lost in a given time, depends not merely upon the difference of temperature between the cooling body and surrounding objects, but also upon its absolute temperature. Thus, for instance, when the temperature of the thermometer was 200°, and that of the globe 0°, the rate of cooling was 7·4; but, when the temperature of the globe was 60°, and that of the thermometer 260°, the rate of cooling was 11·64, although the *difference* of temperature was the same as in the former case, namely 200°. It further appears that the quotient obtained by dividing the rate of cooling corresponding to a given excess of temperature of the thermometer, by the rate of cooling corresponding to the same excess when the temperatures of both thermometer and globe are 20° lower, is constant, namely = 1·16; that is to say, the rate of cooling increases in a geometrical ratio when, for a given excess of temperature of the cooling body, the temperature of an envelope rises in an arithmetical ratio. Hence, if k denotes the rate of cooling corresponding to a given excess of temperature t, when the temperature of the globe is 0°, the rate of cooling corresponding to the same excess of temperature when the temperature of the globe is $\theta°$, will be

$$k \, . \, a^{\theta},$$

where a is the ratio of the rate of cooling when the temperature of the globe is 1° to the rate of cooling when the temperature of the globe is 0°, the excess of temperature being in both cases the same. Making $\theta = 20$, the results contained in the above table give us for $a^{\theta} = a^{20}$ the value 1·16, whence we get $a = \sqrt[20]{1{\cdot}16} = 1{\cdot}0077$. Dulong and Petit found that the dependence of the rate of cooling *in vacuo*, of a heated body, upon its temperature, and its excess of temperature over that of the envelope, might be expressed by the following equation:—

$$\mathrm{A} = \mathrm{M} \, . \, a^{\theta} \, (a^{t} - 1),$$

where A is the rate of cooling, M a constant depending on the mass, extent of surface, and emissive power of the body, and a, θ, and t have the meanings already assigned to them. The numerical value of M in Dulong and Petit's experiments may be deduced from any of the results given in the table: thus, taking $t = 140$ and $\theta = 0$, we have for the rate of cooling $\mathrm{A} = 3{\cdot}88$, and therefore

$$\mathrm{M} = \frac{\mathrm{A}}{a^{\theta}(a^{t} - 1)} = \frac{3{\cdot}88}{1{\cdot}0077^{140} - 1} = 1{\cdot}9829.$$

The values of the constants M and a require to be determined in every case by special experiments; M necessarily varies from one body to another, and it has been proved by De la Provostaye and Desains, that a, or the rate at which the rate of cooling for a constant excess of temperature of 1° increases with rise of temperature, is different for different bodies. If the coefficient a were the same for all bodies, we should have for the rates of cooling of any two bodies under the same circumstances of temperature $\mathrm{A} = \mathrm{M} \, . \, a^{\theta}(a^{t} - 1)$ and $\mathrm{A}^{1} = \mathrm{M}^{1} \, . \, a^{\theta}(a^{t} - 1)$, and therefore

$$\frac{\mathrm{A}}{\mathrm{A}^{1}} = \frac{\mathrm{M}}{\mathrm{M}^{1}} = \text{constant};$$

that is to say, the rates of cooling of the two bodies would be to each other in a constant proportion, so long as they both had the same temperature, and the same excess of temperature over surrounding objects. But the rates of cooling, other things being equal, must depend on the radiating powers of the two bodies, which therefore, under the circumstances above supposed, must be to each other in a constant ratio. To ascertain whether this constant ratio really existed, De la Provostaye and Desains connected a strip of platinum-foil, one face of which was coated with lampblack, and the other with borate of lead, with the terminals of a galvanic battery, so that, by sending through it an electric current of greater or less intensity, its temperature could be raised to any required point, and placed it between two thermo-electric piles, regulating the relative positions so that, when the strip was heated by a moderate current, the effect of its radiation on both piles was exactly the same. On now raising the temperature of the platinum to a higher degree, it was found that this equality of radiation was no longer maintained, the blackened side radiating more heat than the side coated with borate of lead, so that, after the piles had been adjusted to equality of effect with the platinum strip at 100°, they indicated differences in the amount of radiation from its two surfaces in the ratio of 0·75 to 1 when its temperature was 550°. Hence the emissive powers of different substances do not vary according to the same law with variations of temperature, and therefore the quantity denoted above by a is not the same for all bodies.

It was supposed by Newton that the rate of cooling of a given body was directly proportional to the excess of its temperature over that of surrounding objects. It has been already pointed out that Dulong and Petit's experiments prove this not to be the case; nevertheless Newton's law of cooling corresponds very closely with their formula when the value of θ is constant and that of t small, and therefore the factor $a^{t} - 1$, which expresses the effect of the excess of temperature of the cooling body, nearly proportional to t, which denotes that excess. In the cases of most frequent occurrence, in which the law of cooling has to be taken into account,—such, for instance, as the calculation of the corrections to be applied in calorimetrical experiments for differences of temperature between the calorimeter and external objects (see HEAT, iii. 27)—the above conditions are very approximately fulfilled; and hence, in such cases, Newton's law may generally be applied instead of the more accurate, but more complicated, formula of Dulong and Petit.

When a heated body is in contact with air or any other gas, as usually happens in practice, it loses heat not alone by radiation, but also by conduction and communication of heat to the particles of gas. Hence, in such a case, the rate of cooling may be represented by

$$v = A + A_1,$$

where A represents the cooling which is due to radiation, and A_1 the cooling due to conduction, &c. Dulong and Petit found experimentally that the term A_1 may be expressed by the empirical formula

$$A_1 = N \, . \, p^c \, . \, t^{1{\cdot}233},$$

where N is a constant depending on the mass, extent of surface, and nature of the cooling body, and also on the nature of the surrounding gas; p is the pressure of the gas; c is a constant depending on the nature of the gas, being 0·45 for air, 0·38 for hydrogen, and 0·517 for carbonic anhydride; and t is the excess of temperature of the cooling body.

The complete expression for the rate of cooling of any given body whose temperature is $t + \theta$, in a space whose temperature is θ, and in contact with a gas whose pressure is p, is therefore

$$v = M \, . \, a^\theta(a^t - 1) + N \, . \, p^c \, . \, t^{1{\cdot}233}.$$

This equation may be put under a somewhat different form. If we denote the weight of the cooling body by P, its specific heat by C, its superficial area by S, and the quantity of heat given out by a unit of surface in a unit of time by W, we have, for the quantity of heat given out by the whole body in a unit of time,

$$S \, . \, W = P \, . \, C \, . \, v, \text{ and therefore } v = \frac{S \, . \, W}{P \, . \, C}$$

But, since W is made up of two parts, one of which $= w$ is proportional to $a^\theta \, (a^t = 1)$, and the other $= w'$ is proportional to $p^c \, . \, t^{1{\cdot}233}$, we have $\frac{w}{a^\theta(a^t - 1)} = \text{const.} = H$, and $\frac{w'}{p^c \, . \, t^{1{\cdot}233}} = \text{const.} = K$; we may therefore write

$$M = H \, . \, \frac{S}{P \, . \, C} \text{ and } N = K \, . \, \frac{S}{P \, . \, C}$$

and hence

$$v = \frac{S}{P \, . \, C}\left\{H \, a^\theta \, (a^t - 1) + K \, . \, p^c \, t^{1{\cdot}233}\right\},$$

or

$$W = H \, . \, a^\theta(a^t - 1) + K \, . \, p^c \, t^{1{\cdot}233}.$$

In order to apply this formula to special cases, it is necessary to determine, experimentally, the numerical values of the constants H and K. This has been done in the case of several substances by **Hopkins** (Phil. Trans. 1860, p. 379; Proc. Roy. Soc. x. 514), whose principal results are given in the following table, where W expresses, in terms of the quantity of heat required to raise the temperature of 1000 grains of water 1° C., the heat given out by one square-foot of surface in one minute; a, t, θ, and p have the meanings and values already assigned to them, p being measured in metres of mercury:—

Absolute Emissive Powers.

Substances.	Emission per square-foot per minute.
Glass	$W = 9{\cdot}566 \, a^\theta(a^t - 1) + 0{\cdot}03720\left(\frac{p}{0{\cdot}72}\right)^{0{\cdot}45} t^{1{\cdot}233}$
Dry Chalk . . .	$W = 8{\cdot}613 \, a^\theta(a^t - 1) + 0{\cdot}03720\left(\frac{p}{0{\cdot}72}\right)^{0{\cdot}45} t^{1{\cdot}233}$
Dry New Red Sandstone .	$W = 8{\cdot}377 \, a^\theta(a^t - 1) + 0{\cdot}03720\left(\frac{p}{0{\cdot}72}\right)^{0{\cdot}45} t^{1{\cdot}233}$
Sandstone (*building stone*)	$W = 8{\cdot}822 \, a^\theta(a^t - 1) + 0{\cdot}03720\left(\frac{p}{0{\cdot}72}\right)^{0{\cdot}45} t^{1{\cdot}233}$
Polished Limestone .	$W = 9{\cdot}106 \, a^\theta(a^t - 1) + 0{\cdot}03720\left(\frac{p}{0{\cdot}72}\right)^{0{\cdot}45} t^{1{\cdot}233}$
Unpolished Limestone (*same block as the last*)	$W = 12{\cdot}808 \, a^\theta(a^t - 1) + 0{\cdot}03720\left(\frac{p}{0{\cdot}72}\right)^{0{\cdot}45} t^{1{\cdot}233}$

The more recent researches of **De la Provostaye** and **Desains** have served in the main to confirm the accuracy of **Dulong** and **Petit's** formula: but, in order to make it reproduce still more closely the results of observation, they have introduced some modifications; for which we must refer to their original papers. (Ann. Ch. Phys. [3] xvi. 337; xxii. 358.)

Still another circumstance affecting the emissive power of bodies for radiant heat has been pointed out by **Clausius** (Pogg. Ann. cxxi. 43), who arrives by mathematical reasoning at the conclusion that the emissive power of a body depends on the velocity with which rays of heat (or light) are propagated through the surrounding medium, the emissive powers of the same body when immersed in any two media being to each other in the inverse ratio of the squares of the velocities of propagation of radiant heat in those media, or, what comes to the same thing, in the direct ratio of the squares of the indices of refraction of the two media. And by comparing the radiation of heat through hydrogen and through carbonic anhydride, from the blackened surface of a metallic vessel filled with boiling water, v. **Quintus Icilius** (Pogg. Ann. cxxvii. 30), believes that he has obtained an experimental verification of **Clausius's** deduction.

Quality of Emitted Rays.—We have hitherto considered only those circumstances which affect the total intensity of the radiation by heated bodies; but the **quality** of the heat emitted, as well as its quantity, varies with the temperature and nature of the radiating body.

By comparing together the relative penetrating powers of radiant heat from different sources through a great variety of substances, **Melloni** found that, as a general rule, the higher the temperature of the radiating source, the greater was the number of different substances through which a greater or less proportion of the radiated heat was capable of passing. Hence he concluded that the heat radiated by sources of low temperature was more *homogeneous* than the heat radiated by sources of high temperature, the latter containing rays capable of penetrating substances through which none of the rays emitted by sources of low temperature were able to pass. On the theory we have adopted as to the nature of radiant heat, this is equivalent to saying that, among the heat-waves emitted by sources of high temperature, there is a greater variety of wave-lengths than there is among the waves emitted by sources of low temperature. But at the same time that new kinds of rays are successively emitted as the temperature of a radiating body is raised, **Melloni** showed that the rays previously given out by it still continue to be emitted, and with increased intensity. (See *La Thermochrôse*, pp. 311—315.)

By examining, in the manner that has been mentioned, the heat radiated by metals, whether polished, varnished, oxidated, or blackened, as well as by wood, leather, or marble, when each was heated to 160°, **Melloni** was unable to detect any difference of quality (*Op. cit.*, p. 325); but between the heat radiated from a source at 100°, and that radiated from a source at 400°, he found very marked differences. By experimenting in a similar manner, **Knoblauch** could not detect any difference of quality in the heat radiated by such various substances as metals, wood, porcelain, leather, cloth, and cardboard, when heated to temperatures between 30° and 112° (Pogg. Ann. lxx. 352). Moreover, **Draper** (Phil. Mag. [3] xxx. 345) found, by heating very various substances, such as platinum, chalk, marble, fluor-spar, brass, antimony, gas-carbon, and lead, in a gun-barrel, that they all became red-hot, that is to say, they all began to emit red rays, at the same temperature, estimated at 525°; and it has been shown by **Kirchhoff** (Ann. Ch. Phys. [3] lxii. 179), that, on theoretical grounds, such must be the case: that, in fact, *all* bodies whose temperature is gradually raised begin by emitting rays of the same wave-length; at a certain temperature all become red-hot, and at a certain higher temperature, which is the same for all, they begin to emit orange rays, then at a still higher temperature yellow rays, and so on—rays of greater and greater refrangibility making their appearance as the temperature rises. This conclusion is in exact accordance with an experiment long previously made by **Draper** (*loc. cit.*). This consisted in examining, by means of a prism, the rays emitted by a platinum-wire raised to successively higher and higher degrees of incandescence by sending an electric current through it. The first visible rays which the wire emitted were red; then, when the temperature was raised to about 655°, the prismatic appearance of the wire was that of a spectrum extending from the red as far as Fraunhofer's line F in the green (iii. 621); at a temperature estimated as 718°, a narrow strip of blue was visible in addition to the previous colours; at 782° the spectrum reached towards the more refrangible end as far as the line G in the indigo, and at the other end, the portion between the lines B and A which was not visible at first, had made its appearance, thus proving that the emission of rays of greater refrangibility was accompanied by increased intensity of the rays previously emitted. Lastly, at 1165°, the extent of the spectrum was nearly equal to that of daylight.

But although the quality or wave-length of the individual rays which constitute the total radiation from a heated body, depends solely upon the temperature and not upon the nature of the radiating body, the latter circumstance exercises an important influence on the relative intensities of the rays of different wave-length. Comparing radiant heat for a moment to a compound substance, we may say that the radiation from different sources at the same temperature consists of the same component parts, but that these components are not present in all cases in the same relative proportions. Hence when the radiation from different sources at the same temperature is examined as a whole, it sometimes appears to differ not only in intensity, but also in quality: whereas the real difference is in the relative intensity of the rays of particular wave-lengths. It is in this way that we must interpret the observations of De la Provostaye and Desains on the heat radiated from a surface of copper, heated to 173°, one half of which was covered with lampblack, and the other half with cinnabar: observations which proved that the quantity of heat capable of passing through a thin sheet of glass which was radiated by the lampblack, was to the quantity of heat capable of passing through the glass radiated by the cinnabar, as 100 to 67, although the total quantities of heat radiated by the two substances respectively were to each other as 100 to 87. The same remark applies to the experiments of Melloni (*Thermochrôse*, p. 178), Knoblauch (Pogg. Ann. lxxi. 53), and Tyndall (Phil. Mag. [4] xxviii. 527) on the different characters of the heat radiated by certain feebly luminous flames, and by a spiral of platinum-wire made incandescent by the same flames; as well as to Tyndall's experiments (*ibid.* p. 514) on the differences between the radiation from lampblack and platinum at 100°. In certain experiments by Magnus (Pogg. Ann. cxxiv. 476; Phil. Mag. [4] xxx. 81), which appear at first sight to establish a difference of quality, between the heat radiated by polished platinum and by platinum covered with a pulverulent coating of spongy platinum, depending on the nature of the radiating surface, the observed effects were clearly due in reality to difference of temperature, the platinised platinum having a greater emissive power than the bright platinum, and being in consequence more cooled than the latter. Accordingly, the general result of the experiments was that the rays of greatest wave-length (lowest refrangibility) constituted a larger proportion of the total heat radiated by the platinised platinum than of that radiated by the polished metal.

In further illustration of the qualitative differences between the heat radiated by different sources, it may be mentioned that, according to Tyndall's experiments, the proportionate intensity of the rays, whose wave-length is greater than that of red light, to the intensity of the total radiation is as 24 : 25 for the radiation from the brightest part of a flame of coal-gas, as 23 : 24 for the radiation from platinum at a dazzling white heat, and as 9 : 10 for the radiation from the electric light produced by discharging a Grove's battery of 40 cells between carbon points.

In the case of most solid bodies that are sensibly opaque for both light and radiant heat, the emissive power does not exhibit any abrupt variations for rays of different wave-lengths; certain transparent solids, however, have decidedly greater powers of emitting rays of certain determinate wave-lengths, than they have of emitting other rays (*vid. infr.* p. 60). Gases and vapours, on the other hand, generally possess very marked maxima of emissive power corresponding to particular rays: thus, the emissive power of sodium-vapour is incomparably greater for a group of orange-yellow rays, coinciding in refrangibility with Fraunhofer's line D, than for any other visible rays; lithium vapour has a maximum of emissive power for red rays of refrangibility intermediate between Fraunhofer's lines B and C, another, but much smaller maximum for orange rays of somewhat less refrangibility than the line D, and a third, still smaller maximum, for blue rays intermediate in refrangibility, between the lines F and G; potassium-vapour, again, has maxima of emissive power for red rays, equal in refrangibility with the line A, and for violet rays somewhat less refrangible than the line H, while, for nearly all the rays whose refrangibilities are intermediate between those of the lines C and F, it has a low, but almost uniform emissive power (See LIGHT, iii. 622; also SPECTRAL ANALYSIS). About the emissive powers of vapours and gases for rays of lower refrangibility (greater wave-length) than the least refrangible red rays, nothing exact is known; but there is no reason to doubt the essential similarity of their invisible to their visible radiation; and Tyndall has shown that, at temperatures not very greatly exceeding the ordinary temperature of the atmosphere, there are well-marked differences between the emissive powers of different gases and vapours.

Absorption of Radiant Heat.

It has been explained already (p. 43), that when radiant heat arrives at the surface of a material body, part of it is always reflected, either regularly or diffusively; but this reflection is never complete; another portion of the heat penetrates into the substance of the body, and according to the particular properties of the latter, is either wholly or in part transmitted through it, or is wholly or in part annihilated, causing an increase of temperature in the body. It is this extinction of radiant heat in causing rise of temperature in material bodies, that constitutes the phenomenon of absorption. Upon the undulatory theory of radiant heat, we must conceive of it as consisting in the production of vibrations of material particles by the impinging waves of ether. Upon this view, it is obvious that the vibrations excited by radiant heat can never be more rapid than those of the rays themselves, nor, therefore, than those of their source; in other words, a body can never be raised by radiation to a higher temperature than that of the body from which the rays are emitted; and it is likewise obvious that whatever rays a body most plentifully emits, those it will also most plentifully absorb. Both these deductions from theory have received the most complete verification from experiment; in fact the phenomena of absorption have been found to present, even in the minutest particulars, the exact counterpart of those of emission, as upon the undulatory theory they must necessarily do.

The absorptive power of a substance, or its *coefficient of absorption*, is the ratio of the quantity of heat absorbed to the quantity of heat which is incident upon it. Calling the quantity of heat absorbed Q′, and the total quantity of incident heat Q, the coefficient of absorption may be represented by

$$A = \frac{Q'}{Q}$$

If a body absorbed all the heat which fell upon it, its coefficient of absorption would attain a maximum value = 1, but the absorption-coefficient of no known substance quite reaches this maximum, though that of lampblack probably makes a near approach to it.

The experimental measurement of the absorptive powers of different substances is a problem of considerable complexity. The first person to attempt its solution was Sir John Leslie (*Experimental Inquiry into the Nature of Heat*, London, 1804). He coated the bulb of a differential thermometer successively with the different substances to be examined, and observed the temperature which the thermometer attained in each case when it was exposed to the radiation of a source of constant intensity. The results were stated with reference to the absorptive power of lampblack; calling the absorptive power of this substance A_1, and the excess of temperature above the surrounding air attained by the thermometer when its bulb was coated with lampblack t_1, Leslie assumed that the relative absorptive power A of any other substance which caused the thermometer to acquire the excess of temperature t, might be deduced from the equation

$$\frac{A}{A_1} = \frac{t}{t_1}$$

This assumption, however, is not correct. When the thermometer has become stationary at some maximum point of temperature, it is because it is then giving out precisely as much heat as it absorbs. If we denote by Q the constant quantity of heat which falls upon the thermometer, the quantity absorbed in the two cases will be

$$Q \,.\, A \quad \text{and} \quad Q \,.\, A_1\,;$$

and if S is the superficial area of the thermometer-bulb, and E_1 and E the respective emissive powers of lampblack and the substance to be compared with it, we shall have

$$QA = SEt \quad \text{and} \quad QA_1 = SE_1t_1$$

or

$$\frac{A}{A_1} = \frac{E}{E_1} \cdot \frac{t}{t_1}$$

Hence we see that the temperature attained by the thermometer depends on the emissive power as well as on the absorptive power of the substance with which it is coated, and can only be taken as a measure of the former, on the supposition (which we know to be erroneous) that the emissive power of all substances is the same.

A somewhat similar but rather more accurate process was employed by **Melloni**. He coated one side of a thin copper disk, a little larger than the opening of the conical reflector of the thermo-electric pile, with lampblack, and the other side with the substance to be examined, and fixed it close against the open end of the reflector with the blackened side inwards. On now exposing the outer surface of the disk to the radiation from any source its temperature rose, and it consequently itself began to radiate heat from its blackened surface upon the thermo-electric pile: thus causing a deflection of the galvanometer, which, after a certain time, reached a maximum at which it remained constant. Denoting, as before, the quantity of incident heat by Q, the absorptive and emissive powers of the substance by A and E, and the corresponding quantities in the case of lampblack by A_1 and E_1, and further putting S for the area of one side of the disk, we have for the quantity of heat absorbed by the disk QA, and for the quantity of heat emitted by it $SEt + SE_1t$, where t represents the excess of the temperature of the disk above that of surrounding objects. When the temperature of the disk has become stationary, these two quantities of heat are equal, that is

$$Q . A = S(E + E_1) . t;$$

and if both sides of the disk are covered with lampblack, its temperature becomes stationary, when

$$Q . A_1 = 2SE_1 . t_1$$

Hence for the relative absorptive powers, we have

$$\frac{A}{A_1} = \frac{E + E_1}{2E_1} . \frac{t}{t_1}$$

It is evident that the value of the factor $\frac{E + E}{2E_1}$, which appears in this equation, must always lie between the limits ½ and 1, and that it is always more nearly equal to unity than the factor $\frac{E}{E_1}$, which occupies the corresponding place in the equation applicable to Leslie's experiments; in other words, the effects measured by Melloni were more nearly proportional to the absorption-coefficients of the various substances than the effects measured by Leslie. The values of the absorptive powers of various substances, as thus estimated by Melloni, are given in the following table, compared with the absorptive power of lampblack taken as 100:—

Substances.	Sources of Heat.			
	Locatelli's Lamp.	Incandescent Platinum.	Copper at 400°.	Copper at 100°.
Lampblack	100	100	100	100
Indian ink	96	95	87	85
White lead	53	56	89	100
Isinglass	52	54	64	91
Gum-lac	43	47	70	72
Metallic surfaces	14	13·5	13	13

This table shows not only that different substances differ greatly in absorptive power, those substances which have the greatest emissive powers being also the best absorbers, but also that the same substance exerts very different absorbent actions on radiant heat from different sources. And it may be observed that although, for the reasons already stated, the numbers in this table do not represent quite accurately the relative absorptive powers of different substances, they do express accurately the relative absorptive powers of the *same* substance for different kinds of heat. For, if we denote by A and A′ the absorptive powers of the same substance, for the heat from two different sources, and by t and t' the excess of temperature attained by the disk under the radiation from the respective sources, we shall have for the conditions of equilibrium of temperature in the two cases,

$$QA = S(E + E_1) . t \text{ and } QA' = S(E + E_1)t'$$

the difference between t and t' being, under the circumstances of the experiment, so small that we may consider the emissive power of the substance constant, and represent it in each case by E. Hence we get as above:—

$$\frac{A}{A_1} = \frac{E + E_1}{2E_1} . \frac{t}{t_1} \quad \text{and} \quad \frac{A'}{A_1} = \frac{E + E_1}{2E_1} . \frac{t'}{t_1}$$

or,

$$\frac{A}{A'} = \frac{t}{t'}$$

From the foregoing discussion of Leslie's and Melloni's experiments, it will be evident that in order to be able to deduce the absorptive powers of various substances from the elevation of temperature which they undergo under the influence of radiant heat, the conditions of the experiments must be such that the quantity of heat emitted by each substance shall be the same.

These conditions were fulfilled for the first time in the experiments of De la Provostaye and Desains (Ann. Ch. Phys. [3] xxx. 431), the general principle of whose method will be intelligible from the following considerations. If a thermometer, placed inside a closed and exhausted envelope, remains at a constant temperature, it can only be because the quantity of heat which it emits in a given time, is precisely equal to the quantity it absorbs of the heat radiated upon it from the envelope. The quantity of heat emitted in a unit of time is plainly = $v \,.\, P \,.\, c$, if v denotes the rate of cooling of the thermometer under the given conditions of temperature, P its mass, and c its specific heat. Hence, if Q is the quantity of heat radiated by the envelope, and A the coefficient of absorption of the substance,

$$QA = v \,.\, P \,.\, c$$

If now the same thermometer is covered with lampblack, with the absorption-coefficient A_1, the envelope and its temperature remaining unchanged, we have also

$$QA_1 = v_1 \,.\, P \,.\, c$$

and therefore

$$A = A_1 \frac{v}{v_1}:$$

that is to say, the determination of the relative absorbing powers is resolved into a determination of rates of cooling.

In the practical application of these principles, De la Provostaye and Desains employed a very sensitive thermometer with a spherical bulb, which they coated successively with the substances to be examined. The thermometer was fixed in each experiment in exactly the same position in the interior of a metal globe, blackened on the inside, exhausted of air as completely as possible, and kept at a constant temperature by being surrounded with water. In the side of the globe was inserted a convex lens, the focus of which was a little in front of the thermometer-bulb. By means of this lens, the surface of which was so small, compared with the total interior surface of the globe, that it did not make the loss of heat by the thermometer sensibly different from what it would have been if the surface of the globe had been unbroken and of a uniform temperature throughout, the heat of the sun or of a lamp could be concentrated upon the bulb of the thermometer. The temperature of the thermometer then rose, until it became stationary at the point at which the loss of heat by radiation exactly balanced the gain of heat by absorption. The stationary temperature having been found, the rate of cooling corresponding to this temperature was ascertained by separate experiments; and such determinations having been made when the thermometer was coated with several different substances, the coefficients of absorption of these substances could be deduced as above explained. The following table gives the results obtained, compared with the coefficient of absorption of lampblack taken as unity:—

Relative Coefficients of Absorption.

Substance.	Coefficients of Absorption.
Solar heat.	
White lead	0·19
Gold-leaf	0·13
Silver-leaf	0·075
Heat of a "Moderator" lamp.	
Platinum black . . .	1
Cinnabar	0·285
White lead	0·21
Silver, pulverulent . .	0·21
Gold-leaf	0·04

In the case of certain substances, another method is applicable for the determination of their coefficients of absorption, and this method gives absolute values for these coefficients, and not merely comparative values referred to some one substance chosen arbitrarily as a standard. According to what was said above (pp. 43, 44), a quantity of radiant heat Q falling upon a material body is in general broken up into four parts, of which one QA is absorbed, another QT is transmitted, another QR is regularly reflected, while the last QD is diffusively reflected. Hence, we may write

$$Q = Q(A + T + R + D).$$

But, for metallic substances, the power of transmitting radiant heat is imperceptible, and many of them, when thoroughly polished, do not diffuse any sensible quantity of heat. Hence, for perfectly polished metals, T and D in the above equation both become = 0, and, for the coefficient of absorption, we have the expression

$$A = \frac{Q - QR}{Q}.$$

For such substances, therefore, the coefficient of absorption may be found by dividing the difference between the reflected heat and the total incident heat by the incident heat. In this way, De la Provostaye and Desains (*loc. cit.* p. 442) obtained the numbers given in the following table. They remark that they may be considered as applicable to all incidences between 0° and 70°, but that they must be a little in excess of the truth for such metals as cannot be polished sufficiently to completely destroy diffusive reflection:—

Coefficients of Absorption of Polished Metals.

Metal.	Source of Heat.				
	The Sun.	"Moderator" lamp.	Locatelli's lamp.	Flame of alcohol saturated with chloride of sodium.	Copper at 400°.
Steel	0·42	0·34	0·175	0·12	
Speculum metal	0·34	0·30	0·145		
Platinum	0·39	0·30	0·17	0·11	0·105
Zinc	. .	0·32	0·19		
Tin	. .	0·32	0·15		
Brass	. .	0·16	0·07	0·06	0·055
Gold	0·13	. .	0·045	. .	0·045
Plated silver, very bright	0·08	0·035	0·025		

The close agreement between the numbers given in this table and those given in the last for the absorptive powers of gold and silver for solar heat, prove that the numbers of the last table may likewise be taken as very nearly representing the *absolute* coefficients of absorption of the substances included in it, or that the coefficient of absorption of lampblack is very nearly equal to unity, as it is there assumed.

We may mention here an observation of De la Provostaye and Desains which illustrates very strikingly the important influence of the emissive power of a substance as well as of its absorbing power, on the facility with which it is heated by radiant heat. They placed under the receiver of an air-pump a differential thermometer, one of the bulbs of which was covered with gold-leaf, and the other with white lead, a small blackened metallic screen being placed between them in order to intercept their mutual radiation. After the receiver was exhausted, a powerful lamp was placed symmetrically with respect to the two bulbs so as to radiate equally upon each of them, when it was found—notwithstanding the absorptive power of white lead for the heat of the lamp being 0·21 and that of gold-leaf only 0·04—that the gilded bulb was most heated. This, at first sight, paradoxical result is easily understood when it is remembered that, although white lead absorbs five times as much of the heat of the lamp as gold-leaf does, its emissive power for obscure rays is twenty-five times as great as that of gold-leaf.

By comparing the above numbers and those of Melloni (p. 57) with the numbers previously given (p. 48), for the emissive powers of various substances, it will be seen that the best absorbers of heat are also the bodies which radiate most abundantly, while the worst absorbers are also the worst radiaters. And if this comparison is carried further, it is found that the correspondence between the absorptive and emissive powers of bodies is not merely general but exact; that, in fact, any circumstance which modifies the emissive power of a body in any manner whatever, modifies its absorptive power to a precisely similar extent, and in precisely the same way. Thus, taking

Melloni's determinations of the emissive powers of certain substances at 100°, and of the absorptive powers of the same substances for the heat radiated by copper at 100°, we find the following results:—

	Emissive Powers.	Absorptive Powers
Lampblack	100	100
White Lead	100	100
Isinglass	91	91
Indian Ink	85	85
Gum-lac	72	72
Metals	12	13

Again, it has been mentioned (p. 50), that when a heated body is covered with a thin coating of a substance which is more or less transparent for heat, the emissive power increases with the thickness of the superficial film. Precisely similar results have been obtained by Knoblauch in the case of absorption. He covered a metallic plate with layers of varnish, black lac, and white lead of various thicknesses, and found that in each case the absorption increased with the thickness of the layer. In order, however, that this effect may be perceptible, it is necessary that the total thickness should be but small; otherwise the external coating, in consequence of its low conducting power, becomes heated at the surface, and then the increased emission more than counterbalances the better absorption.

The correspondence between emission and absorption naturally extends to visible radiant heat (light), as well as to invisible heat, and in this case many very striking observations in confirmation of it can be made with very simple means. For instance, Balfour Stewart has pointed out (Proc. Roy. Soc. x. 385), that when a black and white china cup is heated in the fire and held in the dark, the parts of the pattern which by daylight are black, in consequence of their absorbing nearly all the visible rays which fall upon them, are more luminous than the parts which by daylight are white, in consequence of diffusively reflecting nearly all the visible rays which they receive. The same observer has also shown that media, which are opaque for certain rays but transparent for others, emit, when heated, rays of the kind for which they are opaque; thus, red glass which absorbs greenish rays, emits greenish rays when heated and viewed in the dark; while green glass, which absorbs red rays, emits red rays. The emission and absorption of rays of the same wave-length is still more strikingly exhibited by gaseous bodies. It has been already stated (p. 55), that these substances usually emit rays of certain definite degrees of refrangibility, or length of wave, with much greater intensity than other rays, and it has been proved by Kirchhoff that the rays which a gas or vapour most readily absorbs are precisely those which it most freely emits (see LIGHT, iii. 622). The identity in the absorbing and emitting properties of the same body has been found to hold good even in respect to the state of polarisation of the rays absorbed or emitted. Thus at ordinary temperatures a plate of tourmaline, cut with faces parallel to the principal axis of the crystal, transmits, with little diminution of intensity, rays polarised in a plane perpendicular to the axis, but absorbs almost completely rays which are polarised in a plane parallel to the axis (iii. 655); and Kirchhoff (Ann. Ch. Phys. [3] lxii. 186) has found, not only that this difference of action on differently polarised rays is retained, though in a less degree, at temperatures at which tourmaline itself becomes luminous, but that the light which the crystal then emits is polarised in the same manner as the light which it absorbs. The same fact was independently observed, at about the same time by Stewart (Proc. Roy. Soc. x. 503), who also showed that the absorption and radiation of heated tourmaline are equal in degree as well as in kind.

Among the non-luminous rays, differences of refrangibility are not recognisable by any character so distinctly marked as the various colours which reveal such differences in the case of the visible rays; hence, at temperatures below that at which they become luminous, it is less easy to demonstrate that the rays which particular substances give out are identical in quality with those which they absorb. Nevertheless the following observations seem to prove conclusively that such is the case. Colourless rock-salt, which is perfectly transparent for visible rays, is likewise so transparent for the invisible rays emitted by a surface of lampblack at 100°, that a plate of rock-salt 0·77 inch thick allows 75 per cent. of them to pass, whereas the same plate allows only 30 per cent. to pass of the heat radiated by rock-salt at 100°. Similarly, a thin plate of crown-glass allows only half as much heat from heated crown-glass to pass as from heated lampblack. (B. Stewart. *Op. cit.* p. 387.)

It has also been shown by Tyndall (Phil. Mag. [4] xxviii. 518) that aqueous vapour is specially opaque for the heat of a hydrogen flame, wherein the principal radiater is no doubt aqueous vapour; that carbonic anhydride is especially opaque for the heat of a carbonic oxide flame; and sulphurous anhydride for the heat radiated by the flame of sulphide of carbon.

From the foregoing facts, we may conclude that the difference between the two processes of emission and absorption of radiant heat, is a difference of the kind which would be represented in mathematics by a difference of sign. The mechanism of the two processes, if we may use the expression, appears to be absolutely identical, but in the one case it operates in the opposite sense to what it does in the other.

The equality of emission and absorption may be deduced from the fact that a body which is in equilibrium with surrounding objects undergoes no change of temperature when the condition of its surface is changed. A thermometer, for instance, is not affected by wrapping its bulb in muslin; and since in this case its emissive power is greatly increased, its temperature can be maintained unaltered by the same quantity of heat falling upon it from without, only if its power of absorbing this heat is increased in exactly the same proportion.

Transmission of Radiant Heat.

In previous parts of this article, we have already had occasion several times to speak of the differences exhibited by various bodies in respect of their power of transmitting radiant heat, and of the differences shown by the same body in its power of transmitting heat from various sources. Before proceeding to a somewhat more detailed consideration of the phenomena of transmission, it will be convenient to explain certain terms that are often employed in the description of them. These terms were introduced by Melloni to facilitate the conception and expression of the fact, first clearly established by his own researches, that the relations of the invisible rays of heat to material bodies, are essentially identical with those of light. Bodies which, like atmospheric air, rock-salt, glass, &c.—afford a more or less free passage to rays of heat, are called by Melloni diathermic; while those which like the metals, entirely obstruct the passage of radiant heat, are called adiathermic; the corresponding properties, which we have hitherto in this article spoken of as *transparence* and *opacity* for radiant heat, being called diathermacy and adiathermacy, sometimes also diathermaneity and adiathermaneity. The property of *selective transmission* which most diathermic bodies possess, that is the property of transmitting rays of certain wave-lengths, and not transmitting other rays, is called thermochrose (from θερμὸν and χρῶσις), and bodies which possess this property are termed thermochroic, and those which do not possess it athermochroic. The terms thermochrose and thermochroic are, however, also used in reference to sources of heat in whose radiation rays of certain wave-lengths predominate, and to the heat itself which such sources give out, as well as to adiathermic bodies which exhibit a power of selective absorption or reflection: just as, in the case of light, the words *colour*, *coloured*, &c., are used equally in speaking for instance, of the flame of alcohol charged with chloride of sodium, of the light which such a flame gives out, of a piece of yellow glass, or of a piece of gold, and the same word, *yellow*, is used to describe the light itself, the flame which emits it, the glass which transmits it, and the metal which reflects it.

By maintaining a constant source of heat at a constant distance from the thermo-electric pile, and interposing between them various substances in succession, Melloni was able to determine, on the one hand, the influence of the transmitting substance on the quantity of heat transmitted; and by placing different sources of heat at such distances from the thermo-electric pile that each caused the same deflection of the galvanometer, and interposing the same substance on the path of the rays from each source, he was able, on the other hand, to measure the influence of the source of heat on its transmission. The following tables contain the results of a large number of experiments of this kind.

The four sources of heat employed in the experiments, the results of which are given in the first table, were—1st, an oil-lamp (Locatelli's), with a solid square wick and without chimney; 2nd, a spiral of platinum-wire heated to incandescence in the flame of a spirit-lamp; 3rd, a plate of copper covered with lampblack, and heated to about 400° by the flame of a spirit-lamp applied to the back of it; 4th, a cubical copper vessel coated with lampblack, and filled with water at 100°. The next table gives in like manner the intensity of the heat of an Argand oil-lamp, provided with a glass chimney, after passing through a thickness of 9·21 millimetres of certain liquids, enclosed between plates of glass, the intensity of the incident heat being taken as 100:—

Transmission of Radiant Heat by Solids.

Substances. (Reduced to a common thickness of 2·6 millimetres.)	Percentage of Heat transmitted—from			
	Locatelli's lamp.	Incandescent platinum.	Copper at 400°.	Copper at 100°.

The following short table gives the quantities of heat transmitted through a layer of water 50 millimetres in thickness, contained between highly polished plates of glass, according to the experiments of De la Provostaye and Desains (Ann. Ch. Phys. [3] xxx. 286). These results illustrate very well the influence which the source of heat exerts upon the relative proportion in which it is able to pass through the same medium. The numbers of this table represent the intensity of the heat transmitted from each source, the intensity of the incident heat being in each case taken as = 100:—

Transmission of Radiant Heat through Water

Source of Heat.	Percentage transmitted.
The Sun. Solar rays which had already passed through 52 centimetres of water	92
The Sun. Total Solar radiation	58
Argand lamp. Rays which had already passed through a lens and 10 centimetres of water	51
Electric light (carbon points)	23 to 24
Lime made incandescent in the flame of ether fed with oxygen	20
The Sun. Invisible rays from a part of the spectrum as far beyond the red as the distance between red and the limits of the green and blue	14
Locatelli or Argand lamp with chimney	10
Flame of alcohol saturated with chloride of sodium	2 to 3
The Sun. Invisible rays still less refrangible than the above	0·

After the explanations that have been already given, the results recorded in the above tables do not call for much further discussion. We must, however, direct attention to the remarkable properties of rock-salt in relation to radiant heat. It will be seen that, according to Melloni's experiments, a plate of clear colourless rock-salt transmits the same proportion (92·3 per cent.) of the heat which falls upon it, from whatever source. Hence Melloni concluded that rock-salt exerts no absorbing power whatever on heat-rays of any kind, or that it is in fact perfectly diathermic and athermochroic. The 7·7 per cent. by which the intensity of the incident rays is diminished by passing through a plate of rock-salt, Melloni attributed to the effect of reflection at the surfaces of entrance and exit, not to absorption within the substance of the plate; for if this loss were due in whole or in part to absorption, its amount could hardly have been the same for heat from sources so greatly differing in temperature. This conclusion is supported by the further observation of Melloni, that the quantity of heat transmitted by perfectly clear and transparent rock-salt is independent of its thickness, being always 92·3 per cent. of the heat incident upon it; whereas if two plates of rock-salt are used instead of one, in which case the number of reflecting surfaces is doubled, the percentage of heat transmitted is reduced to $\frac{92{\cdot}3}{100} \times \frac{92{\cdot}3}{100} =$ 85·2. According, however, to the more recent experiments of De la Provostaye and Desains (Compt. rend. xxxvi. 84, 1073), as well as of Tyndall (Phil. Mag. [4] xxviii. 532), rock-salt does exert a slight but perceptible absorbent action upon rays from sources of low temperature, and an experiment of **Stewart's** has been already mentioned (p. 60) which shows it to be opaque to a great extent for rays emitted by rock-salt.

In the case of all other substances except rock-salt, the thickness of the transmitting stratum, as well as the nature of the source of heat, has a great influence on the amount of heat transmitted. The effect of variations of thickness was made by **Melloni** the subject of an extended experimental investigation, but, before giving the numerical results arrived at by him, it will be well to explain the theoretical investigation of the same subject by **Biot** (*Mém. de l'Académ. des Sciences*, xiv. 466.—**Daguin's** *Traité élémentaire de Physique*, ii. 62). Suppose a pencil of rays of sensibly the same wave-length to fall perpendicularly upon a plate of some diathermic substance and let the intensity of the pencil be represented by I, the reflecting power of the surface of the plate by r, and the thickness of the plate by e. Then a pencil of the intensity Ir will be reflected at the first surface, and the intensity of the pencil which enters the plate will be $I(1 - r)$. Of this, a certain proportion will undergo absorption while traversing the plate, the amount of absorption being some function $f(e)$ of the thickness, which has to be determined. The quantity of heat which arrives at the second surface will therefore be $I(1 - r)f(e)$. Here a second reflection will take place, whereby a fraction r' of this heat will be kept back, and the quantity which issues from the plate will consequently be

$$I(1 - r)(1 - r')f(e).$$

If a second plate of the same substance, having the thickness e', be placed in the path of the pencil emergent from the first plate, the intensity of the heat which issues from the second plate will be found, by reasoning similar to the above, to be

$$i = I(1 - r)^2(1 - r')^2 f(e) f(e').$$

Now let the same original pencil pass through a single plate, still of the same substance, but of the thickness $e + e'$; the intensity of the emergent pencil will be found as above, to be

$$i' = I(1 - r)(1 - r')f(e + e').$$

But it is found by experiment that $i = i'(1 - r)(1 - r')$, that is to say, that the loss by absorption is the same for the same thickness of substance, whether this is disposed in two plates or united into one, the factor $(1 - r)(1 - r')$ representing the additional loss by reflection in the former case. Hence we have

$$f(e + e') = f(e) \cdot f(e'),$$

which can only hold good if $f(e) = a^e$, where a is a constant dependent on the nature of the substance and on that of the incident rays, so that $f(e) \cdot f(e') = a^e \cdot a^{e'} = a^e + a^{e'}$. Consequently, the expression for the quantity of heat which passes through a plate of the thickness e is

$$I(1 - r)(1 - r')a^e,$$

which shows that *the intensity of the transmitted heat varies according to a geometrical progression when the thickness of the plate increases in an arithmetical progression.* The ratio, a, of the former progression, which depends as we have said on the nature of the plate and of the incident heat, is called the *coefficient of transmission* of the substance of which the plate is made, for the particular kind of heat in question; it represents the quantity of heat transmitted through a thickness of 1 millimetre.

It follows also from the above considerations, that the quantities of heat absorbed by successive layers of equal thickness of the same substance likewise form a diminishing geometrical progression; for, calling the intensity of the heat which penetrates the first surface of the substance I', we get, for the quantities transmitted and absorbed by successive layers of the same thickness, the following expressions:—

	Transmitted.	Absorbed.
By the *first* layer . . .	$I'a$	$I' - I'a = I'(1 - a)$
By the *second* layer . .	$I'a^2$	$I'a - I'a^2 = I'a \cdot (1 - a)$
By the *third* layer . . .	$I'a^3$	$I'a^2 - I'a^3 = I'a^2 \cdot (1 - a)$
⋮	⋮	⋮
By the n^{th} layer . . .	$I'a^n$	$I'a^{n-1} - I'a^n = I'a^{n-1} \cdot (1 - a)$

If the incident pencil consists of rays of various wave-lengths, having the respective intensities $I, I_1, I_2, \ldots$ and if the coefficients of transmission of the diathermic plate for these various rays are respectively $a, a_1, a_2, \ldots$ the intensity of the pencil on emerging from a plate of the thickness e will be the sum of the intensities of the rays of each several wave-length, and will therefore be represented by—

$$(1 - r)(1 - r')(Ia^e + I_1 a^{1e}, + I_2 a_2^e + \ldots).$$

Hence it is evident that the composition or *thermochrose* of the emergent pencil will not be the same as that of the incident pencil except when the coefficients a, a_1, a_2, &c. are all equal. We shall see immediately that each of these deductions from theory is fully confirmed by experiment.

The results of **Melloni's** experiments on the transmission of heat through layers of varying thickness are collected in the following table:—

Transmission of Radiant Heat through layers of various Thicknesses.

By subtracting the quantity of heat transmitted by a layer of n millimetres in thickness from that transmitted by a layer of $n - 1$ millimetres, we obtain the quantity of heat *absorbed* by the n^{th} stratum of 1 millimetre thick. Thus, for instance, for the absorption of the heat of a Locatelli's lamp by successive strata of water, 1 millimetre in thickness, we obtain the following results:—

Number of each stratum . .	1	2	3	4	5	6	7	8
Quantity of heat absorbed . .	80·7	5·4	2·5	1·4	0·9	0·5	0·4	0·2

Here the diminution of absorption in successive strata of the same thickness is very apparent, but the ratio of the absorption of a given stratum to the absorption of the previous one is by no means constant, as, according to the foregoing discussion, must be the case for homogeneous heat. The reason of this is, that the heat employed in the experiments was far from homogeneous, but consisted in part of visible and in part of invisible rays, and each of these portions contained rays differing greatly from one another in wave-length. Consequently, the coefficient of transmission of water for visible rays being nearly equal to unity, but very much less for invisible rays, the different component parts of the heat underwent unequal absorption, and hence the quality of the heat which arrived at each stratum was different from that of the heat which arrived at the preceding and the succeeding strata. When, however, homogeneous heat is used, the absorption in successive equal strata of the same material takes place according to a regularly decreasing geometrical series. This is clearly shown in the following experiments by **Masson** and **Jamin** (**Wüllner's** *Lehrbuch der Experimentalphysik* ii. 336). The constituent rays of a beam of solar heat were separated from each other by means of a rock-salt prism, and a portion of the yellow rays of the spectrum so produced was allowed to fall upon one, two, or three pieces of the same yellow glass of equal thickness, and the intensity of the emergent rays was measured in each case. Representing the thickness of each piece of glass by e, and its coefficient of transmission for the rays in question by a, we find the following values:—

For the heat transmitted by 1 piece of yellow glass $= A_1 = I\,(1 - r)\,(1 - r')\,a^e$,

For the heat transmitted by 2 pieces of yellow glass $= A_2 = I\,(1 - r)^2\,(1 - r')^2\,a^{2e}$,

For the heat transmitted by 3 pieces of yellow glass $= A_3 = I\,(1 - r)^3\,(1 - r')^3\,a^{3e}$.

The same beam of yellow rays was next allowed to fall upon one, two, or three thicknesses of clear colourless glass, whose coefficient of transmission was nearly equal to unity, and the intensity of the heat transmitted in each case was determined. Calling these quantities of heat respectively B_1, B_2, and B_3, we have—

$$B_1 = I(1-r)\ (1-r');\ B_2 = I(1-r)^2(1-r')^2, \text{and } B_3 = I(1-r)^3(1-r')^3;$$

$$\text{and consequently } \frac{A_1}{B_1} = a^e;\ \frac{A_2}{B_2} = a^{2e};\ \text{and} \frac{A_3}{B_3} = a^{3e}.$$

The coefficients of transmission for one, two, and three thicknesses of yellow glass were thus found, independently of the effects of reflection at the surfaces. The square-root of the second and the cube-root of the third ought obviously to be equal to the first, if the calculation was made with perfect strictness, and the following numerical results show that such was nearly the case:—

Number of Plates of Glass.	Heat transmitted.	a^e.
1	$a^e = 0{\cdot}497$	0·497
2	$a^{2e} = 0{\cdot}2097$	0·458
3	$a^{3e} = 0{\cdot}094$	0·455

The gradual decrease in the value of a^e is to be attributed to the coefficient of transmission for colourless glass having been taken as exactly equal to unity, whereas in reality it is only nearly so.

The following table, taken from Melloni (*Thermochrôse*, p. 227), illustrates on the other hand, the change of quality which a pencil of non-homogeneous radiant heat undergoes on passing through diathermic substances. The numbers in the table represent the intensities of the transmitted pencils compared to that of the incident pencil taken as 100. The original source of heat was a Locatelli's lamp, and the thickness of the plates, except where otherwise stated, was 2·6 millimetres:—

It will be observed that, of the five substances through which the heat of the lamp was caused to pass in these experiments, rock-salt is the only one which did not materially alter its properties; all the other substances having strongly marked thermochroic characters, or transmitting rays of different wave-lengths with very unequal facility (as may be seen from the table on page 62), emit heat of decidedly different composition from that which falls upon them. Two of these substances indeed, alum and black glass, are to a great extent of opposite thermochroic properties: of the heat emergent from the plate of alum, 90 per cent. was able to pass through a second plate of the same material, but none of it was able to pass through a plate of black glass; while of the heat emergent from the latter body, 52 per cent. was transmitted by a second plate of the same kind, but none at all was transmitted by a plate of alum. Alum, although almost perfectly transparent for visible rays, is in very moderate thicknesses completely opaque for the invisible heat-rays; hence, as shown by the table on page 62, it completely intercepts the heat radiated by sources at temperatures below visible redness. In this property alum closely resembles ice, and it probably owes it in great measure to the large proportion of solidified water (of crystallisation) which it contains. Black glass, on the other hand, is very opaque for visible rays, and relatively transparent for invisible rays. Hence, to some extent, it filters off the visible rays, and allows heat richer in rays of great wave-length to pass. This effect, however, is produced much more completely by blackened rock-salt, or better still, as Tyndall has shown (Phil. Mag. [4] xxviii. 333), by a solution of iodine in bisulphide of carbon. Such a solution, though perfectly opaque for luminous rays, does not absorb any appreciable quantity of the rays of greater wave-length. Hence, by placing a cell filled with this liquid on the path of a beam of rays from a powerful electric lamp, Tyndall has succeeded in cutting off completely the luminous rays, and obtaining a beam of invisible heat-rays of very much greater intensity than has ever been obtained in any other way.

By comparing the absorbing and transmitting powers of various substances in the liquid and vaporous states, Tyndall has arrived at the important conclusion that the numbers by which these properties are measured are to each other in the same relative proportion in the case of vapours, as in the case of the liquids from which those vapours are formed (Phil. Mag. [4] xxviii. 451). The following tables contain some of the results on which this conclusion is founded; the numbers express the percentage of the incident heat *absorbed*, the source of heat being a platinum wire heated by an electric current:—

Absorption of Radiant Heat by Liquids.

Liquid.	Thickness of liquid in parts of an inch.				
	0·02	0·04	0·07		0·27
Sulphide of carbon .	5·5	8·4	12·5	15·2	17·3

Ethylic acetate	49·6	34·6	27·2	

That the quality of the absorption of the same substance may remain constant, notwithstanding great changes of physical condition, is proved by the observation of Bunsen (Ann. Ch. Pharm. cxxxi. 255), that phosphate of didymium in a state of igneous fusion shows the same absorption-band in the yellow as that which characterises didymium-salts in aqueous solution. (See ii. 322.)

From the great absorbing power of water, as shown in the first of the above tables, and from the general correspondence which is apparent between the absorbing powers of liquids and their vapours, it appears probable that aqueous vapour would have a relatively high absorbing power. This view is taken by Tyndall, and is supported by the results of a great number and great variety of apparently conclusive experiments, from which he infers that, "weight for weight, aqueous vapour transcends all others in absorptive power." It is, however, proper to add that Magnus, who has also devoted a great deal of attention to the same point, differs widely from Tyndall in his estimate of the absorptive power of aqueous vapour, regarding it as very much lower; and so long as the source of the divergence in the results of these two experimenters remains unexplained, the question between them cannot be considered as decided.

The transmission of radiant heat through permanent gases has also been investigated by Tyndall, who has found that these substances differ very greatly in their power of absorbing heat from sources of low temperature. The following table gives the relative absorbing powers found by him for a column 32 inches long of several gases, under a pressure of 760 millimetres, for the heat radiated from a plate of copper heated by a Bunsen's gas-lamp:—

Name of gas.	Absorption. (That of air = 1)	Name of gas.	Absorption. (That of air = 1)
Air	1	Carbonic anhydride	90
Oxygen	1	Nitrous oxide	355
Nitrogen	1	Marsh-gas	403
Hydrogen	1	Sulphurous anhydride	710
Chlorine	39	Ethylene	970
Hydrochloric acid	62	Ammonia	1195

When the same gases are compared in shorter columns, or under lower pressures, the difference in their relative absorbing powers becomes even more strikingly evident.

There is one other circumstance, besides the nature of the medium and the wave-length of the rays, which affects the transmission of radiant heat. This is the *amplitude* of the vibrations, or the intensity of individual rays. It has been already stated (p. 54) that, as the temperature of a radiating body is raised, it gives out rays of smaller and smaller wave-length, but that the amplitude of the more slowly vibrating rays, which it gave out at first, is increased at the same time. This is very distinctly proved by some experiments of Tyndall (Phil. Mag. [4] xxviii. 334), from which it appears that the intensity of the invisible radiation (capable of passing through an opaque solution of iodine in bisulphide of carbon) of a spiral of platinum-wire may be increased four-hundredfold by raising the temperature of the wire from a dark heat to a dazzling white heat. Hence the non-luminous rays of luminous sources are not, in all respects, equivalent to the rays of the same wave-length from non-luminous sources; and Tyndall accordingly found that 20 per cent. of the non-luminous rays of the electric lamp passed through a layer of concentrated solution of alum more than an inch thick, although alum and its solution, even in much thinner layers, are quite opaque for the same rays emitted from sources of lower temperature.

The *temperature* of the medium has not been clearly proved to exert any influence on the transmission of radiant heat. According to Wilhelmy (Ann. Ch. Phys. [3] xlvii. 206), glass transmits the rays of an Argand lamp more abundantly when hot than when cold; but De la Provostaye and Desains failed to detect any difference in the transmission of rock-salt or glass at ordinary temperatures, or at 150°. (Daguin, *Traité de Physique*, ii. 52.)

CONDUCTION.

If one part of a material body is at a higher temperature than the rest, the high temperature of this part can be maintained, and the temperature of other parts can be prevented from rising, only by the action of external causes. If the body is left to itself, it will sooner or later acquire a uniform temperature throughout, the hot part losing heat and the colder parts gaining heat. This tendency towards equalisation of temperature throughout any continuous portion of matter, manifests itself in the phenomena of conduction of heat, the property of bodies which is known as their con-

conducting power or **conductivity** being the rapidity with which this equalisation is effected under certain specified conditions. The different degrees of this property in different bodies, as exhibited by the various lengths of time during which equal differences of temperature can be maintained between equally distant parts, are so striking and familiar that there is no need to draw attention to the mere fact of their existence.

The laws of the conduction of heat have been investigated in relation to the two cases of conduction through a plate or wall with parallel surfaces, and of practically unlimited area, and of conduction in a prismatic or cylindrical bar. For these two cases the connection of conducting power with the distribution of temperatures has been investigated mathematically, especially by **Fourier** (*Théorie analytique de la Chaleur*, Paris, 1822) and **Poisson** (*Théorie mathématique de la Chaleur*, Paris, 1835), but we cannot attempt to do more here than to give the principal results that have been arrived at experimentally.

The **coefficient of conductivity** of a substance is defined as *the quantity of heat which passes in a unit of time through a plate of that substance of unit thickness and unit area, whose surfaces are maintained at constant temperatures differing from one another by one degree.* This coefficient has been measured experimentally by three processes, which differ from each other in principle as well as in the manner in which they have been carried out. The most direct process is that adopted by **Peclet** (Ann. Ch. Phys. [3] ii. 107), which consisted in measuring the time required for a given quantity of heat to pass through plates of different materials of definite thickness, the two surfaces being maintained at known constant temperatures. The last condition was attained by keeping the two sides of the plate bathed with water, which, however, it was found needful to agitate very briskly, in order to make sure that the film of water in actual contact with the plate was of the same temperature as the remainder. When the water at one side of the plate was at 25° C., and that at the other side at the temperature of the air, the times required for the same elevation of temperature to be produced in the water at the cooler side, with plates of lead of 20 mm. and 15 mm. thickness, were 500 and 380 seconds respectively, or very nearly proportional to the thicknesses of the plates (20 : 15 = 500 : 375). From experiments of this kind, **Peclet** calculated the number 3·84 for the coefficient of conductivity of lead, expressing thereby the number of kilogramme-water-degrees of heat which pass through a plate of lead 1 millimetre thick, and 1 square-metre in superficial area, in 1 second, when a constant difference of temperature of 1° C. is maintained between the two surfaces. For scientific purposes, it is commonly more convenient to express conducting powers in gramme-water-degrees, *per* second, *per* centimetre of thickness, *per* square-centimetre of surface; the numerical value of coefficients expressed upon the scale is, however, the same as when they are referred to **Peclet's** unit.

By a method essentially similar in principle, but different in the manner of its execution, **Lucien De la Rive** (Ann. Ch. Phys. [4] i. 504) has found for the conducting power of glass the number 0·13, and by a comparative method he ascertained the conducting power of ice to be 1·75 times that of glass: hence, in the same units, the coefficient of conductivity of ice is expressed by the number 0·23.

Calvert and **Johnson** (Phil. Trans. 1858; Proc. Roy. Soc. ix. 169) have also made experiments in order to determine in a similar manner the conductivities of several metals and alloys; but their method was not such as to make their numerical results of great value.

When once the coefficient of conductivity of a substance is known, the quantity of heat Q, which passes through a layer of the substance of the thickness e and area s, in the time T, when its two surfaces are kept at the constant temperatures t° and t'° supposing that these temperatures have been maintained unaltered long enough for the body to have arrived at a stationary condition of temperature throughout its whole thickness, and that none of the heat which enters the first surface escapes elsewhere than at the opposite surface, may be expressed by the following formula:—

$$Q = ks \,.\, \frac{t - t'}{e} \,.\, T, \ldots (1)$$

where k stands for the coefficient in question. Calling $\frac{Q}{T}$, or the quantity of heat which passes in a unit of time, the *strength of the thermal current* = S, and $\frac{e}{ks}$ the *thermal resistance* of the substance, the above formula may be written $S = \frac{t - t'}{R}$, in which form it is seen to be exactly analogous to **Ohm's** formula for the strength of [illegible] the difference of temperature [illegible] being the condition [illegible] and [illegible] comparable with the electromotive [illegible]

The [illegible] within a body can remain constant only when [illegible] as it receives; [illegible] following stratum, [illegible] quantity of heat passing [illegible] in a given time must be the same [illegible] temperature [illegible] strata [illegible] the same amount. Hence in such a case as we have supposed [illegible] successive strata of the substance from [illegible] surface [illegible] that of [illegible] surface [illegible] and [illegible] distance from the latter surface of any given stratum the temperature of this stratum will be expressed by [illegible]

[illegible]

[illegible] stratum of particles is not [illegible] and distribution of [illegible] instance when [illegible] any given stratum of particles [illegible] and so its own [illegible] heat to the next stratum, [illegible] heat as fast [illegible] the more [illegible] and [illegible] has been reached, the [illegible] of the heat which [illegible] successive [illegible] and increases [illegible] the farther [illegible] analogous to the [illegible] successive parts [illegible]

[illegible] a quantity [illegible] conducting power [illegible]

[illegible] and suppose the [illegible] And [illegible] the quantity of heat which [illegible] where the temperature [illegible] the surface remains constant we have [illegible] within equal to the amount imparted [illegible] defines k when k is known.

The remaining methods by which the [illegible] conductivity has been measured may be [illegible] distribution of temperature in [illegible]. This [illegible] be a function of the coefficient [illegible] other things equal, it must necessarily be [illegible] in a bad one, and less uniform in a [illegible] conductivity is high, than in one for which the coefficient [illegible]

mode of experiment depending [illegible] maintaining a temperature at one end [illegible] examined, [illegible] the temperature of the bar at various points [illegible] after the high temperature of the heated end has been kept up long enough for the temperature at every other point to have become invariable. Experiments of this kind were made by **Rumford**, who placed one end of an iron bar in boiling water and surrounded the other with ice; and observed its temperature at three points, equidistant from each other, and from the two ends, by means of three delicate thermometers inserted in holes bored in the side of the bar, and filled up with mercury to render the indication of the temperature more exact. More extensive determinations were made in the same way by **Biot** and afterwards by **Despretz** (Ann. Ch. Phys. [2] xix. 97; xxxvi. 422) and **Gouillaud** (*ibid.* [3] xlviii. 47). From these experiments it results that the temperatures of successive strata of a uniform bar heated at one end *decrease in geometrical progression when the distances from the source increase in arithmetical progression.* From the ratios of the progression for various substances, the ratios of their coefficients of internal conductivity could be calculated, when the coefficients of external conductivity were made the same for all, by giving to each substance the same condition of surface, and making the external medium also the same. But when bars of considerable section are used, the interior of each cross-section must necessarily be at a sensibly higher temperature than the sides, and the holes bored for the insertion of the thermometers must also have affected the results. Hence **Langberg** (Pogg. Ann. lxvi. 1; Ann. Ch. Pharm. lvi. 189) experimented upon various metals in the form of wire, determining their temperatures at different points by means of a small thermo-electric pile applied in contact with them. This method of experimenting was afterwards improved by **Wiedemann** and **Franz** (Pogg. Ann. lxxxix. 497), who made by it the most extensive and, there is little doubt, the most accurate series of observations on the relative conducting powers of various metals that have yet been published. The following table contains the relative conducting powers of the metals examined by them, compared with that of silver taken arbitrarily as 100, and also the absolute conducting powers of the same metals, calculated from their relative numbers by means of **Peclet's** determination of the absolute conductivity of lead (p. 69):—

Conductivity of Metals.

Name of Metal.	Coefficient of Conductivity.		Name of Metal.	Coefficient of Conductivity.	
	Relative.	Absolute.		Relative.	Absolute.
Silver . . .	100	45·2	Iron . . .	11·9	5·38
Copper . . .	73·6	33·4	Lead . . .	8·4	3·84
Gold . . .	53·2	24·0	Platinum . .	8·5	3·79
Brass . . .	23·1	10·4	German silver .	6·3	2·85
Zinc . . .	19·0	8·6	Rose's fusible metal	2·8	1·26
Tin . . .	14·5	6·55	Bismuth . .	1·8	0·81

The relative conducting powers of various rocks have been determined by **Hopkins** (Proc. Roy. Soc. viii. 535). His method of experimenting consisted in placing a cylindrical block of the substance to be examined, with its base just in contact with the surface of mercury contained in a shallow pan, and heated to a constant known temperature, and observing, when the distribution of heat within the block had become stationary, the excess of temperature above the surrounding air attained by a shallow stratum of mercury covering the upper face of the block—precautions being of course taken to prevent loss of heat through the sides of the block, and any disturbing effect of radiation from the heating apparatus. The observed excesses of temperature evidently depended directly upon the internal conductivities of the substances examined, and (inversely) upon the external conductivity of mercury. It has been shown (p. 70) that when the temperature of the surface of a body, whose temperature increases inwards, remains constant, the relation expressed by the following equation holds between its coefficients of internal conductivity k, and external conductivity h:—

$$\frac{k}{h} = \frac{t' - \theta}{t - t'}e.$$

In **Hopkins'** experiments, the external conductivity of mercury ($= c$) took the place of h in the above formula in the case of every substance; k, however, varied from one substance to another. Hence, by putting into the formula the observed values of t, t', θ, and e, the value of $\frac{k}{c}$ could be ascertained. The following are some of the results obtained for substances in the state of dry powder:—

Chalk	0·056
Clay	·07
Sand	·15
Sand and clay	·11

These values are proportional to the absolute internal conducting powers of the several substances, but in order to deduce these conducting powers from them, they require to be multiplied by the unknown absolute value of c, the external conducting power of mercury.

The observation of the distribution of temperature in a mass whose temperature is changing has been employed by Forbes (Trans. Roy. Soc. Edinb. xvi. 206), Ångström (Pogg. Ann. cxiv. 513; Ann. Ch. Phys. [3] lxvii. 379), and Neumann (Ann. Ch. Phys. [3] lxvi. 183) for the determination of coefficients of conductivity. Forbes' investigation related to the rate of penetration downwards into the earth of the solar heat received by the surface. The general effect of the seasons is that the temperature of the surface of the ground oscillates (in Britain) between a maximum which occurs in July or August, and a minimum occurring in January or February. If now the earth's crust were a perfect conductor of heat, the yearly maximum and yearly minimum of temperature would occur at any point below the surface, at the same epochs as they do at the surface itself, and the yearly range of temperature would be as great below the surface as above it. But the earth's crust opposing in reality a very considerable resistance to the propagation of heat, the maxima and minima occur later below the surface (for instance, at a depth of 25·6 feet in the porphyritic trap of the Calton Hill, Edinburgh, the annual maximum occurs in December or January, and the minimum in June or July), and the difference between them, or the yearly range of temperature, is less than it is at the surface. Thus the oscillation of temperature which occurs at the surface suffers a *retardation of phase* and a *diminution of amplitude* as it advances inwards. From these two effects, as revealed by the observation of thermometers sunk to various depths, Forbes was able to deduce the absolute coefficients of conductivity of the strata in which the thermometers were buried.

A method precisely the same in principle has since been employed by Ångström for the determination of the conductivities of certain metals. Square bars of the metals to be examined were alternately heated and cooled at one place, and after a considerable number of such alternations the distribution of temperature was observed by means of thermometers inserted into the bars at intervals of 50 millimetres from each other.

Neumann's method depended on observations of the course of cooling in bars which had been heated at one end until their temperature became stationary throughout, or in cubes or spheres of five or six inches diameter which had been previously heated to a uniform temperature.

The following table gives some of the results obtained by Ångström and by Neumann, reduced to the gramme-water-second-centimetre unit:—

Coefficients of Conductivity.

Substance.	Ångström.	Neumann.
Copper	91·03	110·75
Zinc	. .	30·70
Brass	. .	30·19
Iron	16·30	16·37
German-silver	. .	10·94

The numbers in the following table give the values referred to the same unit, of the ratio $\frac{k}{cD}$ according to Neumann's experiments, k being the coefficient of internal conductivity, c the specific heat, and D the density of the several substances:—

Substances.	$\frac{k}{cD}$
Coal	0·116
Melted sulphur	·143
Ice	1·144
Snow	·367
Frozen earth	·916
Sandstone	1·357

Neumann finds that the conductivity of the same substance varies very sensibly with the temperature.

It will be observed that while the ratios of the conductivities of the metals found by Neumann agree on the whole with the relative conductivities determined by Wiedemann and Franz, they considerably exceed the absolute conducting powers calculated from these by means of Peclet's coefficient for lead. On the other hand, the absolute coefficients obtained by Neumann and Angström for iron are nearly identical, and this value might therefore perhaps be most safely taken in order to convert Wiedemann and Franz's relative numbers into absolute coefficients.

In substances whose elasticity or structure is different in different directions, the rate at which heat is propagated depends upon the direction. Thus in crystals not belonging to the regular or cubical system (CRYSTALLOGRAPHY, ii. 121), Sénarmont has shown that the conducting power in the direction of the principal axis is generally either a maximum or a minimum. If a source of heat be imagined at the centre of such a crystal, the heat would be conducted outwards with different velocities in different directions, and consequently the points which at any moment possessed a common temperature, would be situated on the surface of an ellipsoïd; and Sénarmont found that the axes of the *isothermal ellipsoïds* of crystals coincide with their optic axes. He also found that mechanical strains or pressures are capable of modifying the conducting power of bodies for heat in the directions in which they are applied.

Wood presents somewhat similar phenomena. It was observed by De la Rive and De Candolle that the conducting power of wood is always greater along than across the fibre. These observations were extended by Knoblauch, who showed that, as a rule, the difference of conducting power is least in the hardest and greatest in the softest kinds of wood. Thus in boxwood the ratio of the axes of the isothermal ellipsoïd is 1·25 : 1, in walnut it is 1·45 : 1, in apricot-tree 1·6 : 1, and in soft woods (such as poplar, lime, birch, pine), it is 1·8 : 1. Tyndall has carried the same investigation still further: he finds that at all points not situate in the centre of the tree, wood possesses three unequal axes of calorific conduction, which are at right-angles to each other. The first and principal axis is parallel to the fibre of the wood; the second and intermediate axis is perpendicular to the fibre and to the ligneous layers; while the third and least axis is perpendicular to the fibre, and parallel to the layers.

When two different metals are in contact, the rate of propagation of heat is different on the two sides of the surface of separation, and therefore if heat is flowing across this surface the law of the variation of temperature is different at the two sides of it; but Wiedemann has shown that, when the contact is perfect, there is no finite difference between the temperatures of the surfaces of the two metals which touch each other.

Conduction of Heat by Liquids.—In consequence of the diminution of density which takes place almost universally in liquids when they are heated, an increase of temperature is rapidly communicated by convection to the whole of a quantity of liquid, when heat is applied to it from below. Hence it was formerly supposed that liquids possessed a high degree of conductivity for heat. Rumford however showed, near the beginning of this century, that when heat is imparted to a liquid from above, so that the expansion of the heated portions cannot cause them to rise and so produce a circulation of the liquid, the communication of heat from one part of a liquid to another takes place with extreme slowness, so much so indeed that he concluded that liquids are entirely without any real conducting power for heat. Later observers nevertheless, and especially Despretz, have proved that liquids do conduct heat in the same way as solid bodies, but for the most part very much more slowly. Despretz, in fact, found that when a constant source of heat acts for a long time upon the upper part of a column of water, the heat gradually penetrates downwards; and that when the distribution of temperature in the column has become stationary, the excess of temperature above that of the surrounding air decreases according to a geometrical progression, when examined at points whose depths below the surface increase in arithmetical progression. Hence it follows that the law of conduction in water is the same as the law of conduction in metals, and by comparing Despretz's results for water with those he obtained for copper, it appears that the conductivity of water is to that of copper as 9 to 1000.

Conduction of Heat by Gases.—The distribution of heat in gases certainly takes place chiefly by convection, as it does in liquids, but several observers have concluded that they do nevertheless possess a feeble power of conduction. The most direct experiments on this subject are due to Magnus (Pogg. Ann. cxii. 497); according to them it appears that hydrogen, if not other gases, has a certain degree of conductivity. This conclusion accords with the results of a mathematical investigation of the propagation of heat in gases by Clausius (Phil. Mag. [4] xxiii. 532), who finds that the conducting power of the lighter gases must exceed that of the heavier gases. As a provisional estimate, he gives for the conducting power of air about $\frac{1}{1400}$ of that of lead as determined by Peclet, and for the conducting power of hydrogen about four times that of air. G. C. F.

RADICLES, or **RADICALS.** The notion of compound radicles, as it is at present received in chemical science, has been explained already in previous articles (CLASSIFICATION, i. 1014—1017; EQUIVALENTS, ii. 495; FORMULÆ, RATIONAL, ii. 700); all that is necessary here is therefore to indicate briefly the origin of the idea, and the principal modifications which it has undergone.

The word "radical" is of constant occurrence in the writings of Lavoisier. For him and for his school, chemistry consisted mainly in the investigation of oxygen and its combinations. Compound bodies were divided into the two fundamental classes of acids, which were supposed to owe their essential properties to their containing a large proportion of oxygen, and salifiable bases, which were regarded either as simple bodies or as containing a small proportion of oxygen. In all cases the presence or absence of oxygen, or the proportion of it which a compound body contained, was considered the most important point in its chemical history, and as chiefly determining its properties. In the case of the acids especially, the oxygen, which all were supposed to contain, was looked upon as the sole cause of their characteristic properties; whether the oxygen was combined with sulphur, with phosphorus, or with nitrogen, was regarded as a matter of far less importance. Hence arose the necessity for adopting some common designation for the various substances which were capable of serving as foundations or nuclei upon which oxygen could attach itself, and thus give rise to acids; it was in this sense that the word *radical* was first employed in chemistry. "Il faut donc," said Lavoisier, "distinguer dans tout acide la base acidifiable à laquelle M. de Morveau a donné le nom de radical, et le principe acidifiant, c'est-à-dire, l'oxigène." (*Traité élémentaire de Chimie*, édit. 1789, vol. i. p. 69.) The passage here referred to appears to be in Section ii. "*Des bases acidifiables ou principes radicaux des acides*" of de Morveau's "Mémoire sur le Développement des Principes de la Nomenclature méthodique" (1787). The definition of a radical which is here given is interesting, not only in connection with our present subject, but for the light it throws on the views then entertained with respect to the constitution of acids. After speaking of the acids of nitrogen, carbon, sulphur, and phosphorus, de Morveau goes on to discuss the nomenclature of acids of unknown composition, such as muriatic acid, boracic acid, the acid of vinegar, &c., with regard to which he says: "Nous nous sommes contentés de désigner l'être simple qui y modifie l'oxigène par l'expression de *base acidifiable*, ou, pour abréger, de *radical* de tel acide; afin de garder la même analogie, et de pouvoir considérer à leur tour chacun de ces êtres d'une manière abstraite."

The signification of the word *radical* was soon somewhat extended by Lavoisier. Two years after the publication of de Morveau's memoir, he says: "J'ai déjà fait observer que dans le règne minéral, presque tous les radicaux oxidables et acidifiables étoient simples; que dans le règne végétal au contraire, et surtout dans le règne animal, il n'en existoit presque pas qui ne fussent composés du moins de deux substances, d'hydrogène et de carbone; que souvent l'azote et le phosphore s'y réunissoient, et qu'il en résultoit des radicaux à quatre bases." (*Traité élémentaire*, vol. i. p. 209.) The idea of compound radicles, which we meet with in this passage, occurs very frequently in other parts of the same work, and it is of importance to observe that it is applied to explain the constitution of neutral bodies as well as of acids. This is still more distinctly seen in other passages; thus, of sugar, gum, and starch, it is said (*Op. cit.* pp. 125, 126): "Ces trois substances ont pour radical l'hydrogène et le carbone combinés ensemble, de manière à ne former qu'une seule base, et portés à l'état d'oxide par une portion d'oxygène; ils ne diffèrent que par la proportion des principes qui composent la base." Elsewhere it is suggested that the *oils* may actually constitute compound organic radicles in the free state, thus (pp. 198, 199): "On aperçoit aisément que les huiles étant composées d'hydrogène et de carbone, elles sont de véritables radicaux carbone-hydreux ou hydro-carboneux, et en effet il suffit d'oxygéner les huiles pour les convertir d'abord en oxides, et ensuite en acides végétaux, suivant le degré d'oxygénation. On ne peut pas cependant assurer d'une manière positive que les huiles entrent toutes entières dans la composition des oxides et des acides végétaux; il est possible qu'elles perdent auparavant une portion de leur hydrogène ou de leur carbone, et que ce qui reste de l'une et de l'autre de ces substances ne soit plus dans la proportion nécessaire pour constituer des huiles." Again (pp. 210, 211): "Doit-on conclure de ces réflexions, que les huiles soient la base, qu'elles soient le radical des acides végétaux et animaux? J'ai déjà exposé mes doutes à cet égard. Premièrement, quoique les huiles paroissent n'être uniquement composées que d'hydrogène et de carbone, nous ne savons pas si la proportion qu'elles en contiennent est précisément celle nécessaire pour constituer les radicaux des acides. Secondement, puisque les acides végétaux et animaux ne sont pas seulement composés d'hydrogène et de carbone, mais que l'oxygène entre également dans leur combinaison, il n'y a pas de raison de conclure qu'elles contiennent plutôt de l'huile que de l'acide carbonique et de l'eau. Ils contiennent bien, il est vrai, les matériaux propres à chacune de ces combinaisons ; mais ces combinaisons ne sont point réalisées à la température habituelle dont nous jouissons, et les trois principes sont dans un état d'équilibre, qu'un degré de chaleur, un peu supérieur à celui de l'eau bouillante, suffit pour troubler." This last passage is especially worthy of notice, as showing that Lavoisier distinctly apprehended that the question of what radicle a given complex body contained, involved not only a knowledge of its composition, but also of its constitution, or of the way in which its constituent elements were combined.

The further development of the notion of compound radicles was a consequence of the advance of organic chemistry. Consequently, with the exception of Gay-Lussac's discovery of cyanogen in 1815, we hear little more of either the word or the idea until about the year 1832. It is true that in 1817 Berzelius repeated Lavoisier's statement that all inorganic oxides have simple radicles, and all organic oxides compound radicles; but this remained a general doctrine without precise special application, until, in 1832, Liebig and Wöhler showed that, by regarding oil of bitter-almonds and its derivatives as compounds of a radicle containing C^7H^5O, they became exactly comparable with the compounds of potassium or other metals. This view of the constitution of the benzoyl-compounds was at first eargerly adopted by Berzelius (Ann. Pharm. iii. 282), but was afterwards modified by him on the ground that it was inconsistent with the electro-chemical theory to suppose that oxygen could be a constituent of a radicle. He consequently represented these compounds as containing the radicle $C^{14}H^5$; for instance, benzoic acid, $C^{14}H^5.O^3 + HO$, chloride of benzoyl, $2(C^{14}H^5.O^3) + C^{14}H^5.Cl^3$. The formulæ thus obtained were strictly comparable with those adopted by Berzelius for corresponding inorganic compounds: *e.g.* chromic acid, $CrO^3 + HO$, oxichloride of chromium, $2CrO^3 + CrCl^3$. (See *Berzelius' Jahresbericht*, xiii. 203 [1833]; xviii. 358 [1838]; xix. 345 [1839]).

The next class of bodies to which formulæ were given, founded on the idea of their containing compound radicles, exactly similar to elements in their mode of combination, were the derivatives of alcohol. Alcohol itself was represented by Berzelius (*Jahresbericht*, xiii. 195) as the oxide of the radicle CH^3, and ether as containing the radicle C^2H^5: thus, alcohol $2(CH^3)O$, ether $2(C^2H^5)O$, chloride of ethyl $C^2H^5.Cl$, &c. Liebig soon afterwards (1834) gave the name *ethyl* to the radicle C^2H^5, and represented alcohol as its hydrated oxide (Ann. Pharm. ix. 1; Pogg. Ann. xxxi. 335; Berzel. Jahresber. xv. 343). In 1835, Regnault represented aldehyde, acetic acid, Dutch-liquid, and several of its derivatives as compounds of the radicle C^2H^3, to which he gave the name *aldehydene* (Ann. Ch. Phys. [2] lviii. 301, and lix. 358; also Ann. Pharm. xiv. 22, and xv. 60), and which was afterwards (Jahresber. xvii. 232 [1837]) called *acetyl* by Berzelius; and in the few following years, similar views were applied by Berzelius and the chemists of his school to nearly all known organic compounds. In all cases the leading idea was that which was thus expressed by Dumas in 1837 (Compt. rend. v. 300; Journ. pr. Chem. xiv. 298; Berzel. Jahresber. xviii. 243): "In mineral chemistry the radicles are simple; in organic chemistry they are compound: herein is the only difference between them; the laws of combination and of transformation are the same in both. Even if the radicles of inorganic chemistry, such as sulphur, the metals, and oxygen, are really compound, we cannot look forward to their decomposition; for if this decomposition is possible, it requires forces which we are not acquainted with. In organic chemistry the case is the reverse, and the difficulty is less. Here the radicles are compound, and our whole art consists in treating them so that they are not broken up into their elementary constituents. This decomposition, however, we can foresee and prevent, for it takes place according to easily apprehended laws; so that it is by no means difficult to recognise an organic radicle, and to transfer it undecomposed from one compound to another."

These views were not, however, the only ones that were applied to organic compounds. Mitscherlich, for instance, regarded a certain number of organic bodies as constituted quite differently from any known inorganic compounds (see FORMULÆ, ii. 701, 702); and Laurent, in 1836, proposed a general theory of the constitution of organic compounds, which was entirely inconsistent with the radicle theory as above described (see NUCLEUS THEORY, iv. 143). But the chief opposition to the radicle theory arose,—(1), from the difficulty of reconciling with it, as it was held by Berzelius, its chief supporter, the constitution of substances, such as chloracetic acid, formed by the action of chlorine and its analogues on organic bodies; (2) from the fact that of the very numerous radicles whose existence the theory assumed, scarcely two or three were known in the separate state; and (3) in consequence of Gerhardt and Laurent's discovery that the number of atoms of hydrogen, chlorine, nitrogen, and their analogues, taken together, which was contained in a molecule of any well-investigated compound, was always an *even* number, whereas all the supposed compound radicles contained an *odd* number of such atoms.

We have not space to trace the long and bitter controversies which arose upon each of these points: an excellent account of them will be found in **Kekulé's** *Lehrbuch der organischen Chemie* (vol. i. pp. 59–94, 1859). It must suffice to say here that the objections to the "radicle" theory, referred to under the first of the above heads, arose from its identification with the electro-chemical theory, and therefore lost their force when this theory was abandoned, and it was consequently admitted that radicles playing the part of electro-positive metals might contain not only oxygen, but chlorine, bromine, or in fact any other element. The discovery of cacodyl by **Bunsen** in 1842, of methyl, ethyl, and butyl by **Frankland** and **Kolbe** in 1849, and subsequently of several other of the so-called alcohol-radicles, which at first sight seemed to afford a conclusive answer to all *à priori* objections against the possible existence of radicles in the free state, resulted in its being proved that the molecules of the isolated radicles consisted of two atoms, and thus the "law of even numbers" received a confirmation instead of the expected refutation. (See Alcohol-radicles, i. 96.)

The idea of compound radicles, as it is now entertained, is quite independent of the question whether they can be actually prepared in the separate state or not. A radicle, in modern chemical language, is simply a group of elements which is common to a more or less numerous series of allied compounds, and remains unaffected by the processes whereby these compounds are transformed one into another. It is essentially correlative with the idea of molecular types; and, as pointed out in the places referred to at the beginning of this article (especially ii. 700), the radicle which any complex compound is regarded as containing, must depend upon the type to which the compound is referred, while, conversely, the type is equally dependent on the radicle.

G. C. F.

RADIOLITE. Natrolite, from Brevig in Norway (iv. 29): see also an analysis by **Michaelson**. (Jahresb. 1863, p. 819.)

RADISH. *Raphanus sativus.* Radish-roots contain, according to **T. J. Herapath** (Chem. Gaz. 1847, p. 279), in 1000 pts.:—

Water	959·74	Red colouring-matter	1·77
Woody fibre	17·02	Fat oil	0·40
Nitrogenous substance with a little starch	2·04	Sinapine?	0·04
Albumin	0·91	Alkaline and earthy phosphates, with a little gypsum	0·74
Extractive matter	2·26	Acetates of potassium and sodium	0·22
Gum	4·30	Nitrates of potassium and sodium	5·17
Sugar	1·14	Chlorides of potassium and sodium	4·16

The ash of the root and herb of the radish has also been analysed by **T. Richardson** (Jahresb. 1847–48, Table C to page 1074), with the following results:—

	K^2O.	Na^2O.	CaO.	MgO.	SO^3.	SiO^2.	P^2O^5.	$Fe'''PO^4$	KCl.	$NaCl$.	
Root	21·16	. .	8·78	3·53	7·71	8·17	40·09	2·19	1·29	7·07	= 99·99
Herb	5·05	11·09	27·90	7·08	9·64	8·22	6·07	16·45	. .	8·50	= 100·00

The dried root yielded 6·43 per cent., and the dried herb 2·76 per cent. ash.

RADISH, OIL OF. The roots and seeds of the radish yield, by distillation with water, a milky liquid, from which an essential oil may be obtained by rectification. This oil is colourless, heavier than water, contains sulphur, forms a white precipitate with mercuric chloride, yellow with platinic chloride. It is moderately soluble in water.

The same oil is obtained by distilling, with water, the seeds of *Brassica Napus*, *Cochlearia Draba*, and *Cheiranthus annuus*.

RAMALINA CALICARIS. A lichen which yields alpha-usnic acid. (See Usnic Acid.)

RAMMELSBERGITE. Trimetric arsenide of nickel, $NiAs^2$ (iv. 36).

RANDANITE. An earthy hydrate of silica, occurring near Pont Gibaud in France. (See Opal, iv. 304.)

RANGOON TAR. See Naphtha (iv. 3).

RANUNCULUS. The root of *Ranunculus Ficaria*, gathered in Tuscany in April and May, was found by **Toscani** (Cimento, v. 453) to contain 0·5 to 1·0 per cent. crystallisable sugar, 0·4 to 0·6 dextrin, 28 starch, and an acrid deleterious substance.

The acrid juice of *Ranunculus sceleratus* yields by distillation a clear, sharp-tasting, fetid liquid, which when kept for some time, even in closed vessels, deposits a white amorphous precipitate of anemonin (i. 290). Ether extracts from this distillate a neutral, acrid, golden-yellow, non-sulphuretted oil, heavier than water, which attacks the eyes strongly, and raises blisters on the skin. When kept under water, or in contact with chloride of calcium, it concretes to a white solid mass, which quickly changes into anemonin and anemonic acid. It is to this transformation of the acrid principle of the ranunculus, and not to its volatility, that the loss of acridity of the plant by drying is due. (Erdmann, J. pr. Chem. lxxv. 209.)

RAPAKIVI. A variety of granite containing 60·46 per cent. orthoclase, 31·83 quartz, and 6·71 mica, occurring at Pyterlaks and other localities in Finland. (Jahresb. 1862, p. 784.)

RAPE. See BRASSICA (i. 654).—Rape-seed oil, *Huile de navette*, is a fat oil obtained by pressure from the seeds of winter-rape (*Brassica Napus*), which yield about 33 per cent of it. This oil is yellow, has a peculiar odour, a density of 0·9128 at 15°, and solidifies at a few degrees below 0°. By dry distillation, it yields a mixture of volatile fatty acids, acrolein, and oily hydrocarbons of very variable boiling point. These hydrocarbons are strongly attacked by nitric acid, yielding caprylic, œnanthylic, caproic, valerianic, butyric, propionic, and acetic acids. With chromic acid the same hydrocarbons yield only acetic and propionic acid. (Schneider, Ann. Ch. Pharm. lxx. 107.)

Rape-seed oil is used for illumination, for the manufacture of soft soaps, for oiling woollen stuffs, in the preparation of leather, and for lubricating machinery.

The seeds of summer-rape, *Brassica præcox*, yield a yellow viscid oil of specific gravity 0·9139, which deposits tallow at −8°, and solidifies to a yellowish-white butter at −10°. (Schübler.)

The seeds of the turnip, *Brassica Napus*, yield a smaller quantity of a similar oil, of specific gravity 0·9167.

Colza oil, used chiefly for illumination, is obtained to the amount of about 33 per cent. from the seeds of colza or wild navew, (*Brassica campestris*, var. *oleifera*). It is yellow, of specific gravity 0·9136 at 15°, and solidifies at −6°. It is chiefly a mixture of two glycerides, which yield, by saponification, two peculiar fatty acids. (See BRASSIC ACID, i. 655.)

RAPHANOSMITE. Kobell's name for native selenide of lead and copper from Tilkerode (iii. 557.)

RAPHANUS. (See RADISH, p. 76.)

RAPHILITE. Asbestiform tremolite from Lanark, in Canada. (See HORNBLENDE, iii. 169.)

RASTOLYTE. A reddish-grey micaceous mineral occurring in monoclinic forms at Monroe, Orange County, New York, analysed by Shepard (Sill. Am. J. [2] xxiv. 128), and by Pisani (Compt. rend. liv. 606; Jahresb. 1862, p. 749), whose results differ widely from one another:—

SiO^2.	Al^2O^3.	FeO.	CaO.	MgO.	Alkali and loss.	H^2O.		
42·3	6·5	38·25	2·0	1·0	6·15	3·8*	= 100	(Shepard).
34·98	21·88	28·44	. .	6·24	. .	9·22	= 100·76	(Pisani).

From the physical characters of the mineral, Pisani regards it as allied to ripidolite.

RATANHIA. In the bark of ratanhia or rhatany-root, *Krameria triandra*, Wittstein (Jahresb. 1854, p. 656) found a peculiar iron-greening tannin, a body analogous to cinchona-red, or rather to quinova-red, resulting from the decomposition of the tannin; also gummy and extractive matters, wax, sugar, starch, and oxalate of calcium. In the American extract of ratanhia, Wittstein found a nitrogenous body, which he regarded as tyrosine. (See the next Article.)

RATANHINE. $C^{10}H^{13}NO^3$. (E. Ruge, Viertelj. d. naturforsch. Gesellsch. in Zürich, vi. Heft 3; Jahresb. 1862, p. 493.)—A compound homologous with tyrosine ($C^9H^{11}NO^3$), occurring to the amount of 1·26 per cent. in the extract of rhatany-root. It was first observed by Wittstein, who regarded it as tyrosine. To prepare it, the solution of rhatany extract is precipitated with basic acetate of lead; the filtrate, freed from lead by sulphydric acid, is evaporated to a small bulk; the crystals, which separate after 12 hours, are pressed, washed, and dissolved in ammonia; the solution is left to evaporate; and the crystals which then separate are further purified by precipitating their solution with basic acetate of lead, and treating the filtrate with sulphydric acid at the boiling heat.

---

* With fluorine.

Ratanhine, thus purified, crystallises in large spherical aggregates of delicate white needles, drying up to an interlaced mass. It dissolves in 125 pts. of boiling water, and, like tyrosine, has a great tendency to form supersaturated solutions. It is slightly soluble in boiling spirit of ordinary strength, quite insoluble in absolute alcohol and in ether. It is not precipitated by neutral or basic acetate of lead, or by mercuric acetate. A solution of ratanhine saturated at 15°, assumes a rose-red colour when heated with a few drops of *mercuric nitrate*, and on further addition of the latter, deposits brown-red flocks. When ratanhine triturated with a small quantity of water is mixed by drops with dilute *nitric acid*, and heated to the boiling-point, the liquid becomes rose-red, then ruby-red, then gives off gas and assumes a deep indigo-blue colour, due to the formation of resinous bodies. This coloration is perceptible even to the 50,000th degree of dilution. With a larger quantity of nitric acid, more complete decomposition takes place. Ratanhine moistened with water is coloured rose-red to violet-red by *nitrous acid*, and with a larger quantity of water, a blue or green solution is ultimately formed.

Ratanhine, like tyrosine, unites both with mineral acids and with alkalis: it decomposes the carbonates of the alkaline earths. A solution of ratanhine in baryta-water deposits part of the ratanhine unaltered, while the compound $C^{10}H^{11}Ba''NO^3$ remains dissolved.

Hydrochlorate of ratanhine, $C^{10}H^{13}NO^3.HCl$, crystallises by spontaneous evaporation in colourless acid prisms or laminæ, which are decomposed by water or alcohol, with separation of ratanhine.

Ratanhine-sulphuric or *Sulpho-ratanhic acid*.—The dark-red solution of ratanhine in 5 pts. of warm concentrated sulphuric acid becomes colourless on dilution, and if then neutralised with carbonate of barium, deposits slender silky needles of the salt, $C^{10}H^{11}Ba''NO^3.SO^3.\frac{5}{2}H^2O$, and the mother-liquor dries up to an amorphous mass, consisting chiefly of the salt $C^{20}H^{24}Ba''N^2O^6.S^2O^6.5H^2O$. The acid $C^{10}H^{15}NSO^7$, or $C^{10}H^{13}NO^3.SH^2O^4$, separated from the latter salt by sulphuric acid, crystallises from absolute alcohol in large colourless square plates. Both the acids and their barium-salts react with ferric chloride like tyrosine-sulphuric acid, producing a splendid violet coloration.

RATOFFKITE. A granular or earthy blue variety of fluor-spar, mixed with clay, from Ratoffka in Russia.

RAUMITE. A mineral, apparently allied to esmarkite, from Raumo, in Finland, containing, according to Bonsdorff, 43·0 per cent. silica, 19·0 alumina, 19·2 ferric oxide, 12·55 magnesia, and 6·9 water. (Rammelsb. Mineralch. p. 836.)

RAZOMOFFSKIN. An argillaceous substance from Kosemuth in Silesia, containing, according to Gellner, 54·50 per cent. silica, 27·25 alumina, 2·00 lime, 0·37 magnesia, 0·25 ferric oxide, and 14·25 water (= 98·62).

REALGAR. Native protosulphide of arsenic, AsS (i. 386).

RECTIFICATION. The concentration of a volatile substance by distillation.

RED ANTIMONY. Native oxysulphide of antimony, or *Kermesite*, Sb^2OS^2 (iii. 446).

RED CHALK, or **REDDLE.** Earthy red hæmatite having a flat conchoïdal fracture; used as drawing chalk.

RED COPPER-ORE. Native cuprous oxide (ii. 70).

RED DYES. See DYEING (ii. 355).

RED HÆMATITE, or **RED IRON ORE.** Native anhydrous ferric oxide (iii. 337, 393).

RED IRON-VITRIOL, or *Botryogen*. Native ferroso-ferric sulphate from Fahlun (i. 651).

RED LEAD, or *Minium*. Red oxide of lead (iii. 551).

RED LEAD-ORE, or *Crocoïsite*. Native chromate of lead (i. 934).

RED MANGANESE, or *Diallogite*. Native carbonate of manganese (i. 789).

RED OCHRE. Red hæmatite of a soft earthy consistence. The same name is applied to a pigment prepared by calcining yellow ochre (clay containing ferric hydrate).

RED PIGMENTS. The red pigments most commonly used are red oxide of iron in various states, red oxide of lead, and vermillion. *Indian red* is pure red hæmatite finely ground. The same name is applied to a dark-red ferric silicate from the Persian Gulf, also used as a pigment. *Venetian red* and *colcothar* are coarser varieties of red hæmatite.—*Red ochre* (vid. sup.). *Bole of Armenia* is a red oxide of iron mixed with clay.—Respecting *red lead* or *minium*, see LEAD (iii. 551). A fine *red-brown* is obtained by mixing red lead with ferric oxide. *Vermillion* is mercuric sulphide prepared by sublimation (iii. 913). Native cinnabar is of a duller red colour. —*Antimony-vermillion*, a sulphide of antimony prepared by precipitating an antimony-salt with an alkaline hyposulphite, generally with hyposulphite of calcium, is a very solid red colour, little subject to change except by the action of strong alkalis. When triturated with drying oils, it acquires great vivacity and lustre, and forms an oil-colour well adapted for house and furniture painting (Hofmann's *Exhibition Report*, 1862, p. 79).—*Realgar*, or native red sulphide of arsenic, is also used as a red pigment.—*Mercuric iodide* affords a splendid scarlet, but it is very liable to change by the action of light.—*Cobalt-rose* is a fine rose-colour obtained by calcining nitrate of cobalt with magnesia.—*Arsenate of cobalt*, both the native variety and that which is prepared by calcining the arsenio-sulphide of cobalt in contact with the air, affords a very rich and permanent red colour; but it is very poisonous.—Various *red lakes* are prepared by precipitating infusions of madder, cochineal, and brazil-wood with solutions of alumina. (i. 656, 804; iii. 466, 750. See also *Chimie des Couleurs*, par J. Lefort, Paris, 1855, pp. 133—195.)

RED SILVER-ORE. See PROUSTITE (iv. 740), and PYRARGYRITE (iv. 753).

RED VITRIOL, or *Biberite.* Native cobalt-sulphate. (See SULPHATES.)

RED ZINC-ORE, or *Zincite.* Oxide of zinc containing manganese. (See ZINC.)

REDDLE. Syn. with RED CHALK.

REDRUTHITE, or *Copper-glance.* Native cuprous sulphide (i. 74).

REDUCTION. The abstraction of an electro-negative from, or addition of an electro-positive element to, any compound: thus an oxide deoxidised by the action of hydrogen, charcoal, &c., is said to be reduced: the addition of hydrogen to an organic compound, by the action of sodium-amalgam, &c., is also called an operation of reduction.

REFLECTION and **REFRACTION.** See LIGHT (iii. 608).

REGULUS. A metal reduced from its oxide or other compound by fusion with a reducing agent.

REISET'S SALTS. The diammonio- and tetrammonio- platinous salts, discovered by Reiset (iv. 673).

REISSACHERITE. A brown-black spring-deposit, occurring between slabs of gneiss at Wildbad-Gastein, and containing, according to Hornig, 34·15 per cent. manganic oxide, 14·16 ferric oxide, 7·59 calcic carbonate, 16·9 water, and 27·27 sand. (Rammelsb. Mineralch., p. 1008).

REMINGTONITE. Hydrated carbonate of cobalt, occurring as a rose-coloured incrustation at Finksburg, in Maryland (i. 782).

REMOLINITE. Syn. with ATACAMITE (i. 429).

RENSSELAËRITE. A mineral having the composition of talc, but the crystalline form of augite. It has a fine compact texture, is unctuous to the touch, translucent, and of a grey, whitish, greenish, brownish, or sometimes black colour. Hardness = 3·4. Specific gravity = 2·87. On account of its softness, translucency, and fine texture, it is worked in the lathe into inkstands and other forms. It occurs over large areas in Northern New York. Two specimens analysed by T. S. Hunt (Jahresb. 1858, p. 743), *a* from Grenville in Canada, *b* from Canton, New York, gave the following results:—

	SiO^2.	MgO.	FeO.	H^2O.		
a.	61·60	31·06	1·53	5·60	=	99·79
b.	61·10	31·63	1·62	5·60	=	99·95

RESIGALLUM. A term applied both to realgar and to orpiment.

RESINAPITIC ACID. A crystallisable acid resin obtained, together with other products, from the root of butter-bur (*Tussilago Petasites*). See TUSSILAGO.

RESINATES. A general name for the salts of the acids obtained from turpentine—viz., sylvic, pinic, and pimaric acid (*q.v.*). The general formulæ of these salts are $C^{20}H^{29}MO^2$ and $C^{40}H^{58}M''O^4$.

RESINEÏN, or **RESINONE.** This name is given by Frémy to a hydrocarbon (probably impure colophene, i. 1086) obtained by the dry distillation of colophony.

RESINS. A class of compounds of vegetable origin, characterised by being insoluble in water, mostly soluble in alcohol, uncrystallisable, and softening or melting at a moderate heat. They may be divided into—

1. Resins which *exude* spontaneously from plants, or from incisions in the stems and branches, and harden on exposure to the air. These are mostly mixtures, sometimes containing considerable quantities of gum or mucilage (*Gum-resins*), or of volatile oil (*Balsams*). They are for the most part produced by the oxidation of volatile oils secretd by the plant.

2. *Oxidised Fossil Resins*, occurring in beds of coal lignite, &c., and apparently produced in a similar manner from plants of a bygone age. The term fossil resin is sometimes, but inappropriately, extended to certain hydrocarbons, such as scheererite, ozokerite, &c., occurring in similar localities.

3. Resins *extracted* from plants by alcohol, and consisting in many cases of definite proximate principles.

Resinous bodies are also produced, artificially, by the oxidation of volatile oils in contact with air, or by the action of nitric acid; in the desiccation of drying oils; in the decomposition of alcohol, aldehyde, and similar compounds by potash, and in the dry distillation of many organic compounds.

Natural resins may be freed from admixed volatile oil by exposure to the air, by boiling with water, or by fusion; gummy or mucilaginous substances may be extracted from them by water.—When a resin has been extracted from a plant by hot alcohol or ether, the solution on cooling deposits the greater part of the wax or fat contained in it; and if it be then distilled with water, the resin remains behind, and may be further purified by washing with water.

The products thus obtained frequently retain small quantities of acid, fat, volatile oil, colouring-matter, &c., and may in some cases be resolved into two or more resins, differing in composition and properties.

Resins are transparent or translucent; a few are colourless, but the greater number are yellow, brown, or otherwise coloured. Some of them are hard and friable, a few are crystalline; others are soft and greasy, or elastic like caoutchouc. They become electric by friction. When heated they soften or melt, mostly without decomposition, to a thick tenacious liquid, generally more viscid than melted fat. They are not volatile, but when strongly heated, they carbonise, and give off carbonic anhydride, water, gaseous hydrocarbons, and volatile oils varying greatly in composition. (See COLOPHONY, i. 1087.)

Resins are insoluble in *water*; most of them dissolve freely in cold *alcohol*, some scarcely at all, or only in hot alcohol. The alcoholic solutions, when exposed to the air, give off the alcohol, and leave the resin in the form of a varnish. They are rendered milky by water, from separation of the resin; more complete separation is effected by mineral acids. Most resins are soluble in *ether*. *Volatile oils* likewise dissolve them, and the solutions, on exposure to the air, leave first a balsam-like mass, then the resin. Resins may be melted together with *fats*; their solutions in drying oils harden in contact with the air.

Resins are either *neutral* or *acid*. The former, when dissolved in alcohol, do not redden litmus, and they are insoluble or only sparingly soluble in *alkalis*. The latter, which are the more numerous, redden litmus in alcoholic solution, and dissolve in caustic alkalis and alkaline carbonates, the solutions, when evaporated, leaving amorphous masses, called resin-soaps, often precipitable from the solution by excess of alkali. Common yellow soap consists of tallow-soap mixed with a resin-soap, formed by dissolving colophony in caustic soda or carbonate of sodium. By decomposing the solutions of the resin-soaps with metallic salts, compounds of the acid resin with metallic oxides are formed, for the most part insoluble in water.

Resins are used for a variety of purposes. Their solutions in alcohol, oil of turpentine, and drying fat oils, yield the several kinds of varnish used for covering wood, metal, &c. with a thin but impermeable coating, in order to protect them from air and moisture. Spirit-varnishes are the most brilliant, but also the most brittle; their rigidity may be diminished by the addition of oil of turpentine. The resins commonly used for varnishes are copal, elemi, lac in scales, mastic, and sandarach.

The following is a list of the natural resins, showing, except in the case of the fossil resins, the plants from which they are derived:—

RESINS EXUDING FROM PLANTS.

a. Containing Benzoic or Cinnamic acid.

1. Acaroïd resin, from *Xanthorrhœa hastilis*.
2. Benzoïn, from *Styrax Benzoin*.
3. Dragon's-blood, Oriental, from *Calamus Draco*.

Dragon's-blood, Canarian, from *Dracæna Draco*.

Dragon's-blood, American, from *Pterocarpus Draco*.

α. *Containing Benzoic and Cinnamic Acid* (continued).

4. Peru Balsam, from *Myroxylon peruiferum*.
5. Liquid Storax, American, from *Liquidambar styraciflua*.
6. Liquid Storax, Oriental, from *Liquidambar Altingia*.
7. Solid Storax, from *Styrax officinalis*.
8. Tolu Balsam, from *Myrospermum toluiferum* or *frutescens*.
9. Mecca Balsam, from *Opobalsamum verum*, s. *gileadense*.

β. *Not containing Benzoic or Cinnamic Acid.*

1. Alouchi resin, from a tree growing in Madagascar.
2. Gum ammoniacum, from *Dorema ammoniacum*.
3. Anime resin, from *Hymenæa Courbaril*.
4. Arbol-a-Brea, from *Canarium album?*
5. Asafœtida, from *Ferula Asafœtida*.
6. Bdellium, from *Balsamodendron* (various species).
7. Betulin, from *Betula alba*.
8. Caranna, from *Amyris caranna*, *Bursera gummifera* or *acuminata*.
9. Ceradia resin, from *Ceradia furcata*.
10. Copaiba balsam, from various species of *Copaïfera*.
11. Copal, Brazilian or West Indian, from *Hymenæa Courbaril*.
    Copal, African and East Indian, from *Hymenæa verrucosa* or *Elæocarpus copaliferus*.
    Copal, North American, from *Rhus copallina*.
    Dammara resin, Australian, from *Dammara australis*.
    Dammara resin, East Indian, from *Pinus Dammara* or *Dammara alba*.
13. Elemi, from *Amyris* or *Icica* (various species).
14. Euphorbium, from *Euphorbia officinarum*, *antiquorum*, and *canariensis*.
15. Galbanum, from *Babon Galbanum?*
16. Gamboge, from *Stalagmites cambogioïdes* or *Hebradendron cochinchinense*.
17. Gomart resin, from *Bursera gummifera*.
18. Guaiacum, from *Guaiacum officinale*.
19. Icica-resin, from various species of *Icica*.
20. Ivy-resin, from *Hedera Helix*.
21. Jalap-resins, from *Convolvulus Schiedanus*, &c.
22. Labdanum or Ladanum, from *Cistus creticus*.
23. Lac, from *Aleurites laccifera*, *Croton aromaticus*, *Butea frondosa*, *Ficus religiosa*, and *Zizyphus Jujuba*.
24. Laëtia-resin, from *Laëtia resinosa*.
25. Masopin, from a Mexican tree.
26. Mastic, from *Pistacia Lentiscus*.
27. Maynas, from *Calophyllum Calaba*.
28. Myrrh, from *Balsamodendron Myrrha*.
29. Olibanum or Incense, Indian, from *Boswellia serrata*.
    Olibanum or Incense, Arabian, from *Amyris Kataf*.
30. Opoponax, from *Ferula Opoponax*.
31. Palm-wax (Cera de Palma), from *Ceroxylon andicola*.
32. Pasto-resin, from a Mexican tree.
33. Sagapenum, from *Ferula persica*.
34. Sandarach, from *Thuja articulata*.
35. Scammony, from *Convolvulus Scammonium* and other species.
36. Tacamahac, West Indian, from *Amyris tomentosa*.
    Tacamahac, East Indian, from *Calophyllum Inophyllum*.
37. Turpentine, from coniferous trees.

B. Fossil Resins (containing oxygen).—Amber, Ambrite, Anthracoxene, Asphalt, Berengelite, Boloretin, Bucaramanga-resin, Copalin, Euosmite, Fossil Caoutchouc, Guayaquillite, Hartin, Inolyte, Jaulingite, Krantzite, Melanchym, Middletonite, Peat-resins, Piauzite, Pyroretin, Retinasphalt, Retinite or Walchovite, Scleretinite, Resin from Settling Stones in Northumberland, Tasmannite, Xyloretin, Resins from the Lignite of Weissenfels—viz., Geoceraïn, Geoceric acid, Geocerinone, Geomyricin, Geoceric acid, Leucopetrin.

C. Resins extracted from Plants by Alcohol.

Nearly all plants yield resins when thus treated. Among them may be mentioned the resins of Angelica-root, Indian hemp, Cubebs, Manna, Poplar-buds, Butter-bur (*Tussilago Petasites*), Spanish pepper (capsicin), Squill (*Scilla maritima*), and Turpethum (*Ipomæa Turpethum*).

Most of the resins above enumerated have been or will be described in their alphabetical places. Some are not sufficiently important to require special description. We give here a few that have been omitted. (See further *Gmelin's Handbook*, xvii. 382—455):

1. *Gum Ammoniacum.*—This gum-resin exudes from an umbelliferous plant (*Dorema ammoniacum*, Don.; *Heracleum gummiferum*, Willd.) growing in the northern parts of Persia and Armenia. It occurs in commerce, sometimes in white, yellow, or reddish

grains of various sizes, sometimes in cakes mixed with sand and sawdust. It has a strong disagreeable odour, resembling that of garlic and of castoreum, and arising from the presence of an essential oil (probably sulphuretted), which may be separated by distillation with water. It softens at the heat of the hand, and becomes brittle when cooled. Specific gravity = 1·207. It contains, according to Bucholz, 72·0 per cent. resin, 22·4 soluble gum, 1·6 bassorin, and 4·0 volatile oil and water; according to Braconnot, 70·0 resin, 18·4 soluble gum, 4·4 bassorin, 7·2 volatile oil and water.

By digesting gum-ammoniacum with alcohol, a clear yellow solution is obtained, which yields by evaporation a transparent nearly colourless resin, containing, according to Johnston, 71·9 per cent. carbon, 7·6 hydrogen, and 20·5 oxygen. By heating this resin to 130 as long as it gives off vapour, another resin is obtained containing more carbon.

2. *Resin of Ceradia furcata.*—This plant, growing on the coast of Africa, opposite the island of Ichaboe, yields an amber-coloured resin, having the odour of olibanum, and a specific gravity of 1·197. It appears to have the composition of the turpentine resins, $C^{20}H^{30}O^2$.

3. *Gomart-resin*, from *Bursera gummifera.*—Solid, dry, rather soft in the middle, nearly white, and of crystalline structure, exhibiting cavities lined with shining crystals, slightly fusible; spreads out on boiling water in adhesive grains. The odour is intermediate between that of turpentine and that of elemi. Yields by distillation with water, a transparent colourless volatile oil, having the odour and composition of turpentine-oil, $C^{10}H^{16}$, vapour density = 4·7, and forming with hydrochloric acid gas a hydrochlorate, $C^{10}H^{16}.2HCl$, which crystallises in dazzling white silky needles.

4. *Ivy-resin*, from *Hedera Helix.*—Red-brown or greenish brittle lumps, having a specific gravity of 1·294 (Brisson). Has a faint aromatic taste and odour. Contains, according to Pelletier, 23 per cent. resin, 7 gum, 70 woody fibre, with malic acid and salts. It burns with a bright flame and agreeable odour; yields by dry distillation, first acid, then ammoniacal water, together with yellow and red oil.

5. *Resin of Laëtia resinosa.*—Small yellowish-white, transparent, green, brittle grains, with conchoïdal fracture. Has a faint aromatic odour. Yields a small quantity of volatile oil by distillation with water. When heated, it melts, swells up, burns with a white very smoky flame, leaving a bituminous cinder. Dissolves completely in boiling alcohol, and partly separates on cooling. (Macaire-Prinsep, Bibl. univ. xlv. 431.)

RESORCIN. $C^6H^6O^2$.—A compound homologous with orcin ($C^8H^{10}O^2$) produced by the action of potash on galbanum (iv. 215).

RESPIRATION. All animals, so far as we know, have need of oxygen in order that the oxidative processes, whereby their life is manifested, may be carried on. Some, the so-called air-breathing animals, obtain the oxygen they require from the atmosphere; others, the so-called aquatic animals, live on the free oxygen always to be found in those waters which are capable of supporting life. In order to bring the oxygen-bearing medium into close contact with the blood or internal juices of the body, a special mechanism is in most cases provided. Thus in man, by the alternate expansion and relaxation of the chest-walls, a quantity of air is alternately drawn into and driven out of hollow organs called lungs, situated in the chest, but having a direct connection with the external air; by means of bloodvessels ramifying over the lungs, the blood is brought very near to the air. Similar organs, with various modifications, are found in all the higher and in some of the lower air-breathing animals. In other cases, *e. g.* insects, air is carried by means of ramifying tubes all over the body. In many aquatic animals the blood or nutritive fluid is made to pass into or through organs called gills, so constructed that the water in which the animal is living is separated from the blood or nutritive fluid by a very thin membrane only. In others water is carried by canals (water-vascular organs), by a system of irrigation as it were, through a smaller or larger portion of the body. Finally, all animals are capable, to a greater or less extent, of acting upon and being acted upon by the surrounding oxygen-bearing medium, be it air or water, through the external surface of their bodies and through the walls of various cavities (digestive, &c.). In many of the lower animals this is the only way in which oxygenation takes place, no special organ of any kind being provided for that purpose.

The word breathing or respiration was at first used to denote the visible play of the mechanism, whereby the oxygen-bearing medium was brought near to the fluids of the economy,—namely, the driving air into (inspiration) and out of the lungs (expiration), or analogous functions, in other animals,—and is still often employed in this limited sense. Inasmuch, however, as a particular respiratory mechanism is not essential to the gaining of oxygen, while the gaining of oxygen is the end of every respiratory mechanism, it has become a habit to consider respiration to mean the absorption of free oxygen by any means whatsoever. And since it so happens that at the same time and place, and by the same organs that oxygen is taken into the economy, carbonic acid is also given out from it, and other changes of gases possibly take place, the term has acquired the still wider signification of "the interchange between the gases of an organism, and the gases of the medium in which it lives."

Theory of Respiration.

The ancients were for the most part agreed that the great use of breathing was to cool the lungs and moderate the heat generated in the viscera; and this opinion maintained its ground, to a great extent, through the middle ages into modern times, in spite of the anatomical and physiological labours of Vesalius and Harvey. The observations of Van Helmont (1648), on the unfitness of *gas sylvestre* for breathing purposes; of Boyle (1670), on the necessity of air for the respiration, not only of all terrestrial but also of aquatic creatures, and on the unfitness of respired air for further respiration; of Hook (1664) on artificial respiration; and of Lower (1669), on the change of colour to be observed in blood while passing through the lungs, prepared the way for the striking views of John Mayow (1674). This young physiologist recognised, as a constituent of atmospheric air, of nitre, and of other substances, and as a necessary factor of combustion, a something which he calls *spiritus nitroaëreus* or *particulæ nitroaëreæ sive igneoaëreæ*, and by which he evidently meant what we now call oxygen. He observed that by respiration, as by combustion, air was deprived of its *particulæ nitroaëreæ*; and he was the first to remark that when animals were made to breathe in a limited space, as in a bell-jar over mercury, the volume of the air was lessened. He maintained that the use of respiration was not to cool the blood, or to promote the transit of that fluid through the lungs, or to encourage a due mixture of its component parts, but to supply it with the *particulæ nitroaëreæ*; and he was of opinion that these particulæ, embraced by the blood and carried by it to the muscles, entered into such a violent molecular conflict with the combustible or (as he calls it) sulphureous material there stored up, as to produce the phenomena of muscular contraction. With these views Mayow mixed up many crude and immature ideas, from which, had he lived longer (he died A.D. 1679, æt. 33) he might have freed himself. His great lack was the failing to recognise that in respiration (and combustion) there was something produced as well as consumed. This, however, was not fully shown until Black (1757) demonstrated the existence of carbonic acid in expired air. The next step was made by Priestley, who showed (1771) that air which had become unfit for respiration or combustion, by reason of animals having breathed, or candles having burnt, or substances having putrefied in it, regained its lost properties on being submitted to the influence of living plants (*On Air*, 2nd ed. 1775). He marred the good of his discovery by adopting a retrograde theory of the nature of respiration and combustion. He maintained that the carbonic acid (fixed air) of expired air did not come from the lungs, but pre-existed in common atmospheric air, and was "precipitated" therefrom by the union of the air of inspiration with the phlogiston (ultimately derived from the food) which was thrown off by the lungs. Living animals (and burning or putrefying bodies) phlogisticated, he said, and living plants dephlogisticated common air. Priestley, however, prepared the overthrow of his own views by the discovery of oxygen (1774–5). Through experiments made in 1777, but not published till 1779, Crawford (*Animal Heat*, 2nd ed. 1788) was led to connect animal heat with respiration. He says (p. 361): "The pure air is received into the lungs containing a great quantity of elementary fire; the blood is returned from the extremities impregnated with the inflammable principle; the attraction of pure air to the latter principle is greater than that of the blood. This principle will therefore leave the blood to combine with the air; by this combination the air is obliged to deposit a part of its elementary fire; and as the capacity of the blood is at the same moment increased, it will instantly absorb that portion of fire which had been detached from the air. The arterial blood, in its passage through the capillary vessels, is again impregnated with the inflammable principle, in consequence of which its capacity for heat is diminished. It will therefore, in the course of the circulation, gradually give out the heat which it had received in the lungs, and diffuse it over the whole system. Thus, in respiration, the blood is continually discharging the inflammable principle, and absorbing heat, and in the course of the circulation is continually imbibing this principle and emitting heat."

Meanwhile the true theory of respiration had been more clearly and distinctly propounded by Lavoisier, who, following up his investigations on oxidation and on the constitution of air, in 1777 (*Expériences sur la Respiration des animaux et sur les changements qui arrivent à l'air en passant par leur poumon*, Mémoire lue à l'Académie des Sciences le 3 Mai 1777, Œuvres, éd. imp. 174), demonstrated that animals by the act of breathing took away from the atmosphere oxygen (*l'air éminement respirable*), and loaded it with carbonic acid (*l'acide crayeux aëriforme*). He hesitated to decide whether the oxygen was converted into carbonic acid while passing in and out of the lungs, or whether oxygen was absorbed into, and carbonic acid exhaled from, the blood during its passage through the lungs; but inclined to the former opinion. In 1780 he showed, in conjunction with La Place (Mémoire sur la Chaleur, Art. iv., Œuvres, éd. imp. ii. 283), that by far the larger portion of the heat given out by animals during a given period could be accounted for by considering it to be due to the combustion of a quantity of carbon sufficient to produce the carbonic acid exhaled during the same time. In 1785 (*Altérations qu'éprouve l'air respiré*, Œuvres, éd. imp. ii. 676), he recognised that the whole of the oxygen which disappeared during respiration, did not return in the form of carbonic acid; and while admitting the possibility of the missing portion having "combined with the blood," thought it more probable that it united with hydrogen in the lungs to form water. He had by this time definitively adopted the theory that the formation of carbonic acid took place in the lungs, and in a memoir published in 1790 (*Premier Mémoire sur la Transpiration des Animaux*, par Séquin et Lavoisier, Œuvres, éd. imp. ii. 708), he gives the following account of his views on the subject. There is continually transuding from the blood through the pulmonary membranes into the air-tubes, a humour which is principally composed of carbon and hydrogen. This humour, issuing from the minute exhalant vessels of the lungs in a state of very fine division, unites with the oxygen in contact with it, and is thus converted into water and carbonic acid. The carbonic acid is driven out by the action of the lungs while the accompanying water (water of respiration), together with the water which transudes into the air-tubes along with the hydrocarbonous respiratory material (water of pulmonary transpiration) is carried off in the form of vapour by the heated air of the lungs.

The difficulty felt in supposing that, while the whole body is nearly of the same temperature, combustion takes place in one spot only, to wit the lungs, was met by Lavoisier and La Place with the reflection that the rapidity of the circulation, the evaporation by the lungs, and an augmentation of the capacity for heat in decarbonised blood (theory of Crawford), were sufficient to account for the phenomena. Lagrange however, dissatisfied with this explanation, put forward through Hassenfratz the theory (which Lavoisier had discarded) that oxygen was absorbed into the blood, and, during the course of the circulation, combined with the carbon and hydrogen of that fluid, giving rise to carbonic acid and water, which were in turn exhaled through the lungs. Lagrange supported his views by no facts or experiments, and they did not meet with any general acceptance.

In 1799 H. Davy (Beddoe's Med. Contrib. p. 128) published a theory that in the act of respiration, phosoxygen, as he called it, combined with venous blood, while at the same time "carbonic acid and water were liberated, either by the increase of temperature, or from the superior affinity of phosoxygen for venous blood." He was able to obtain a small quantity of carbonic acid from venous, and a very small quantity of oxygen from arterial blood. In 1800, however (*Researches*, p. 447), he had abandoned his phosoxygen theory, and embraced the views of Lavoisier, though he was led, by his experiments on the respiration of hydrogen and nitrous oxide, to believe that some at least of the carbonic acid of expired air did not arise directly from a combustion of carbon in the lungs, but pre-existed in venous blood, and transpired from it through the coats of the minute bloodvessels.

Spallanzani (*Memoirs on Respiration*, by Sennebier) in the course of some experiments which were not published until 1803, found that snails placed in an atmosphere of pure hydrogen, still continued for some time to give off carbonic acid, which in this case could not have arisen from any direct combustion of carbon. Singularly enough, he explained this fact by supposing that carbonic acid was generated by the food in the stomach, entered thence into the blood, and so made its way through the skin and lungs.

These observations of Davy and Spallanzani were overlooked by physiologists, until W. F. Edwards (*Influence of Physical Agents on Life*, by Hodgkin, p. 226), showed in 1823 that frogs, fish, and infant mammalia, when placed in an atmosphere of hydrogen, exhaled a quantity of carbonic acid, far too great to be accounted for by the consumption of the small amount of oxygen still remaining in the lungs of the animals at the moment of their being removed from atmospheric air.

About this time, and for some years afterwards, there may be said to have been three main theories of respiration adopted or discussed by physiologists. There was the theory of Lavoisier, either in the actual form in which he enunciated it, or that modification of it which was more generally received in England—viz., that the hydrocarbonous material which suffered combustion in the lungs was not secreted as such into the air-vesicles, but was oxidised while still in the venous blood by means of the passage of air or oxygen through the coats of the bloodvessels. This, which might be called the "combustion" theory, obtained by far the greatest amount of support, and indeed may still be found in books of the present day. Another opinion was that either air as a whole, or the oxygen of it only, passed through the coats of the blood-vessels and combined with the blood, while at the same time the lungs, out of the hydrocarbonous material with which venous blood was supposed to be loaded, developed or secreted carbonic acid. This "secretion" theory, constructed chiefly to explain the results of Edwards, corroborated as they were by those of Collard de Martigny, Bergmann, Müller, &c., was embraced by a few only. It is somewhat strange that the tendencies of the present day seem nevertheless to be turning back to a modification of this view. Lastly, there was the old suggestion of Lagrange, that oxygen passing by solution into the blood was consumed in the capillaries, giving rise to carbonic acid, which escaped by the lungs. This "diffusion" theory was mostly rejected by reason of the difficulty that was met with in attempting to demonstrate the existence of free carbonic acid in venous or of free oxygen in arterial blood. Thus while H. Davy, Nasse, Vogel, Brande, Home, Scudamore, Collard de Martigny, Maitland, Vauquelin, Stevens, Hofman, Entschut, and Bischof obtained, either by heat or the vacuum, or by a current of some indifferent gas, evidence of the existence of free carbonic acid in venous blood, J. Davy, Strohmeyer, Bergmann, J. Müller, and Tiedemann with Gmelin and Mitscherlich, failed to do so; and while H. Davy obtained a small quantity of oxygen from arterial blood, subsequent observers were unsuccessful. The "combustion" theory therefore, in consequence of this discordance, retained its hold upon physiologists until the experiments of Magnus in 1837, who made an epoch in this subject by definitely determining the gases of blood.

In his first researches (Pogg. Ann. xl. p. 583) Magnus repeated the experiments of his predecessors, who attempted to drive off from blood its free carbonic acid by means of a stream of hydrogen. By continuing the current for 24 hours, he obtained as much as 34 cc. of carbonic acid from 62·9 cc. of blood. Subsequently, on observing that in using the air-pump blood could not be made to give up its gases until a very great exhaustion had been arrived at, he constructed a mercurial air-pump, and by this means was enabled to demonstrate the existence in both arterial and venous blood of very considerable quantities of oxygen, nitrogen, and carbonic acid:—

	Quantity of blood used.	Total quantity of gas.	CO^2.	O.	N.
Horse: artery . . .	125 cc.	9·8 cc.	5·4 cc.	1·0 cc.	2·5 cc.
" vein . . .	205	12·2	8·8	2·3	1·1
" " . . .	195	14·2	10·0	2·5	1·7
Very old Horse: artery .	130	16·3	10·7	4·1	1·5
" " " .	122	10·2	7·0	2·2	1·0
" " vein .	170	18·9	12·4	2·4	4·0
Calf: artery . . .	123	14·5	9·4	3·5	1·6

Hence, while both kinds of blood alike contain oxygen and carbonic acid, arterial blood contains more oxygen and less carbonic acid than does venous blood. Although the quantities of these gases thus obtained could not be supposed to represent all the gas really present in a free state in the blood, Magnus satisfied himself that the amount of carbonic acid determined by his experiments was sufficient to account for the whole quantity given off by the body in health. Further experiments (Poggend. Ann. lxvi. p. 177, 1845) taught him that blood shaken up in an atmosphere of oxygen will absorb from 10 to 12 per cent. (of volume) of that gas, a quantity sufficient to account for all the oxygen consumed by the economy. He was thus led to adopt in its entirety the "diffusion" theory; and the demonstration of the existence of free gases in the blood having been the one thing lacking to this theory, he was in this followed by nearly all physiologists. He regarded the gases as simply dissolved in the blood, and explained the entrance of oxygen and the exit of carbonic acid by a reference to the Henry-Dalton law of pressures (see GASES, ABSORPTION OF, BY LIQUIDS). According to this view, which was more fully elaborated by Vierordt (*Physiologie des Athmens*), the carbonic acid neither replaces nor is replaced by the oxygen, but both are taken up and given off independently of each other. (The idea of Valentin and Brunner, that the phenomena of respiration form an example of Graham's law of transpiration of gases, was shown by Regnault and Reiset to be erroneous; these observers having proved that in the animal economy the ratio between the amount of oxygen absorbed and that of the carbonic acid exhaled is not constant). The venous blood laden with carbonic acid, on being exposed, during the passage through the lungs, to an atmosphere containing but little of that gas, must, in obedience to the law of pressures, give off a portion of its carbonic acid, and will continue to do so until an equilibrium is established between the tension of the carbonic acid in the air of the lungs, and the tension of carbonic acid in the blood. Similarly venous blood, poor in oxygen, on being exposed to the air of the lungs, will absorb oxygen until an equilibrium is established between the tension of oxygen in the air of the lungs, and the tension of oxygen in the blood. And inverse processes will take place in the systemic capillaries between the arterial blood and the tissues. In each case the exact point at which equilibrium is established will depend on the so-called "absorption-coefficient" of blood for oxygen and carbonic acid respectively.

Before long, however, it began to be seen that this view was open to many objections. Liebig, in his *Chemical Letters* (by Gregory, 3rd ed. p. 332), strongly advocated the opinion that the condition of the greater part of the oxygen in the blood was one not of simple physical absorption, but of chemical combination—a combination, however, so loose that it was capable of being disturbed by the action of indifferent gases or of the vacuum. In support of his view, he drew attention to an analogous combination between carbonic acid and aqueous solutions of phosphate of sodium, cited the experiments of Regnault and Reiset, which showed that in an atmosphere of pure oxygen, animals consumed the same amount of that gas as when breathing ordinary air, and instanced the fact that in high regions, where the absolute quantity of oxygen taken into the chest at a breath is only about two-thirds of that taken in at the sea-level, the vital processes do not suffer any marked changes, such as would certainly follow variations in the quantity of oxygen absorbed. He, moreover, pointed out the necessity for accurately determining the absorption-coefficients of blood for its gases. This was afterwards attempted by Lothar Meyer, Fernet, and others, whose investigations, while they may be considered to have explained the entrance of oxygen into the blood, have left the question of the exit of carbonic acid still somewhat unsettled.

Absorption of Oxygen.

L. Meyer (for whose figures see vol. i. p. 606, vol. ii. p. 803) found that when blood was exposed to oxygen at various pressures, the quantity of that gas taken up might be regarded as consisting of two portions, one following the law of pressures, the other wholly independent of pressure. The former however, in respect to which blood differed very little from water, was found to be so small compared with the latter that the increments of absorption due to increments of pressure were almost covered by errors of observation. He accordingly drew the conclusion that oxygen was chemically combined with the blood during the passage through the lungs, though in *so loose* a fashion that it could be driven off again by the action of indifferent gases, or of the vacuum assisted by heat. Fernet (Ann. Sc. Nat. [iv.] viii. p. 125) arrived at the same conclusion, and moreover pointed out that this special affinity for oxygen was possessed not by the serum or plasma, but by the red corpuscles. Thus the proper absorption-coefficient of blood for oxygen was found to be ·0288 at 16°, of serum ·0288 at 16·8° (the absorption-coefficient of water at 16° for oxygen being ·02949); while 1 vol. blood chemically combined with ·0958 vol., and 1 vol. serum with ·00117 vol. oxygen at the same temperature. Neither Meyer nor Fernet, however, were able to obtain from arterial blood, by means of the vacuum, as much oxygen as was absorbed by venous blood when agitated in an atmosphere of that gas. But this difficulty was removed by Setschenow (Wien. Akad: Ber: xxxvi. p. 293), who, using a much larger vacuum, was enabled to drive off from blood much larger quantities of oxygen (see table below). The affinity for oxygen possessed by blood was also shown by the experiments of W. Müller (Ann. Ch. Pharm. cviii. p. 257), who found that animals (rabbits), made to breathe a limited amount of oxygen, consumed the whole of it, provided that the quantity placed at their disposal did not exceed 150—200 cc. The same observer ascertained that the residual air in lungs of asphyxiated animals contained a trace only of oxygen, a fact which was corroborated by Setschenow, and is directly opposed to the theory that the absorption of oxygen takes place according to pressure.

The behaviour of blood towards carbonic oxide has been found to illustrate the chemical nature of the process of absorption (Bernard, Leçons, Subst. Toxiq. 1857, p. 157; L. Meyer; Hoppe, Virch. Arch. xi. 288). Blood, when agitated with or treated with a stream of carbonic oxide, becomes of a peculiar bright red colour, and is found, not only to have given off its oxygen, but to have become incapable of absorbing that gas. It has lost the property of becoming arterialised. There is reason to believe that carbonic oxide has a stronger affinity than oxygen for the hæmoglobin or red colouring-matter of the blood, and forms with it a more stable compound (see below). Nawrocki (Henle u. Meissner, 1863, p. 298) finds that the amount of oxygen driven off by a stream of carbonic oxide tallies extremely well with that obtained by means of the mercurial vacuum, and it has been adopted by some subsequent observers (Bernard, Estor et Saintpierre) as a method of estimating the amount of oxygen in blood.

A still further advance has been made by the optical studies of Hoppe-Seyler (Virch. Arch. xxxiii. 446, xxix. 233 and 597; Med. Centralbl. 1864, p. 817; Handb. Chem. Anal. p. 201) and Stokes (Proc. Roy. Soc. xiii. 355). The red corpuscles of vertebrate animals consist for the most part of a substance which has been called *hæmatocrystallin* or *hæmatoglobulin*, or shorter *hæmoglobin* (Hoppe) or *cruorin* (Stokes), and which may often be obtained in a crystalline form. When tolerably concentrated solutions of this body, which are found to contain free oxygen and are of a blood-red colour, are examined with the spectroscope (or simply with a prism and slit in Stokes' way) there is found to be little absorption of light in that part of the spectrum which reaches from the extreme red to ¾ths of the distance between C and D, while in the remaining ¼th the absorption is much stronger. When the oxygen has been driven out of the solution by a current of hydrogen or carbonic acid, there is witnessed a very great increase of absorption of light at the red end, except in the space between *a* and B, and even in this part there is a slight increase of absorption. Upon these optical properties probably depends the difference in colour between arterial and venous blood. Venous blood viewed by the spectroscope without exposure to air, shows a very distinct absorption of light from B to beyond C, an effect which disappears when the blood is oxygenated by agitation with air. (Hoppe.)

Dilute solutions of blood-colouring-matter show two very dark and sharply-defined absorption-bands (visible in a 1 cc. thick layer of a solution of 1 grm. of colouring-matter in 10,000 cc. of water) between D and E, one being close to D, the other and thicker one being close to E; if D is at 80 of the scale and E at 106, the first band reaches from 81 to 87, the second from 95 to 106 (Hoppe, Stokes). When such a solution is treated with any reducing agent, such as a solution of ferrous sulphate or stannous chloride with tartaric acid and ammonia, it assumes a purplish colour, loses the two distinct bands, but gains a new one reaching from 82 to 97, with fainter bands extending on either side from 77 to 82 and from 97 to 99. If the solution be now agitated with air, it becomes blood-red again, and exchanges the new band for the two original ones (Stokes, Hoppe). The same effects may be produced by using sulphide of ammonium as a reducing agent, or by passing a stream of carbonic acid, hydrogen, nitrogen, &c. through the solution, or by keeping the solution for some little time at a blood-heat, or for a longer time at the ordinary temperature. In all these cases, the two original bands are found to be replaced by an intermediate band, and may be brought back again by agitating the solution with air or oxygen, the phenomena being accompanied by a change of colour from scarlet to purple and *vice versâ*. Hence the conclusion has been come to that there is a substance, holding oxygen in loose combination, giving two absorption-bands, and possessing a scarlet hue—the *scarlet cruorin* of Stokes, the *oxyhæmoglobin* of Hoppe; this body may give off its loose oxygen, either to some reducing agent or to some of its fellow blood-constituents (or to the tissues), and then has a purple hue and shows only one marked band—the *purple cruorin* of Stokes, the *hæmoglobin* of Hoppe; on exposure to air or oxygen, the purple cruorine or hæmoglobin absorbs oxygen, and becomes once more the scarlet cruorin or oxyhæmoglobin. And it is presumed that this is the way in which the red corpuscles of blood perform their share in the work of respiration. The hæmoglobin or purple cruorin of the blood of the pulmonary artery, absorbing oxygen, becomes oxyhæmoglobin or scarlet cruorin, and in the course of the circulation gives up its oxygen, becoming mere hæmoglobin or purple cruorin. Since venous blood always contains some oxygen, one must expect to find the spectrum of oxyhæmoglobin even in venous blood examined without any exposure to air, and such is the case (Stokes, Hoppe). The blood of an animal dying of asphyxia, however, contains no oxygen, and shows very distinctly the band of hæmoglobin or purple cruorin alone. (Hoppe.)

When a solution of oxyhæmoglobin is treated with carbonic oxide, oxygen is set free; the carbonic oxide, however, does not act as a reducing agent, the blood does not become purple from the formation of hæmoglobin, but of a peculiar bright red colour from the combination of carbonic oxide with hæmoglobin, to form carboxydhæmoglobin, whose spectrum is similar to that of oxyhæmoglobin, there being only a slight difference in the position of the bands—one reaching from 82 to 90, the other from 95 to 106 (Hoppe). The combination between carbonic oxide and hæmoglobin is not (or at least only slowly and partially) decomposed by exposure to air or oxygen. The carbonic oxide may, however, be replaced by nitric oxide, the blood being scarcely changed in colour, remaining still a bright red, and the spectrum resembling that of oxyhæmoglobin, but with bands less strongly marked. Nitric oxide may also be directly combined with hæmoglobin, and also with oxyhæmoglobin; in the latter case some nitric oxide is oxidised at the expense of the loose oxygen. A given quantity of hæmoglobin unites with equal *volumes* of oxygen, carbonic oxide, and nitric oxide (Hermann, L. Arch. Anat. Phys. 1865, p. 469). It is calculated that 1 grm. hæmoglobin unites with 1·3 cc. of gas.

The entrance of oxygen into the economy being therefore in the main not a physical process of absorption, but a chemical one of oxidation (and reduction) the amount of the oxygen in the inspired air, provided only there is enough for ordinary purposes, will have little or no effect on the amount of oxygen taken into the blood. We accordingly find that animals consume the same amount of oxygen and produce the same amount of carbonic acid when breathing pure oxygen as when breathing ordinary air (Regnault and Reiset). Nevertheless, many observers have from time to time described as effects of breathing pure oxygen, symptoms which have been interpreted as indicative of increased oxidation, which can hardly be considered as due to an augmentation of that fraction of oxygen which is really physically absorbed, and which have not been otherwise clearly explained.

Exhalation of Carbonic Acid.

L. Meyer (*op. cit.*), by exposing blood to carbonic acid at various pressures, found that the quantity of that gas absorbed might be divided into two portions, one obedient to and the other independent of the law of pressures. The absorption of carbonic acid differed notably from that of oxygen, inasmuch as the portion following the law of pressures was much larger than that which was independent. Thus at 11°—12° the former per vol. blood was, measured at 0° and ·76 met., 1·151, the latter ·630. Since blood contains carbonate and phosphate of sodium, and since aqueous solutions of these salts possess the power of holding, in loose combination, a quantity of carbonic acid over and above that due to simple physical absorption, it had been suggested that the absorption of carbonic acid by blood might bear some relation to these saline constituents. Fernet accordingly (*op. cit.*) studied the behaviour towards carbonic acid of aqueous solutions of these salts, taking the average composition of blood as a standard. He found that on the one hand they absorbed a quantity of carbonic acid according to the law of pressures (and in this respect possessed absorption-coefficients differing very slightly from that of water); while on the other hand the solution of carbonate of sodium absorbed, independently of pressure, a quantity of carbonic acid sufficient to convert the simple carbonate into bicarbonate, and the solution of phosphate of sodium similarly absorbed a quantity at the rate of two equivalents of carbonic acid to each equivalent of the salt. (According to recent researches of Heidenhain and Meyer, Stud. Bresl. ii. 103, Fernet's results require some corrections). He moreover found that blood behaved in respect to the absorption of carbonic acid almost exactly as if it were a mere aqueous solution of the saline constituents in their proper proportions; neither the corpuscles nor the organic substances of the serum had any marked share in the matter.

By submitting blood to the action of a vacuum and moderate heat, Meyer obtained only small quantities of carbonic acid; by far the greater part of the total amount contained in the blood could not be driven off unless acids were employed. Setschenow, however (*op. cit.*), by the help of his larger vacuum, gained much larger quantities without using any acids. His results, together with those of some subsequent observers, are given in the following table, where "loose" carbonic acid means that which is given off to a vacuum, and comprises both that which is physically absorbed, and that which is retained by the carbonate and phosphate of sodium, while "fixed" means that which is driven off by the use of acids:—

Gases (measured at 0° 1ʹ) in 100 vols. Blood.

The recent observations of Plüger (*Ueb. d. Kohlensäure d. Blutes*) seem to invalidate these results. This observer, by using a vacuum free from aqueous vapour, was enabled to drive off the whole of the carbonic acid, so that no more could be obtained by the addition of acids; even neutral carbonate of sodium previously added to the blood was decomposed. It is probable that this result was brought about, in part at least, by acids arising from the decomposition of the hæmoglobin; and, though a portion of the carbonic acid was obtained much more readily than the rest, the experiments suggest the question whether generation of acids does not take place in all cases where the vacuum is used—whether, in fact, the above distinction between loose and fixed carbonic acid is not in great measure a factitious one.

That the escape of carbonic acid is, taken as a whole, a matter of pressures is shown by the results of all observers; but there are considerable difficulties connected with the subject, which have not as yet been thoroughly cleared up. Were the venous blood, during its passage through the lungs, exposed to air containing little or no carbonic acid, the law of pressures would readily suggest a cause for the immediate escape of the due amount of that gas. Such, however, is not the case. We are led to believe (Becher) that the air in the pulmonary air-cells contains habitually about 8 per cent. of carbonic acid. Hence, any just explanation of the process of exhalation must take into account the existence to that extent of a tension of carbonic acid in the lung-air, which has to be overcome before any escape can take place from the blood. Thus the hypothesis that in the lungs the acid carbonate of sodium is reduced, by mere exposure to lung-air, to the neutral carbonate, with escape of carbonic acid, is untenable, because the acid carbonate refuses to give up its extra atom of carbonic acid to air containing above 1 per cent. of that gas (Meyer). Similarly the carbonic acid retained by a solution of phosphate of sodium is not given off to an atmosphere of like carbonic acid tension (Schöffer, Wien. Akad. Ber. xli. p. 589). Holmgren (*loc. cit.*, xlviii.) has attempted to determine the actual degree of tension of carbonic acid which a vacuum (containing aqueous vapour) must acquire before blood ceases to give off to it its carbonic acid. This he found to be, at 40° C., 22·3 mm. of mercury for arterial blood, 30·6 mm. for venous blood, and 38·1 mm. for the blood of asphyxia. In two cases, where the normal expired air contained respectively 2·94 per cent. and 4·31 per cent. of carbonic acid, and therefore gave tensions of 22·18 mm. and 31·98 mm., the blood ceased to give off carbonic acid at the tensions of 22·13 and 28·20 mm. Since the carbonic acid tension of the interior lung-air is much higher than that of the expired air, it is obvious that in these cases the blood could not have got rid of its carbonic acid while passing through the lungs, through the simple working of the law of pressures, unless there were something at hand in the lungs temporarily augmenting the carbonic acid tension of the blood, or otherwise assisting the escape of that gas. This is still more strikingly shown in two cases of asphyxia, where the tension of the blood was 34·76 and 41·41, of the lung-air 98 and 91·6 mm. respectively. Holmgren further observed that blood gave up its carbonic acid more readily to a rarefied atmosphere of oxygen than to a vacuum containing nothing but aqueous vapour. Thus 153 cc. of blood gave up to a vacuum of 150 cc. at 22°, 0·418 cc. and 0·583 cc. of carbonic acid (measured at 0° 1′), while to the same space containing 8·99 cc. and 20·16 cc. oxygen, there were given up 1·375 cc. and 1·997 cc. of carbonic acid by the same quantities of the same blood. These results suggest the idea that the act of the absorption of oxygen in some way or other momentarily augments the tension of carbonic acid in the blood. But in what way is it able to produce such an effect? It has been shown that a certain portion of the carbonic acid of the blood is given off more readily than the rest, and it has been also shown that this fixed or stable remainder is greater in venous than in arterial blood (vide table, *ante*). In other words, during the passage through the lungs, a certain portion of the fixed or stable carbonic acid becomes unstable or loose, and it has been maintained by Schöffer (*op. cit.*) that the amount thus converted is sufficient to account for the quantity escaping into the air. Now Preyer (Wien. Akad. Ber. xlix.) has shown that the same conversion of stable into unstable carbonic acid takes place when venous blood is artificially arterialised by agitation with air or oxygen, whereas the amount of stable carbonic acid existing in serum is wholly unaffected by any such treatment. Hence it has been supposed that oxygen in the act of combining with hæmoglobin effects in some way or other (by the development of an acid?) some kind of decomposition, whereby a certain amount of fixed or stable carbonic acid is converted into loose carbonic acid, the tension of carbonic acid in the blood proportionately augmented, and the escape of that gas into the air thus brought about: or, disregarding the distinction between loose and fixed, we may say that the absorption of oxygen is attended with a liberation of carbonic acid within the blood, leading to an increase in the tension of the gas, and its consequent escape.

Absorption and Exhalation of Nitrogen.

The quantity of nitrogen in blood is very small, and the observations with regard to its being absorbed or exhaled by the lungs have been remarkably discordant. Fernet (*op. cit.*) found the absorption-coefficient of serum for nitrogen to be nearly exactly that of an aqueous solution of its saline constituents in their proper proportions, that is to say, a little less than that of water (at 15° 3′ serum, ·0141, at 15° water ·01478). Setschenow (*op. cit.*), on the other hand, obtained for blood as a whole a higher absorption-coefficient than that of water, and therefore concluded that the blood-corpuscles are able chemically to combine with a small quantity of nitrogen.

Qualities of Respiratory Oxygen.

Schönbein and His remarked that the red corpuscles of the blood acted like finely-divided platinum, &c., upon a mixture of tincture of guaiacum with peroxide of hydrogen, ozonised turpentine, ether, &c., in producing a deep blue colour. Various animal substances possess this property in a greater or less degree, but none approach the red corpuscles, or rather the colouring-matter of the red corpuscles, in intensity of effect. The presence of red corpuscles also vastly augments the rapidity with which a solution of indigo is decolorised and hydriodic acid decomposed by peroxide of hydrogen, ozonised turpentine, &c. These observers were unable to produce any oxidative action on guaiacum with blood, unless one of the so-called ozone-bearers were present. A. Schmidt (*Ueber Ozon im Blute*, 1862), however, has shown that, under certain precautions, blood by itself will turn guaiacum blue. If a strip of paper be dipped in tincture of guaiacum (1 pt. gum to 6 of 80 per cent. alcohol) and dried, a drop of dilute blood or of dilute solution of hæmoglobin placed on it will give an intense blue ring. No other substance in the animal body is able to produce this effect. A similar process of oxidation may with care be witnessed when hydriodic acid or an indigo solution is treated with blood. Blood, or a solution of hæmoglobin, will also decompose peroxide of hydrogen with an energetic evolution of oxygen; and will decompose sulphydric acid with precipitation of sulphur. According to the ozone theory, therefore, oxygen in combination with hæmoglobin is that form or kind which is called ozone. The oxygen, however, which is driven off from blood by the passage of a stream of other gases, gives none of the reactions of ozone, and blood entirely deprived of its oxygen by carbonic oxide still gives the reaction with guaiacum; this reaction, however, ceases to be manifested when the experiment is conducted with total exclusion of atmospheric air. Hæmoglobin therefore, in addition to its power of absorbing oxygen and of transferring it in an active state to other bodies, is able, like finely-divided platinum, to intensify the action of oxygen, or, according to the ozone theory, to ozonise oxygen, without attaching the oxygen to itself. (Kühne and Scholz, Virch. Arch. xxxiii. p. 96.)

Place of Oxidation.

It has not as yet been decided whether the oxidations for which the oxygen of the blood is destined, take place in the blood only, or in the tissues only, or in both. On the one hand, we know that muscular and, probably, all other tissues continue to respire, as it is said (that is, to absorb oxygen and produce carbonic acid), even when totally deprived of blood; and actions probably requiring oxygen, muscular contractions, for example, take place when the blood contains no oxygen at all, as in asphyxia (Setschenow). On the other hand, the experiments of Harley (Proc. Roy. Soc. viii. p. 78; xiii. p. 157) show that blood itself removed from the body will continue to absorb oxygen and exhale carbonic acid, and that this "respiration" is affected by various physical and chemical agents. Sachs, too (Arch. Anat. Phys. 1868 p. 345), finds that, after removal from the body, blood secluded from air gains in carbonic acid (both loose and fixed) and loses oxygen, but his experiments are open to objections. Nawrocki also arrives at the same result (*op. cit.*). Estor and Saintpierre (Robin's Jour. ii. 302) find that the oxygen of arterial blood (determined by the carbonic oxide method) diminishes the farther the artery is situate from the lungs. Thus for 100 vols. they found in the carotid artery 21·06, in the renal 18·22, in the splenic 14·38, in the crural 7·62 vols. of oxygen. They argue that oxidations of respiration take place exclusively in the blood and are most active in the arterial system. Yet the capability of the blood for oxidising oxidisable substances directly injected into it seems very limited.

Qualities of Expired Air.

1. Volume.—The volume of air given out by an expiration is found to be less than that taken in by a corresponding inspiration, when both are dried and measured at the same temperature. This difference, due to the fact that the whole of the oxygen absorbed does not reappear in the carbonic acid exhaled, is variable, but may be said to amount on the average to $\frac{1}{40}$ or $\frac{1}{50}$ of the total volume.

2. Temperature.—The temperature of expired air naturally approaches that of the lungs, the exact degree depending on the relation of the temperature of the atmosphere to that of the blood, on the mode and rate of breathing, the extent and duration of the breath, &c. According to Valentin and Brunner, it is 29·8° for a surrounding temperature of 6·3°, 37·25° for 19·5°, 38·1° for 41·9°. For 22°, Gréhant (Robin's Journal, i. p. 523) puts it at 35·3° when inspiration is made through the nose, 33·9° when through the mouth.

3. Moisture.—The air as it returns from the lungs is laden with watery vapour; saturated, for its own temperature, according to Valentin, not much more than half saturated according to others (Moleschott). Gréhant states that it is saturated for 35°. E. Smith (Phil. Trans. 1852) found it during fasting to be little more than half saturated. The total quantity of water contained in the air expired by the human body during 24 hours has been estimated at 385—773 grms. (Valentin), 557 grms. Gréhant. The total quantity of water passing away within the 24 hours from the human body, as aqueous vapour of expired air, varies greatly, being affected by the temperature of the atmosphere and of the body, by atmospheric humidity and pressure, condition of the organism, &c.

4. Oxygen and carbonic acid.—The decrease of the oxygen and the increase of the carbonic acid is shown by the following average composition of 100 volumes of—

	Oxygen.	Nitrogen.	Carbonic acid.
Atmospheric air	20·81	79·15	·04
Expired air	16·033	79·557	4·380.

In rough numbers, air may be said to lose from 4 to 5 per cent. of its oxygen and to gain from 3 to 4 per cent. of carbonic acid by being breathed. For further details see below.

5. Nitrogen.—W. Edwards found an exhalation of nitrogen in warm weather, an absorption in cold. Regnault and Reiset (Ann. Ch. Phys. 1849, [3], xxvi. 32) concluded from their experiments that warm-blooded animals, living on an ordinary diet, constantly exhaled a small quantity of nitrogen, which was never greater and often much less than $\frac{1}{50}$ of the total weight of oxygen consumed. In frogs, the amount either exhaled or absorbed was too small to be appreciated. In fishes Humboldt and Provencal remarked a constant absorption of nitrogen. An exhalation of nitrogen is constantly observed in animals breathing an atmosphere free from that gas, and W. Müller (*op. cit.*) observed an exhalation of nitrogen when rabbits were made to breathe a limited amount of air. More recently Reiset (Ann. Ch. Phys. [3] lxix. p. 129) found that sheep exhaled from 5—8 grms., calves from 6 – 7 grms., pigs about 1 grm., and turkeys 2 grms. in the 24 hours. In these experiments, as in the earlier ones of Regnault and Reiset, the respiration of the whole animal and not of the lungs only was studied, and it is possible that some of the animals parted, during their stay in the respiratory chamber, with some of the nitrogen contained in their intestines before the beginning of the experiment. The calculations of Boussingault and Barral led them to think that a very large amount of nitrogen passed from the body through the skins and lungs, but such a conclusion is most probably erroneous (see NUTRITION). Pettenkofer indeed argues that Reiset's results are wholly mistakes, and that the amount of nitrogen exhaled or absorbed by the lungs is too small to be appreciated.

6. Ammonia.—The presence of ammonia in the breath has been affirmed by many observers. Thiry (Zeitschr. Rat. Med. xvii. p. 166) has shown that it can be detected in expired air taken directly from the trachea (so as to exclude the fluids of the mouth as a possible source) when the inspired air had been carefully freed from it. Regnault and Reiset failed to assure themselves of its presence in expired air. Grouven (Fütterungs-Versüche, p. 232) has obtained the following quantities (in grms.), the mean being about ·1 grm. in the 24 hours for 100 kilos. of body-weight, when animals were placed in a "respiration chamber:"

	Man.	Boy.	Fat Ox.	Starved Ox.	Ass.	Dog.	Pig.
Per diem	·0488	·0343	·7218	·0958	·2514	·0398	·2026
Per 100 kilos. per diem	·057	·0910	·1146	·0198	·1344	·1326	·1842

Young animals give out proportionally more ammonia than old, small more than large, fat more than lean.

Lossen (Zeitschrf. Biol. i. 207) places the quantity for man in 24 hours at ·0140 grm.

7. Hydrogen and Marsh-gas.—These gases were observed by Regnault and Reiset, by Reiset, and by Pettenkofer, in the air of the respiration chamber. They probably came from the intestines. (See p. 92.)

8. **Other substances.**—Besides the above-described chief ingredients of expired air, it is probable that there are also minute quantities of perhaps many other bodies, and there are many reasons for thinking that these minute quantities are not without importance. (See p. 96, on the effects of impure air). Their exact nature is at present unknown. **Wiederhold** (Henle u. Meissner Bericht. 1858, p. 316) states that he had detected in the condensed vapour of expired air, chloride of sodium, uric acid, and urates of soda and ammonia! The fluid obtained by condensing the vapours of expiration rapidly putrefies.

Cutaneous Respiration.—In man and the higher animals a slight interchange between the gases of the blood and the atmosphere takes place through the skin. There is an exhalation of carbonic acid, and probably an absorption of oxygen. The following table is by **Scharling** (from Gorup-Besanez):—

		Body-weight in kilos.	Carbonic acid in grammes. By lung and skin in 1 hour.	Carbonic acid in grammes. By skin in 1 hour.
Boy	9¾ years	22·0	20·338	0·181
Youth	16 „	57·75	34·280	0·181
Man	28 „	82·	36·623	0·373
Girl	10 „	23	19·162	0·124
Woman	19 „	. . .	. .	0·272

When **Regnault** and **Reiset** examined the products of cutaneous respiration by placing an animal in a bag with the head free, and passing a current of air through the bag, they obtained the following results:—

	Weight.	Duration of exp.	Total quantity of carbonic acid in grms. during time of exp. By skin only.	Total quantity of carbonic acid in grms. during time of exp. By skin and lungs.
Fowl	1940 grms.	8h. 40m.	·336	18·62
„	„	7h. 30m.	·076	16·13
„	„	8h. 45m.	·164	18·70
Rabbit	2425 „	8h. 15m.	·358	20·63
„	„	7h. 45m.	·197	19·38
Dog	4159 „	7h. 50m.	·136	39·15
„	„	8h. 30m.	·176	42·50

When the animal (with head free) was placed in a closed bag for some hours, an examination of the air of the bag at the end of the experiment gave the following results:—

	Length of time.	In 100 vols. of air of bag. CO_2.	In 100 vols. of air of bag. O.	In 100 vols. of air of bag. N.
Fowl as above	8h.	·27	20·76	78·97
Rabbit „	8h.	·36	20·55	79·09
Dog „	8h. 10m.	·29	20·67	79·04

Among the lower animals the skin takes a much larger share in the general respiration. Thus frogs, which uninjured were consuming oxygen at the rate of ·063 (*bis*) ·089, ·103, ·05 grms. per kilo. per hour, continued to consume at the rate ·047, ·063, after their lungs had been cut away; that is to say, they respired nearly as well without their lungs as with them.

Intestinal Respiration.—**Planer** (Wien. Akad. Ber. xlii. p. 307) found the intestinal gases of a dog (killed a few hours after food) to have the following percentage composition:—

		C.	N.	O.	H.	SH^2.
Fed on Meat.	Gas of Stomach	25·20	68·68	6·12		
„	„ Small Intestine	40·1	45·52	trace ?	13·86	
„	„ Large Intestine	74·19	23·0	0·63	1·41	·77
Fed on Pulse	„ Stomach	32·91	66·30	·79		
„	„ Small Intestine	47·34	3·97	. .	48·69	
„	„ Large Intestine	65·13	5·9	. .	28·97	

Ruge (Wien. Akad. Ber. xliv. p. 739) found *flatus* of man, obtained per rectum, to be as follows, in 7 experiments on 3 persons:—

	A.				B.		C.
Carbonic acid	14·94	40·51	21·86	12·77	21·59	54·12	11·87
Nitrogen	45·31	17·50	44·42	43·10	41·82	22·45	40·69
Marsh-gas	39·75	19·77	32·93	44·13	17·52	8·67	47·44
Hydrogen	. .	22·22	0·79	. .	19·07	14·76	

with traces only, and that not always, of sulphuretted hydrogen.

The nitrogen in these cases was probably due to air which had been swallowed, and which had lost its oxygen chiefly within the stomach. The intestines are probably the source of the marsh-gas and hydrogen met with when the respiration of the whole body has been examined. Reiset (*op. cit.*) found in sheep and calves as much as 1 to 2 litres of marsh-gas exhaled per hour, while pigs gave only ·134, ·097 litres of marsh-gas, and ·628 litres hydrogen per hour.

It may seem extravagant to speak thus of an intestinal respiration, yet in some animals this is really an important function. Thus the loach (*Cobitis fossilis*) is in the habit of rising to the surface of water, where it swallows air. In descending it emits from the vent bubbles of gas, which when examined are found to contain only from 12 to 7 per cent. of oxygen, and from 1 to 2 per cent. of carbonic acid. During this process of atmospheric deglutition, the gills are temporarily inactive. It appears that this creature thus obtains a supply of oxygen, which being absorbed from the intestine is consumed by the tissues, the carbonic acid resulting being exhaled chiefly by the gills or skin, and only to a small extent by the vent. (Baumert, An. Ch. Pharm. lxxxiii. p. 1.)

Air-bladder of Fishes.—Many fishes possess an air-bladder (either with or without a pneumatic duct), the contents of which consist of nitrogen, a very small quantity of oxygen in the case of freshwater fishes, a larger quantity in sea-fishes, especially in those dwelling at great depths, and a trace of carbonic acid (Owen). Moreau (Compt. rend. 1863, pp. 37, 816) finds in the air-bladder of the perch 19—25 per cent. of oxygen, of the tench 8 per cent., wholly disappearing when the fish is asphyxiated. The amount of carbonic acid never exceeds 3 per cent. When the air-bladder of a fish possessing a pneumatic duct is exhausted by means of the air-pump, and the animal is replaced in water, the quantity of oxygen in the air-bladder is found in a short time to be very much increased, probably by diffusion from the blood. The percentage may temporarily reach 60 or even 87.

Eggs.—The respiration of hens' eggs has been studied by Baumgärtner (Henle u. Meissner, 1861, p. 304). The following table gives in grms. the changes of 24 hours on several days of incubation of a single egg (initial weight about 55 grms.):—

Day.	Loss of weight.	CO^2 exhaled.	O absorbed.	Water exhaled.
1st	·125	·009	·0074	·123
5th	·232	·016	·0149	·230
10th	·100	·050	·0325	·082
15th	.134	·290	·2355	·079
20th	·212	·56	·4435	·095
21st (hatched)		1·008	·7317	

Variations in the Quantity of Carbonic Acid exhaled.

1. Dependent on the mode of breathing.

In a single breath the air at the beginning of an expiration is poorer in carbonic acid than towards the close; this difference disappears when, after completion of an inspiration, the breath is held for 40 seconds before commencing the expiration.

Inspiration having been made, the longer the breath is held before beginning the expiration, the greater is the percentage of carbonic acid in the expired air. Thus, with an inspiration of 4560 cc. and with pauses between inspiration and expiration of 0, 20, 40, 60, 80, 100 seconds respectively, the percentage of carbonic acid was found by Becher to be 3·6, 5·6, 6·3, 7·2, 7·3, 7·5. The increase of carbonic acid diminishes rapidly with the duration of the pause; and 7·5 or 8 per cent. may be taken as the limit of the amount of carbonic acid present in the deeper layers of the air in the lungs.

During a given time, and for the same rate of breathing, the deeper the breath, the less is the percentage of carbonic acid in the expired air, but the greater the total quantity exhaled.

For a constant depth of breath, the quicker the rate of breathing, the less is the percentage, but the greater the total quantity of carbonic acid exhaled.

2. Dependent on extrinsic conditions.

Temperature.—With cold-blooded animals (frogs), the quantity of carbonic acid exhaled varies directly as the temperature (Moleschott, Untersuch. ii. 315). The same law holds good with mammalia passing in or out of the state of hybernation. With warm-blooded creatures in general, the amount of carbonic acid varies inversely as the temperature, when the latter is neither too low nor too high to injure the economy (Letellier Vierordt). The observations of E. Smith (Phil. Trans. 1859), on the influence of temperature as manifested in the effects of seasons, while leading to the same conclusion, show "that there is no absolute relation between a given temperature and the quantity of carbonic acid exhaled."

Pressure.—The influence of pressure has not been exactly determined. According to **Hervier** and **St. Lager**, the quantity of carbonic acid increases with the atmospheric pressure up to 773 mm., beyond which it decreases. **E. Smith** observed an inverse relation between pressure and carbonic acid, which however was very general only, and subject to marked exceptions.

Light.—Frogs exhale more carbonic acid in a strong than in a weak light. (**Moleschott.**)

Humidity of the atmosphere increases the quantity of carbonic acid. (**Lehmann.**)

Seasons.—**E. Smith** observed that the amount of carbonic acid expired began to decline in early June and continued to do so till September. In October the amount began to rise, and continued to do so with more or less uniformity during the winter months. Spring is the season of the greatest and autumn that of the least activity of the respiratory functions. The influence of seasonal changes is one that cannot be explained solely by reference to changes in temperature and barometric pressure.

Changes in the nature of inspired air.—When the amount of **carbonic acid** in the inspired air is increased beyond that proper to the atmosphere, the quantity of carbonic acid exhaled is proportionately decreased. **W. Müller** found that when rabbits were made to breathe a limited amount (150—250 cc.) of oxygen they consumed the whole of the gas. At first they took in the oxygen and gave out carbonic acid; but through the diminution of the volume of the gas at their disposal, caused by the consumption of oxygen, the tension of the carbonic acid that had been expired became so much increased as after a while to exceed the tension of the carbonic acid in the blood. Hence not only the exhalation of carbonic acid ceased, but that which had been expired was reabsorbed. When the amount of **oxygen** in the inspired air is increased beyond that proper to the atmosphere, no appreciable increase can be observed in the amount of carbonic acid exhaled (**Regnault** and **Reiset**). When **hydrogen** is substituted for **nitrogen** in the inspired air no essential change in respiration takes place.

3. Dependent on **intrinsic conditions.**

Food: **Abstinence, Hunger.**—All observers agree in stating that during starvation the amount of carbonic acid falls. In **Bidder** and **Schmidt's** experiments on a cat, which endured 18 days' deprivation of food, the amount per diem, except during the first and last days, was remarkably constant for each kilo. of body-weight (though for the whole body it gradually lessened from day to day). (See NUTRITION.) **E. Smith** found, during a 24 hours' fast, the carbonic acid diminished about 25 per cent (7 grains per minute instead of 9·77 grains). The minimum was arrived at within 4½ hours after the last meal, and from that point onward there was no marked decrease; thus indicating the existence of a tolerably uniform "normal" or "basal" line, below which the system does not pass in health. **Pettenkofer** and **Voit** found that their dog passed (30 kilos. *circa*), with 1800 grms. meat and 350 grms. fat, 840·4 grms. of carbonic acid, but after 10 days' fasting only 289·4 grms. **Ranke, J.** (*Tetanus*, p. 234), weight 70 kilos. *circa*, determined, by means of Pettenkofer's apparatus, the total quantity of carbonic acid exhaled by himself during 24 hours under the following circumstances, to be:

	grms. carbonic acid.	grms. carbon.
Starving	662·9	180·8
do.	663·5	180·9
Pure meat diet (1832 grms.)	847·5	231·2
A diet of 150 grms. fat 300 „ starch 100 „ sugar	735·2	200·5
Ordinary mixed diet	791·1	215·7
Mixed diet, as much as possible eaten . .	925·6	252·4
A diet in which the nitrogen of ingesta and egesta were in equilibrium	759·5	207

Meals.—An increase in the production of carbonic acid begins directly after a meal and progresses to a maximum, after which the amount gradually declines to the basal minimum. The maximum was observed in from one to two hours after a meal, and was greatest after breakfast and tea (with a midday dinner). On a day of fasting a slight rise was observed about the times when the influence of meals, if taken, would have been felt. (**E. Smith.**)

Kinds of food.—**E. Smith**, taking the minimum quantity exhaled when fasting in the early morning, has investigated the effects of various articles of food. He finds that the exhalation of carbonic acid is increased by the following "excito-respiratory" articles, which are here placed in a series of decreasing intensity of effect:—Tea, sugars (cane-sugar, milk-sugar, grape-sugar), coffee, rum, milk, cocoa, stout, ale, chicory, casein, gluten, gelatin, albumin. Compound aliments containing several of these substances have an action greater than that of any of their constituents. In most of these instances, the increase in the evolution of carbon was greater than could be accounted for by the amount of carbon contained in the article, ex. tea; in others less, ex. sugar. The effect was evident within a few minutes of partaking of the food, and was not investigated for periods of longer than two hours. Other substances do not increase the carbonic acid, are non-excito-respiratory, ex. starch, fat, brandy, whisky, gin, and the volatile elements of wine, spirits, &c. The influence of water does not seem to have been studied. These observations apply to the, so to speak, superficial effects of the various kinds of food; the ulterior effects of diet will be discussed below.

Sleep.—During sleep the amount of carbonic acid is lessened. In man, the quantity expired per minute when asleep is to the quantity when awake as 1 : 1·84 (E. Smith). During the condition known as hybernation, the diminution in the quantity of carbonic acid exhaled is exceedingly marked. Thus a hedgehog, which when awake gave 1·352 grms. of carbonic acid per hour, produced when in complete torpor no more than ·066 per hour, and a marmot 1·076 and ·0144 respectively. (Valentin.)

Exercise.—The quantity is very largely increased, according to all observers. E. Smith, whose average during the day was 9·77 grains per minute, exhaled 5·94 grains per minute, when lying down but not asleep; 18·1 when walking at the rate of 2 miles an hour; 25·83 at 3 miles an hour; and 43·36 and 42·9 on two occasions when working the treadwheel.

Sex.—Men produce a larger quantity of carbonic acid than women.

Age.—The quantity of carbonic acid exhaled by children is absolutely less than that given out by adults, but compared with the body-weight is greater, as is shown in the following table from Lehmann (Lehrb. iii. 320):—

Subject.	Age.	Body-weight.	Carbonic acid per hour.	Carbonic acid per hour per kilo. of body-weight.
Boy . . .	9¾ yrs.	22·00 kil.	20·338 grm.	·9245 grm.
Girl . . .	10 „	23·00 „	19·162 „	·8831 „
Youth . .	16 „	57·75 „	34·280 „	·5887 „
Young woman .	17 „	55·75 „	25·342 „	·4546 „
Soldier . .	28 „	82·00 „	86·632 „	·4466 „
Man . .	35 „	65·5 „	33·530 „	·5119 „

The same applies to animals.

According to Andral and Gavarret, the quantity produced daily by the male sex goes on increasing, with a sudden rise at puberty, up to about 30 years, remains tolerably stationary until between 40 and 50 years, after which it diminishes, especially beyond 60. In the female sex the amount increases up to puberty, then remains stationary, with temporary increase during pregnancy, until the climacteric, after which it rises up to 60 years and then finally falls.

Consumption of Oxygen.

The whole of the oxygen absorbed by the blood from the inspired air does not always reappear in the carbonic acid of the expiration; in general the amount of oxygen consumed during a given interval is greater than the amount of oxygen contained in the carbonic acid expired during the same time. The difference is not a constant one, but varies according to the nature of the food taken, &c.; it is least marked in herbivora living on their ordinary diet, or in animals fed largely on carbohydrates, and most marked in carnivora or in animals fed largely on a meat diet. Regnault and Reiset found in the carbonic acid exhaled by rabbits fed on carrots, &c., 91·7 per cent. of the oxygen consumed; in dogs fed on meat, 74·5 per cent.; in fowls fed on grain, 92·7 per cent.; in dogs fed on bread, 91·3 and 94·3 per cent.; in fowls fed on meat, 76·7 and 63·6 per cent.; in ducks fed on bread and grain 89·2 per cent., on meat 73·8, on fat 62·3. They also found that herbivora when starving gave the proportion of carnivora, that is, they fed on their own flesh. Thus, rabbits starving afforded 69 per cent., ducks starving 69·3 per cent., and fowls 70·7 and 63·9 per cent. The observations of Pettenkofer (Ann. Ch. Pharm. 1863, Suppl. ii.) on the respiration of the dog led to some very remarkable results. After 16 days' meat diet, 63·7 per cent. of the oxygen consumed reappeared in the carbonic acid expired. During a hunger period of 10 days immediately following, the percentage was on an average 63·5. The dog was then fed for 7 days on meat, at the end of which the oxygen in the carbonic acid expired almost exactly equalled the total quantity consumed. After 8 days' rations of 100 grms. fat only, the result was still the same. The animal being then put on a rich meat diet, on the 4th day, the oxygen in the carbonic acid exceeded that consumed by 17 grms.; on the following days, however, the diet and excretion of urea remaining the same, the consumption of oxygen had increased so much, that on the 13th day the oxygen in the carbonic acid had assumed the standard percentage of 65·1. The animal then being fed on 500 grms. of meat and 200 grms., first of starch and then of sugar, the relations of carbonic acid expired and oxygen consumed became so changed that at last the carbonic acid contained 150 (in a second trial 125) parts of oxygen for every 100 parts of oxygen consumed. These remarkable variations serve, on the one hand, to illustrate the character of the changes going on in the body under the influence of different kinds of food; on the other hand, the great excess of carbonic acid, coinciding with the appearance of 7·2 grms. of hydrogen and 6·3 grms. of marsh-gas, indicates that the carbonic acid was not wholly due to combustion of the tissues or plasma, but perhaps arose in part from fermentation of the food within the alimentary canal (see NUTRITION). Hence the consumption of oxygen and not the production of carbonic acid must be taken as a measure of the activity of the vital processes. The following table shows in grammes the amount of oxygen consumed per hour per kilo. of body-weight by members of the various kinds of animals. It will be seen that small creatures consume more than larger ones for the same amount of body-weight:—

The amount in grammes of oxygen consumed per hour per kilo. of body-weight.

Sheep	(Reiset)	·497	Fowls	(Regnault and Reiset)	1·147
Calves	„	·480	Ducks	„	1·850
Pigs	„	·466	Small Birds	„	11·473
Dogs	(Regnault and Reiset)	1·183	Geese	(Reiset)	·677
Rabbits	„	·918	Turkeys	„	·702
„	(Valentin)	1·714			
Marmots: awake	(Regnault and Reiset)	1·198			
„ torpid	„	·040	Frogs	(Regnault and Reiset)	·034
„ awake	(Valentin)	·973	Lizards	„	·1916
„ light sleep	„	·144	Silkworm	„	1·170
„ quite torpid	„	·0238	Earthworm	„	·1613
Hedgehog: awake	„	1·376			
„ torpid	„	·075			

A curious observation was made by **Regnault** and **Reiset** on the consumption o oxygen by the marmot. These animals when wide awake give in their carbonic acid a percentage of oxygen consumed 76·9, when half asleep 54·7, when completely dormant 39·9. This remarkable deficiency explains how it is that these animals may, while in a dormant state, provided that they do not pass urine, actually increase in weight from formation and retention of water.

Breathing Impure Air.—When an animal is suddenly cut off from its usual supply of air, as by closure of the windpipe, by immersion in water, or by being plunged into some irrespirable (but otherwise innocuous) gas, such as nitrogen or hydrogen, the breathing is at first hurried and laboured, but after a while becomes slow and weak; conciousness is lost, convulsions take place, and death by suffocation or asphyxia is the result. In such cases, the air remaining in the lungs contains a trace only of oxygen with a great excess of carbonic acid, the blood both in the arteries and veins is of a dark colour, holding scarcely any oxygen but a very large quantity of carbonic acid. It is not yet clear how far the phenomena belonging to this particular mode of death are due to the absence of oxygen, or to the increase in carbonic acid, or to both of these causes combined. Some observers witnessed no convulsions or dyspnœa, but only a kind of narcotic poisoning, when animals were made to breathe oxygen containing a great excess of carbonic acid; whereas when they were made to breathe air diluted with nitrogen, dyspnœa came on as soon as the proportion of oxygen fell below 5 per cent. These experiments seem to show that the dyspnœa of asphyxia arises from the lack of oxygen. But other observers have found dyspnœa and convulsions to follow the inhalation of oxygen containing 10 per cent. of carbonic acid, and the opinion that carbonic acid is an excitant of muscular and other actions has many supporters.

Similar results are produced more gradually when an animal is confined in a limited space without renewal of air, and has therefore to breathe the same air over and over again. In such cases life is prolonged if the carbonic acid be absorbed by potash as soon as it is formed. If at the death of the animal the air is examined, it is found to contain from 5 to 7 per cent. of oxygen and from 10 to 12 per cent. of carbonic acid (**Bernard**). These figures may be taken to represent the limit, in either direction, at which air ceases to be respirable. When animals or human beings remain for any length of time in ill-ventilated crowded rooms, the resulting impurity of air produces symptoms of discomfort and stiffening, and may, as in some well-known instances, lead to fatal results. These minor ill-effects are in part due to lack of oxygen and increase of carbonic acid, but it is highly probable that they are chiefly owing to the exhalation of various (unknown) substances from the skin and lungs. According to Pettenkofer it is possible to breathe an atmosphere containing 1 per cent. of *pure* carbonic acid for a length of time without any injurious results following, or indeed any discomfort being felt. But 1 per cent. of carbonic acid may be fairly taken as a limit of the impurity of air due to bad ventilation, and respired air containing a much smaller quantity is found to be unbearable. The effects, moreover, which have been described as resulting from the inhalation of small quantities of carbonic acid (Smith) are distinct from those resulting from ordinary impure air. The latter, too, may be imitated by breathing respired air freed from its carbonic acid, and containing therefore the other impurities only; by experimenting on animals, fatal results may be produced. At the same time the carbonic acid may be taken as an indirect measure of the impurity of respired air, and accordingly air which by respiration has acquired more than ·08 per cent. of carbonic acid should be considered as unfit for further respiration. M. F.

RETENE. $C^{18}H^{18}$.—A hydrocarbon polymeric with benzene, discovered in 1837 by Fikentscher and Trommsdorff, and examined chiefly by Fritzsche (J. pr. Chem. lxxv. 281; Jahresb. 1860, p. 475; Gm. xviii. 8). It occurs in thin unctuous scales on fossil pine-stems, in beds of peat and lignite in Denmark and other localities, and together with fichtelite on the Fichtelgebirge, and at Utznach in the Canton of St. Gall. It is produced also by the dry distillation of very resinous pine and fir-wood, passing over together with the heavy tar-oil, and separating in scales like paraffin (Krauss, Ann. Ch. Pharm. cvi. 391). By submitting colophony to dry distillation, and passing the vapour through a red-hot tube, Fritzsche obtained several hydrocarbons, forming compounds with picric acid, amongst them probably retene. *Retisterene*, or *Metanaphthalene* (p. 98), which is obtained in a similar manner by Pelletier and Walter (Ann. Ch. Phys. [2] lxvii. 296), is perhaps impure retene. (Fritzsche.)

Preparation: From fossil wood.—The comminuted wood is exhausted by boiling with alcohol; the greater part of the alcohol is then distilled off; and the remainder of the decoction is evaporated to dryness, and treated with sulphide of carbon, which dissolves retene and other substances, leaving a red-brown acid resin. On removing the sulphide of carbon by distillation, and dissolving the residue, together with picric acid, in benzene, a compound of retene with picric acid and benzene separates out in yellow needles on cooling. These are pressed and recrystallised from alcohol, with addition of excess of picric acid, the compound of retene and picric acid is decomposed by ammonia, and the separated retene is recrystallised from alcohol. (Fritzsche.)

Retene forms soft shining unctuous laminæ, inodorous, tasteless, sinking in cold but floating in boiling water (Fritzsche). It melts at 98—99° (Fehling, Ann. Ch. Pharm. cvi. 388). According to Fritzsche, melted retene solidifies at 90°, the temperature rising to 95°. It evaporates gradually in the air and over the water-bath, and when melted gives off white clouds, which condense to a woolly sublimate (Krauss, Ann. Ch. Pharm. xxviii. 345). It boils at about the boiling-point of mercury, and distils almost unchanged (Fritzsche, Fehling). It is insoluble in *water*, dissolves slowly in cold, much more readily in boiling *alcohol*, easily in warm *ether*, and in *oils*, both *fixed* and *volatile*.

Retene burns with a bright but smoky flame. It is converted into resinous products by treatment with *chromic acid*, with *hydrochloric acid* and *chlorate of potassium*, and with strong *nitric acid*. With more dilute nitric acid, it also forms crystalline products. (Fehling.)

By prolonged contact with strong *sulphuric acid*, retene is converted into retene-disulphuric or disulphoretetic acid, $C^{18}H^{18}S^2O^6$, which crystallises in a solid mass and forms a soluble *barium-salt*, $C^{18}H^{16}Ba''S^2O^6$, crystallising in needles. The *lead-salt*, $C^{18}H^{16}Pb''S^2O^6$, dissolves slightly in cold, easily in boiling water, and separates therefrom in white flocks.

A solution of retene in moderately dilute sulphuric acid deposits on standing, crystals containing $C^{18}H^{18}S^2O^6.5H^2SO^4$.

Retene heated with strong sulphuric acid is converted into the compound $C^{18}H^{20}SO^4$, called by Fritzsche sulphoretene, which separates from boiling water in thin laminæ, from alcohol as a sandy powder or in crusts; is decomposed by heat and forms a crystalline compound with hydrochloric, oxalic, and picric acids.

Retene with Picric acid.—A solution of 1 pt. retene and 3 pts. picric acid, in hot alcohol or ether, deposits on cooling, delicate woolly orange-yellow needles of the compound $C^{18}H^{18}.C^6H^3(NO^2)^3O$, which is partially decomposed by alcohol of 90 per cent., completely by more dilute alcohol, into picric acid and retene.

A mixture of retene and picric acid dissolved in hot *benzene*, deposits on cooling needles of the compound $C^{18}H^{18}.C^{6}H^{6}.C^{6}H^{3}(NO^{2})^{3}O$, which on exposure to the air becomes opaque, and gives off the whole of the benzene. (Fritzsche.)

RETENE-SULPHURIC ACID. See the last article.

RETINALITE. A green translucent variety of serpentine from Canada, having a resinous aspect. (See SERPENTINE.)

RETINAPHTHA. Syn. with toluene or hydride of benzyl (i. 573).

RETINASPHALT. A fossil resin of yellow-brown colour, earthy aspect, rarely dense and shining; of specific gravity 1·07 to 1·35; fusible, burns with a white flame, and aromatic odour. Retinasphalt from the lignite of Bovey in Devonshire, where it was first observed, contains, according to Hatchett (Phil. Trans. 1804, p. 404), 55 per cent. resin soluble in alcohol, 42 per cent. insoluble resin; according to Johnston (Phil. Trans. 1840, p. 347), 13·23 per cent. mineral constituents, 27·45 resin insoluble in alcohol, and 59·23 per cent. soluble in alcohol—the latter constituting Johnston's *retinic acid*. Retinasphalt from Halle contains, according to Bucholz (Schw. J. i. 290), 91 per cent. easily soluble resin, and 9 per cent. insoluble resin, resembling amber; that from Cape Sable, United States, contains 42·5 per cent. easily soluble resin, 55·5 per cent. insoluble resin, and 1·5 ferric oxide and alumina. (Troost.)

RETINIC ACID. The portion of retinasphalt from Bovey, which is soluble in alcohol (Johnston). It remains, on evaporating the alcoholic solution, as a yellow-brown resin, which melts, with loss of weight, at 120°, and gives off gas-bubbles at 205°. It dissolves abundantly in ether, whence it is for the most part precipitated by alcohol, sparingly in alcohol, and is precipitated by water. The alcoholic solution gives a slight precipitate with chloride of calcium, more abundant with alcoholic acetate of lead. The acid contains, at 100°, 75·03 per cent. C, 8·77 H, and 16·20 O: after fusion, 77·08 C, 8·70 H, and 14·22 O; the calcium-salt yielded 10·26 per cent. lime, the silver-salt 41·78 to 43·58 per cent. silver-oxide. From these results Johnston deduced the formula $C^{40}H^{54}O^{6}$.

RETINITE. *Walchovite.* A fossil resin found in the coal-mines of Walchow, in Moravia, in rounded lumps, varying in size from that of a pea to that of a man's head. It is brittle, of specific gravity 1·035 to 1·069, has a yellow colour, a conchoïdal fracture, and fatty lustre. At 140° it becomes translucent and elastic without fusing, and at 250° melts to a yellow oil. By dry distillation it yields combustible gas, tar, and aqueous formic acid. Alcohol extracts from it 1·5 per cent., and ether 7·5 per cent. of resin, both the resins thus obtained being transparent, yellow, and tough. It dissolves slightly in sulphide of carbon, and in boiling rock-oil, but softens in the former. Contains 80·40 per cent. C, 10·68 H, and 8·74 O, agreeing approximately with the formula $C^{40}H^{62}O^{3}$. (Schrötter, Pogg. Ann. lix. 61: see also Cerutti, N. Br. Arch. xxii. 286.)

The lignite of the Wilhelmszech mine, in the Westerwald, contains reddish-yellow brittle deposits of retinite. Branchite or scheererite likewise changes to a resin, which has the colour and soft waxy consistence of retinite. (Casselmann.)

The name retinite is used by Rammelsberg (*Mineralchemie*, p. 966) as a generic name for fossil resins containing oxygen.

RETINOLE and **RETINYL.** Hydrocarbons obtained in the rectification of the products of the dry distillation of turpentine-resins (Pelletier and Walter, Ann. Ch. Phys. [2] lxvii. 269). See TURPENTINE.

RETISTERENE. *Metanaphthalene.* A solid hydrocarbon, probably identical with retene, obtained by the distillation of resins, and passing over with the last portions of the distillate. (Pelletier and Walter, Ann. Ch. Phys. [2] lxxii. 296.)

RETORT. This name was originally applied to the well-known vessel, consisting of a bulb and inclined neck, used for distillation: but it is now, especially in technological language, applied to distillatory vessels of other shapes—for example, to the cylinders of iron or earthenware used for the distillation of coal, &c.

RETZBANYITE. A massive grey mineral from Retzbanya, in Hungary, of specific gravity 6·21. It is mixed with oxidised products, and gives by analysis 7·14 per cent. oxygen, 11·93 sulphur, 38·38 bismuth, 36·01 lead, 4·22 copper, and 1·93 silver. (Hermann, J. pr. Chem. lxxv. 450.)

RETZITE. Syn. with EDELFORSITE (ii. 361).

REUSSIN. A salt occurring as an efflorescence at Saidschitz, in Bohemia, and consisting of a mixture of the sulphates of sodium, calcium, and magnesium, with chloride of magnesium [and water], but varying in composition according to the locality and the season of the year. (Reuss, Crell. Ann. 1791, ii. 18.)

RHAMNETIN. $C^{11}H^{10}O^5$. (Gellatly, N. Edinb. Phil. J. vii. 256.)—A pale-yellow crystalline substance, formed, together with glucose, by boiling xanthorhamnin with dilute sulphuric or hydrochloric acid:

$$C^{23}H^{28}O^{14} + 3H^2O = C^{11}H^{10}O^5 + 2C^6H^{12}O^6.$$

A similar transformation takes place when Persian berries, which contain xanthorhamnin, are stirred up with cold water, the rhamnetin being deposited from the filtrate as a yellow powder.

Rhamnetin is nearly insoluble in water, easily soluble in alkalis, and precipitated therefrom by acids; insoluble in alcohol and ether. Hlasiwetz regards it as identical with quercetin (p. 4).

RHAMNIN. (Fleury, J. Pharm. xxvii. 226.—Winckler, Jahrb. pr. Pharm. xxiv. 1.—Binswanger, Repert. Pharm. civ. 54.—Gm. xvi. 80).—A yellow substance contained, together with rhamnocathartin, in the unripe berries of the buckthorn (*Rhamnus catharticus*). It may be prepared by pressing the berries to remove the juice, boiling the residue repeatedly with water, setting the decoctions aside to crystallise, and purified by recrystallisation from boiling alcohol, with aid of animal charcoal. It forms rounded groups of pale-yellow granules or, more rarely, tufts of needles. It is decomposed by heat, is nearly or quite insoluble in cold water, swells up in boiling water, dissolves sparingly in cold, easily in boiling alcohol, but is insoluble in ether. It dissolves easily in alkalis, and is precipitated therefrom by acids; dissolves with saffron-yellow colour in strong hydrochloric or sulphuric acid, and is precipitated by water; in hot nitric acid, forming a dark-brown solution, which becomes yellow on continued heating, and then leaves on evaporation a crystalline mass, mostly soluble in water, together with a bitter yellow powder, probably picric acid.

The name rhamnin is applied also by Ortlieb (Mulhous. Soc. Bull. xxx. 16) to a product obtained from Persian berries. According to his observations, the aqueous decoction of the berries, after the colouring-matter has separated from it, contains a large quantity of sugar, and after fermentation deposits yellow crystalline grains of *hydrate of oxyrhamnin*, $C^{21}H^{18}O^{11}$, isomeric or perhaps identical with euxanthic acid (ii. 609), then yellow-green flocks of *hydrate of rhamnin*, $C^{21}H^{18}O^{10}$; and the mother-liquor, if boiled with sulphuric acid, yields flocks of *rhamnin*, $C^{21}H^{16}O^9$. These results, however, do not agree with those obtained by Kane and by Gellatly (p. 100). See also XANTHORHAMNIN.

RHAMNOCATHARTIN. *Cathartin.* (Hubert, J. Chim. méd. vi. 193.—Winckler, Jahrb. pr. Pharm. xix. 221; xxiv. 1.—Binswanger, Repert. Pharm. civ. 54.—Gm. xvi. 81.)—The uncrystallisable bitter principle of buckthorn berries. To prepare it, the juice of the ripe berries is evaporated to an extract; this extract is exhausted with hot alcohol, the tincture evaporated, and the residue mixed with water, which separates yellow-green pulverulent rhamnotannic acid. The filtrate, shaken up with coarsely-pounded, purified bone-charcoal, as long as it retains any bitter taste, yields rhamnocathartin to the charcoal; and on washing this charcoal with cold water, drying, treating it with hot alcohol, and evaporating the tincture, the rhamnocathartin is left behind. (Binswanger.)

Rhamnocathartin is a translucent, amorphous, yellowish, brittle mass, which emits a peculiar smell when rubbed. It has a bitter and very repulsive taste, is neutral, and tolerably permanent in the air. When heated, it melts to a yellow oil, turns brown, gives off inflammable vapours, and leaves combustible charcoal. With *nitric acid*, it yields a large quantity of picric acid (Winckler). It is not decomposed during the fermentation of the juice. (Hubert.)

It is soluble in all proportions in *water* (Winckler), insoluble in cold, somewhat soluble in boiling water, to which it imparts a very bitter taste, while the remainder melts and adheres to the sides of the vessel. The hot solution becomes turbid on cooling (Binswanger). The aqueous solution is coloured brownish gold-yellow, without precipitation, by *ammonia*, the *fixed alkalis*, and *basic acetate of lead*, and becomes colourless again on addition of acids. It colours *ferric chloride* dark-brown-green. (Winckler.)

Rhamnocathartin dissolves in all proportions in *alcohol*, but is insoluble in *ether*.

RHAMNOTANNIC ACID. (Binswanger, *loc. cit.*)—Obtained, as above, in the preparation of rhamnocathartin, and purified by washing, drying, solution in ether, and evaporation.—It is a neutral, greenish-yellow, amorphous, easily friable mass; tastes bitter and astringent; melts and decomposes when heated; is nearly insoluble in cold water, somewhat soluble in boiling water, and in aqueous ammonia, forming a golden-yellow liquid which gradually turns brown. With lime-water and potash-ley it forms yellow solutions, which do not change in contact with the air; the former, however, gradually deposits yellow flocks. The aqueous solution, added to neutral or basic acetate of lead, throws down orange-yellow flocks; it colours ferric salts olive-green, and then precipitates them. In tartar-emetic it forms, after some time, a yellow precipitate; does not precipitate solution of gelatin. The acid dissolves readily in alcohol and ether.

RHAMNOXANTHIN. A yellow, crystalline, sublimable substance identical with *Frangulin*, under which name it has already been described (ii. 706). It exists in the root, bark, and stem-bark of *Rhamnus Frangula* (Buchner, Binswanger), and according to Phipson (Compt. rend. xlvii. 153), in the bast, and in the vessels of the medullary sheath of the branches. Phipson prepares it by macerating the branches for three or four days in sulphide of carbon, evaporating the extract to dryness, exhausting the residue with alcohol, which leaves fat undissolved, again evaporating, and recrystallising from ether.

RHAMNUS. The several species of *Rhamnus* yield yellow or green colouring-matters, which have been examined by different chemists, not always with accordant results:—

1. Persian or Turkey-berries, the seeds of *Rhamnus amygdalinus*, *R. oleoïdes*, *R. saxatilis*, and Avignon-grains, the seeds of *R. infectorius*, which are employed in dyeing for the production of yellow colours, yield: *α*. According to Kane (Phil. Mag. [3] xxiii. 3), in the unripe state, chrysorhamnin, $C^{23}H^{22}O^{11}$ (i. 960), and when ripe, xanthorhamnin, $C^{23}H^{24}O^{14}$.—*β*. According to Gellatly, xanthorhamnin, $C^{23}H^{28}O^{14}$, with rhamnetin, $C^{11}H^{10}O^{5}$, as a product of its decomposition.—*γ*. According to Ortlieb (Mulhous. Soc. Bull. xxx. 16), rhamnin, $C^{21}H^{16}O^{9}$, hydrate of rhamnin, $C^{21}H^{18}O^{10}$, and hydrate of oxyrhamnin, $C^{21}H^{18}O^{11}$.

2. The bark of the berry-bearing alder (*Rhamnus Frangula*), and of the buckthorn (*R. catharticus*), yields the yellow dye called rhamnoxanthin by Buchner and Binswanger, frangulin by Casselmann.

3. The berries of *R. catharticus* yield the rhamnin of Henry, Winckler, and Binswanger (p. 99); also Binswanger's rhamnocathartin, called cathartin by Hubert (p. 99). These berries and the syrup prepared from them possess purgative properties; but their action is violent and dangerous, so that their use in medicine is not to be recommended.

The berries of some species of rhamnus are used for dyeing morocco-leather of a yellow colour; others for dyeing wool; and the bark of some is employed for striking a black with salts of iron. Those of *Rhamnus catharticus* yield the pigment called sap-green, or bladder-green; and recently M. Charvin of Lyons has obtained from them a splendid green dye called *Vert Venus*, *Vert-Azof*, or *Vert-Lumiere*, identical with, or very similar to, the Chinese Lo-Kao. (See DYEING, ii. 358; also Wagner's Jahresbericht, 1861, p. 567.)

RHAPONTICIN. Syn. with CHRYSOPHANIC ACID (i. 958).

RHEADIC ACID. According to Leo Meier (Repert. Pharm. [3], xli. 325), the red colouring-matter of the flowers of the common red poppy (*Papaver Rheas*) consists of two acids, called *rheadic* and *papaveric acid*, separable by neutral acetate of lead, which precipitates only the former; they do not appear to have been obtained pure. (See *Gmelin's Handbook*, xvi. 527.)

RHEIC ACID.
RHEIN. } Syn. with CHRYSOPHANIC ACID (i. 958).

RHEOMETER. Syn. with GALVANOMETER. (See ELECTRICITY, ii. 443.)

RHEOSTAT. An instrument for regulating and measuring the force of electric currents. (See ELECTRICITY, ii. 464.)

RHEUM. See RHUBARB (p. 107).

RHEUMIN. Syn. with CHRYSOPHANIC ACID (i. 958).

RHODANIDES. A name applied to sulphocyanates, on account of the red colour which they produce with ferric salts.

RHODEORETIN. Syn. with CONVOLVULIN (ii. 15).

RHODEORETINOL.
RHODEORETINOLIC ACID. } Syn. with CONVOLVULINOLIC ACID (ii. 15).

RHODIUM. *Atomic Weight*, 104; *Symbol*, Rh.—A metal belonging to the platinum group, discovered by Wollaston in 1804. He found the ore from Brazil to contain 0·4 per cent., and native platinum from another locality has been found to contain as much as 3 per cent. of rhodium. It often occurs in considerable quantity in platinum residues.

Preparation.—1. Platinum-ore is dissolved in nitromuriatic acid; the platinum and iridium are precipitated by sal-ammoniac, and the palladium by cyanide of mercury; the liquid is then saturated with carbonate of sodium; hydrochloric acid is added, to decompose the excess of mercuric cyanide; the liquid is evaporated to dryness; and the residue is treated with alcohol. The whole then dissolves, excepting the chlororhodiate of sodium, which remains as a red-brown powder. This salt, reduced by hydrogen and washed with a large quantity of water, yields pure rhodium.

2. Granular platinum-residue, consisting chiefly of rhodium and iridium, with small quantities of osmium and ruthenium, is treated, as described under IRIDIUM (iii. 315, No. 4), to separate the other metals; and the residue insoluble in nitromuriatic acid, consisting of rhodium with a small quantity of iridium, is mixed with a large excess of common salt, and heated to low redness in a current of dry chlorine, whereby the rhodium is converted into chlororhodiate of sodium, which may be dissolved out by water and crystallised by evaporation. The metal may then be obtained from it by reduction with hydrogen, or by precipitation with zinc: or, better, the concentrated solution may first be mixed with sal-ammoniac, which will throw down any iridium still remaining, and the filtrate evaporated. It then yields fine prisms of chlororhodiate of ammonium, which when calcined leaves pure rhodium. (Frémy.)

3. Platinum-residue, precipitated by metallic iron from the mother-liquors from which platinum has been extracted (iv. 683), is fused at a bright red-heat with 1 pt. lead and 2 pts. litharge; and the regulus thus obtained, after being carefully freed from slag, is treated with nitric acid diluted with an equal volume of water. The pulverulent mass which remains undissolved is then heated to redness with 5 pts. of barium-peroxide; the ignited mass is treated with water, and then with nitromuriatic acid (which eliminates osmic acid); the barium is precipitated from the solution by sulphuric acid, the quantity required having been previously calcinated; the liquid is heated to the boiling-point, and filtered; the filtrate is evaporated to dryness at 100°, with addition, first of a little nitric acid, then of a large quantity of sal-ammoniac; and the solution is washed with a strong solution of sal-ammoniac, which dissolves out all the rhodium. The filtered liquid is then heated with a large excess of nitric acid (to decompose the sal-ammoniac), and finally evaporated to dryness in a porcelain crucible; and the rhodium-salt thus obtained, after being moistened with sulphide of ammonium, is mixed with three or four times its weight of sulphur, and heated to bright redness in the covered porcelain crucible, enclosed for the purpose in an earthen crucible, the space between the two being filled up with powdered charcoal. There then remains a regulus of metallic rhodium, which may be purified by continued boiling with nitromuriatic acid, and then with strong sulphuric acid. To obtain the metal quite pure, it is fused at a low red-heat with 3 or 4 pts. of metallic zinc, and the fused and cooled mass is treated with concentrated hydrochloric acid, which leaves undissolved a crystalline alloy of the two metals. This alloy is dissolved in nitromuriatic acid; the solution is mixed with ammonia, till the precipitate formed at first is redissolved, then boiled and evaporated, whereby a yellow precipitate is formed, consisting of ammoniochloride of rhodium, $5NH^3.RhCl^3$; and this salt, after being purified by recrystallisation, is calcined with a small quantity of sulphur, in a graphite crucible, at a very strong red-heat. Metallic rhodium then remains, which may be fused in the oxyhydrogen furnace (iv. 313). (Deville and Debray, Ann. Ch. Phys. [3], lvi. 385; Jahresb. 1850, p. 238.)

According to Claus (J. pr. Chem. lxxxv. 129; Jahresb. 1861, p. 327), the above-described method of disintegration with peroxide of barium does not give good results; because the rhodium, though oxidised thereby, is rendered very difficult of solution in acids, and indeed will not dissolve at all, unless iridium is also present, to assist the solution by contact-action. Claus therefore gives the preference to Wöhler's method of decomposition, by mixing the substance with chloride of sodium and igniting it in chlorine-gas (iii. 314). For the separation of the iridium and rhodium in the solution obtained by treating the resulting mass with water, he recommends that the trichloride of iridium be first converted into tetrachloride by boiling with nitriomuriatic acid, and the iridium then separated by fractional precipitation with sal-ammoniac. The mode of separation by digesting the dried saline residue in sal-ammoniac solution, he regards as objectionable; because the rhodium-salt, when once crystallised, dissolves but slowly in that liquid, and adheres obstinately to the iridium-salt, so that a very large quantity of the sal-ammoniac solution is required to dissolve it.

Properties.—Rhodium is a whitish-grey metal, very hard, much less ductile than platinum. It is somewhat more fusible than iridium, but scarcely softens in the flame of the oxyhydrogen blowpipe; it may, however, be fused in Deville's oxyhydrogen furnace (iv. 313). The melted metal absorbs oxygen, and spits as the globule sets. The specific gravity of unfused rhodium is 10·64; that of the pure metal after fusion is 12·1.

Rhodium is unalterable in the air at ordinary temperatures, but oxidises at a red heat, and with great facility if in the state of powder. It combines also with chlorine at a red heat. When pure it resists the action of the strongest acids, even of nitromuriatic acid, but when alloyed with certain metals (as with lead, bismuth, copper, and platinum), it dissolves in nitromuriatic acid, together with those metals; when fused with gold or silver, however, it does not dissolve. It is readily oxidised by fusion with nitre, or with peroxide of barium. By fusion with sulphate of potassium, it is converted into soluble rhodiopotassic sulphate. Mixed with chloride of sodium, and ignited in a stream of chlorine gas, it is converted into chlororhodiate of sodium, which is likewise easily soluble.

RHODIUM, ALLOYS OF. Rhodium unites with most other metals. Some of the alloys, as already observed, dissolve completely in nitromuriatic acid, whereas others yield to this solvent only the metal alloyed with the rhodium. An alloy of rhodium and *gold* found in Mexico contains from 34 to 43 per cent. rhodium. (Del Rio, Ann. Ch. Phys. [2], xxix. 137.)

One pt. of rhodium and 1 pt. of *steel* form an alloy, which has a specific gravity of 9·176, a very fine colour and surface for metallic mirrors, and does not tarnish in the air.—One pt. rhodium with 50 to 100 steel forms a very hard and rather tough alloy, which requires for tempering a heat higher by 39° than common steel, and 17° higher than Indian steel. (Faraday and Stodart.)

Rhodium also unites with *zinc* and *tin*, forming the crystallised alloys, $RhZn^2$ and $RhSn$. (Deville and Debray.)

RHODIUM, CHLORIDES OF. A *dichloride*, $RhCl^2$, is said by Fellenberg to be obtained by heating the corresponding sulphide, RhS, in chlorine-gas; but according to Claus, there is but one definite compound of rhodium and chlorine—viz., the trichloride or rhodic chloride, $RhCl^3$. It is obtained in the anhydrous state by igniting the pulverised metal in a stream of chlorine, or, more easily, by heating one of its double salts (*infra*) for some time with strong sulphuric acid, and pouring the mixture when cold into water, which dissolves the alkaline sulphate and a small quantity of undecomposed double chloride, leaving the rhodic chloride undissolved. As obtained by either process, it is a brownish-red indifferent body, insoluble in all acids and alkalis. When heated with *nitrite of potassium*, it turns yellow, and is resolved into an orange-yellow powder, slightly soluble in water, but easily soluble in hydrochloric acid, and a soluble compound precipitable by alcohol. With *nitrite of sodium* it yields only the soluble salt. *Sulphide of ammonium* added to these solutions, throws down sulphide of rhodium, soluble in excess of the alkaline sulphide, and completely precipitable therefrom by acids. (W. Gibbs, Sill. Am. J. [2] xxxiv. 341; Jahresb. 1863, p. 293.)

Hydrated rhodic chloride, $RhCl^3.4H^2O$, remains in the form of a red-brown vitreous mass, on evaporating over the water-bath a solution of rhodic oxide in hydrochloric acid, previously freed from potash by treatment with nitric acid. It yields a red powder, is deliquescent, soluble in alcohol, insoluble in ether; at a red heat it gives off its water, and becomes insoluble.

Chlororhodiates of Ammonium.—The salt $2(3NH^4Cl.RhCl^3).3H^2O$ is obtained by decomposing the corresponding sodium-salt with sal-ammoniac; it crystallises in fine rhombohedral prisms, easily soluble in water, insoluble in alcohol. The boiling aqueous solution deposits on cooling, prisms and hexagonal plates of the salt $2NH^4Cl.RhCl^3.H^2O$, less soluble and darker-coloured than the preceding.

Chlororhodiates of Potassium.—The salt $3KCl.RhCl^3.3H^2O$, formed by mixing the solutions of rhodic oxide in hydrochloric acid with a strong solution of potassic chloride, crystallises in sparingly soluble prisms, which effloresce and give off all their water on exposure to the air. Another double salt, $2KCl.RhCl^3.H^2O$, is obtained by heating, in a current of chlorine, a mixture of pulverised rhodium or rhodic chloride with chloride of potassium. The black saline mass dissolves in water, and the solution yields by evaporation dark-red crystals soluble in alcohol.

Chlororhodiate of Sodium, $3NaCl.RhCl^3.12H^2O$, is obtained by heating a mixture of 1 pt. rhodium and 2 pts. common salt in a stream of chlorine; it crystallises like the corresponding potassium-salt.

RHODIUM, CYANIDE OF. $RhCy^3$. See CYANIDES (ii. 271).

RHODIUM, DETECTION AND ESTIMATION OF. Rhodium forms only one class of salts, viz. the rhodic salts, corresponding in composition with the trichloride. These salts are for the most part rose-coloured (hence the name of the metal), and exhibit the following reactions in solution:—With *sulphydric acid*, a brown precipitate of sulphide, which is slowly deposited; with *sulphydrate of ammonium*, a brown precipitate, insoluble in excess: with *sulphurous acid* and *sulphites*, a pale-yellow precipitate, affording a very characteristic reaction; with *potash*, a yellow precipitate of hydrated rhodic oxide, soluble in excess; with *ammonia* also a yellow precipitate, which, however, does not form immediately; with *alkaline carbonates*, a yellow precipitate after a while. *Iodide of potassium* produces a slight yellow precipitate; *stannous chloride* imparts a dark colour to the solutions, but forms no precipitate. *Mercurous nitrate* and *nitrate of silver* form with rhodic chloride, precipitates analogous in composition to the argento-iridic chloride already mentioned (iii. 318). *Zinc* precipitates metallic rhodium. In a solution of rhodium mixed with excess of potash, *alcohol* forms, even at ordinary temperatures, a black precipitate, probably consisting of metallic rhodium; with the other platinum-metals, this reaction takes place only when the liquid is heated. No precipitate is formed by sal-ammoniac, chloride of potassium, chromate of potassium, oxalic acid, cyanide of potassium, cyanide of mercury, ferrocyanide or ferricyanide of potassium, or gallic acid. *Hydrogen gas* reduces the anhydrous salts at a moderate heat.

Chlororhodiate of sodium (p 102) forms with soluble *borates*, a yellow precipitate of rhodic oxide, RhO^3, containing the whole of the metal. A similar reaction is produced by *trisodic phosphate* and by *alkaline carbonates*, but part of the rhodium then remains in the solution, giving it a yellow colour. (Claus, Jahresb. 1863, p. 697.)

Estimation and Separation.

Rhodium is estimated in the metallic state. The solution containing it is mixed with excess of sodic carbonate and evaporated to dryness, the residue ignited, and the calcined mass treated with cold water; oxide of rhodium then remains, and may be reduced by hydrogen.

Rhodium is separated from many metals with which it may be alloyed, by fusing the alloy with acid sulphate of potassium; the rhodium is thereby converted into sulphate of rhodium and potassium, which may be dissolved out by water.

The separation of rhodium from other metals in solution is somewhat difficult, because it is not completely precipitated by sulphydric acid. To separate rhodium from *copper*, the solution is saturated with sulphydric acid and left to stand in a stoppered bottle for twelve hours, then filtered, and the filtrate heated to separate an additional portion of sulphide of rhodium. The whole of the precipitate is then roasted in a platinum crucible till the sulphides are completely oxidised, and the product treated with strong hydrochloric acid, which dissolves the copper and leaves the oxide of rhodium. The liquid filtered from the sulphydric acid precipitate still contains a small portion of rhodium, which may be precipitated by carbonate of sodium, and converted into oxide as above. The whole of the oxide is then reduced by hydrogen.

To separate rhodium from *iron*, the rhodium is precipitated as completely as possible by sulphydric acid; the liquid filtered; and the iron in the filtrate precipitated by ammonia, after having been brought to the state of ferric oxide. The iron-precipitate carries down with it a certain portion of rhodium, which may be separated by igniting the precipitate in a current of hydrogen, and treating the reduced metals with hydrochloric acid, which dissolves the iron and leaves the rhodium: the latter is then converted into oxide by ignition in the air. The precipitated sulphide of rhodium is likewise oxidised by roasting. The small quantity of rhodium which remains in solution after precipitation by ammonia is precipitated by carbonate of sodium, and converted into oxide by ignition. The whole of the oxide of rhodium is then reduced to the metallic state by hydrogen.

The separation of rhodium from the alkali-metals is easily effected by converting the metals into chlorides, and igniting the chlorides in a current of hydrogen, which reduces only the chloride of rhodium.

The methods of separating rhodium from the other metals of the platinum-group have already been given (iv. 680—684). The insolubility of chlororhodiate of sodium in alcohol affords in many cases a good mode of separation (p. 101). To separate it from *iridium*, Gibbs (Jahresb. 1863, p. 293) heats the solution of the two metals with excess of nitrite and carbonate of sodium, till a light orange-yellow colour is produced; adds sulphide of sodium by small quantities, till the precipitate of rhodium sulphide begins to redissolve (p. 105); then boils for a few minutes, and mixes the solution when cold with a slight excess of hydrochloric acid. The sulphide of rhodium thereby precipitated is washed with cold water, dissolved in nitromuriatic acid, and the rhodium is converted, first into the double chloride $3NH^4Cl.RhCl^3$, then into the compound $5NH^3.RhCl^3$. (See further Gibbs, Jahresb. 1864, p. 287; and Carey Lea, *ibid.* 291.)

Atomic weight of Rhodium.—3·146 grammes of chlororhodiate of potassium, $2KCl.RhCl^3$, heated in a current of hydrogen, were found by Berzelius (Pogg. Ann. xiii. 435) to lose 0·930 grm. chlorine, leaving a mixture of 0·912 grm. of rhodium and 0·515 of potassium-chloride. In another experiment, 1·3 grm. of the salt lost 0·335 grm. chlorine, leaving 0·358 grm. rhodium and 0·515 grm. potassium-chloride. The mean of these results gives for the atomic weight of rhodium, very nearly the number 104.

RHODIUM, OXIDES OF. Rhodium forms four oxides, having the formulæ RhO, Rh^2O^3, RhO^2, and RhO^3. (Claus.)

The *protoxide*, RhO, is formed, with incandescence, when the hydrated sesquioxide, $Rh^2O^3.3H^2O$, is heated in a platinum crucible. It is a dark-grey substance, perfectly indifferent to acids.

The *Sesquioxide* or *Rhodic Oxide*, Rh^2O^3, obtained by heating the nitrate, is a grey porous mass, with metallic iridescence; insoluble in acids, easily reduced by hydrogen. It forms two hydrates.

The *trihydrate* or *normal rhodic hydrate*, $Rh^2O^3.3H^2O$ or RhH^3O^3, is produced by precipitating a solution of chlororhodiate of sodium with potash, in presence of alcohol; or, without the aid of alcohol, by heating the rhodium-solution with very strong potash-ley. It is gelatinous, shrinks to a very small bulk when dried, and is almost indifferent to acids. Hydrochloric acid, however, dissolves a very small quantity of it, acquiring the fine rose-colour characteristic of rhodic salts.

The *pentahydrate*, $Rh^2O^3.5H^2O$ or $RhH^3O^3.H^2O$, is formed by treating a solution of chlororhodiate of sodium with aqueous potash. It has a lemon-yellow colour, and retains 3 or 4 per cent. potash even after washing. The mother-liquor has a yellow colour, and still retains rhodium.

Dioxide, RhO^2.—Obtained by fusing pulverised rhodium or the sesquioxide, with nitre and potash, and digesting the fused mass with nitric acid, to dissolve off the potash. It is a dark-brown substance, insoluble in acids.

When chlorine is passed into a solution of rhodic pentahydrate, $Rh^2O^3.5H^2O$, a black-brown gelatinous precipitate of the trihydrate, $Rh^2O^3.3H^2O$, is formed at first; but this compound gradually loses its gelatinous consistence, becomes lighter in colour, and is finally converted into a green hydrate of the dioxide, $RhO^2.2H^2O$. The alkaline solution at the same time acquires a deep violet-blue colour.—The green hydrate treated with hydrochloric acid dissolves, with evolution of chlorine, forming a rose-coloured solution of the sesquichloride:

$$2RhO^2 + 8HCl = Rh^2Cl^6 + 4H^2O + Cl^2.$$

Trioxide, RhO^3.—The blue alkaline solution above mentioned deposits, after a while, a blue powder, becoming green when dry, and yielding, when treated with nitric acid, a blue flocculent substance, consisting of the trioxide, easily reduced to the green dioxide. (Claus.)

RHODIUM, OXYGEN-SALTS OF. These salts, analogous in composition to the trichloride, do not crystallise very readily. Moreover, the only rhodic oxygen-salts that can be obtained pure, are those which contain acids capable of expelling nitric acid from its combinations; because, in order to obtain rhodic oxide free from potash, it must be washed with water containing nitric acid, which then unites with the rhodic oxide. The weaker acids are not capable of removing the whole of the potash.

Rhodic acetate, $Rh^2O^3.3C^4H^6O^3.5H^2O = \left.\begin{matrix}(C^2H^3O)^3\\ Rh'''\end{matrix}\right\}O^3.\tfrac{5}{2}H^2O$.—Recently prepared rhodic oxide dissolves in acetic acid, forming an orange-yellow solution, which when evaporated over the water-bath, leaves a transparent orange-yellow, amorphous, non-deliquescent mass, soluble in water and in alcohol; it always, however, retains 3 or 4 per cent. of potash. (Claus.)

Nitrate, $Rh^2O^3.3N^2O^5.4H^2O$ or $\left.\begin{matrix}(NO^2)^3\\ Rh'''\end{matrix}\right\}O^3.2H^2O$.—The yellow hydrate of rhodic oxide dissolves very easily in nitric acid, and the solution evaporated over the water-bath leaves a gummy, very hygroscopic mass, insoluble in alcohol. The nitrate when ignited leaves the insoluble sesquioxide.

Phosphates.—Rhodic oxide dissolves partially in aqueous phosphoric acid, forming the salt $Rh^2O^3.2P^2O^5.6H^2O$, very soluble in water, and precipitable by alcohol. The residue constitutes a basic phosphate.

Sulphate, $Rh^2O^3.3SO^3.12H^2O$, or $\left.\begin{matrix}(S\overset{\prime\prime}{O}{}^2)^3\\ (Rh''')^2\end{matrix}\right\}O^6.12H^2O$.—Yellowish-white crystalline mass, having a styptic and acid taste.—When the mother-liquor of potassio-rhodic cyanide is boiled for some time with strong sulphuric acid, the liquid then evaporated, and the residue digested with water, a potassio-rhodic sulphate dissolves, and another double sulphate remains as a reddish-yellow crystalline powder, consisting of $\left.\begin{matrix}(SO^2)^3\\ Rh'''K^3\end{matrix}\right\}O^6$ (Claus). The same salt is formed when sulphuric acid is added to a solution of chlororhodiate of potassium. (Berzelius.)

Sulphite, $Rh^2O^3.3SO^2.6H^2O$, or $\left.\begin{matrix}(S\overset{\prime\prime}{O})^3\\ (Rh''')^2\end{matrix}\right\}O^6$.—Resembles the sulphate, but is white, soluble in water, insoluble in alcohol. When heated it gives off sulphurous and sulphuric acids, and leaves an oxide of rhodium. A compound of this salt with sulphite of potassium, $3K^2SO^4.Rh^2(SO^3)^3.6H^2O$, may be obtained by treating a solution of chlororhodiate of potassium with excess of acid sulphite of potassium, first at ordinary temperatures, then for a long time at a higher temperature.

RHODIUM, SULPHIDES OF. A *protosulphide*, RhS, is obtained by heating rhodium (Berzelius), or chlororhodiate of ammonium (Vauquelin), with sulphur; also by heating the sesquisulphide in an atmosphere of carbonic anhydride (Fellenberg). It has a greyish-blue colour and metallic lustre (Vauquelin), and melts only at a very high temperature (Berzelius). When heated in a current of dry chlorine, it is converted into the dichloride. (Fellenberg, Pogg. Ann. i. 63.)

Sesquisulphide of Rhodium, Rh^2S^3, is obtained as a black-brown precipitate by the action of sulphydric acid on a solution of an alkaline chlororhodiate.

RHODIUM-COMPOUNDS, AMMONIACAL. These compounds, discovered by Claus (*Beiträge zur Geschichte der Platinmetalle*, Dorpat, 1854; Jahresb. 1854, p. 369; 1855, p. 433), are analogous to the ammoniacal iridium-compounds (iii. 324). A dilute solution of the ammonium-salt, $3NH^4Cl.RhCl^3.\frac{3}{2}H^2O$, mixed with excess of ammonia, assumes a lemon-yellow colour, and deposits a precipitate of rhodic hydrate; and the filtered liquid leaves on evaporation a light-yellow saline residue, from which water extracts sal-ammoniac, leaving a yellow crystalline powder, consisting of the ammonio-trichloride of rhodium, $5NH^3.RhCl^3$, which may be formulated as *chloride of diammo-rhodio-triammonium*, $N^3[(NH^4)^2Rh'''H^7].Cl^3$. It may be purified by dissolving it in boiling aqueous ammonia, and evaporating the filtered solution over the water-bath; and is deposited at a certain degree of concentration, in small transparent prisms, triclinic according to Claus, rhombic according to Keferstein (Jahresb. 1856, p. 421). It is sparingly soluble in water, insoluble in alcohol, soluble without decomposition in potash and in ammonia, slowly and imperfectly decomposed by acids. When heated, it gives off ammonia, sal-ammoniac, and free nitrogen, and leaves metallic rhodium.

The corresponding *oxide*, $10NH^3.R^2O^3$, is obtained by digesting the ammonio-chloride with water and silver-oxide, and evaporating the resulting yellow solution in a vacuum; it then remains in the solid state. It dissolves in acids, forming the corresponding ammoniated rhodium-salts, and expels ammonia from sal-ammoniac.—The *carbonate*, $10NH^3.Rh^2O^3.3H^2CO^3$, is a white, strongly alkaline, saline mass, easily soluble in water, insoluble in alcohol.—The *nitrate*, $10NH^3.Rh^2O^3.3N^2O^5$, is a neutral yellowish-white salt, which does not decompose till heated above 160°.—The *sulphate*, $10NH^3.Rh^2O^3.3H^2SO^4$, forms yellowish-white prismatic crystals, which do not decompose till heated above 180°.—The *oxalate* is also crystalline; the *phosphate* was obtained only as a yellowish gummy mass.

RHODIUM-GOLD. See RHODIUM, ALLOYS OF (p. 102).

RHODIZITE. A mineral supposed to be a lime-boracite, occurring in minute, monometric, tetrahedral crystals, on red tourmalines from the neighbourhood of Mursinsk in Siberia. Hardness = 8. Specific gravity = 3·3 – 3·42. Tinges the blowpipe flame green above and red below, and finally red throughout: hence its name. (G. Rose, Pogg. Ann. xxxiii. 253.)

RHODIZONIC ACID. This name is applied to two acids produced, under different circumstances, from carboxide of potassium (iv. 696). Berzelius and Wöhler noticed that a red substance is produced by the action of water on the black mass formed in the preparation of potassium by Brunner's process (iv. 693). L. Gmelin found that the aqueous solution of this substance yields croconate of potassium when evaporated in contact with the air, and inferred that it contains an acid different from croconic acid. Heller, in 1837 (Ann. Ch. Pharm. xxiv. 1), examined this acid more particularly, and gave it the name of rhodizonic acid. It was further examined by Werner (J. pr. Chem. xiii. 404), but the experiments of these chemists did not determine the composition of the acid. Brodie, in 1859 (Chem. Soc. Qu. J. xii. 269), by treating pure carboxide of potassium with anhydrous alcohol, obtained a red salt, $C^{10}K^6O^8$, which he regarded as rhodizonate of potassium, identical with that previously obtained by Heller and Werner. On the other hand Will, in 1861 (Ann. Ch. Pharm. cxviii. 187), by the analysis of several salts of the acid obtained in a similar manner from the impure carboxide of potassium formed in the preparation of the metal, concluded that its composition is $C^5H^4O^6$, or $C^{10}H^8O^{12}$; and this result is confirmed by the experiments of Lerch (Ann. Ch. Pharm. cxxiv. 20), who has obtained rhodizonic acid in the free state by decomposing the salts of carboxylic acid, $C^{10}H^4O^{10}$ (iii. 190, iv. 296), with acids. It appears then that the name rhodizonic acid has been applied to two distinct compounds. It will be convenient to designate the acid originally obtained by Heller, and analysed by Will and Lerch, as α-rhodizonic, and that obtained by Brodie as β-rhodizonic acid.

α-Rhodizonic acid, $C^5H^4O^6 = \left.\begin{matrix}(C^5HO^3)''' \\ H^3\end{matrix}\right\}O^3$.—This acid is formed from carboxylic acid by the assumption of water: $C^{10}H^4O^{10} + 2H^2O = 2C^5H^4O^6$ (Lerch). When dried in a vacuum it contains $C^5H^6O^7 = C^5H^4O^6.H^2O$, and gives off 1 at. H^2O at 100°. The vacuum-dried acid forms colourless rhombic prisms, easily soluble in water and in alcohol; the colourless acid aqueous solution becomes yellow or roseate when heated, and colourless again on cooling. The crystals turn yellow and brown-red on exposure to the air, and at 100° black with loss of water; at a higher temperature the acid decomposes, leaving a carbonaceous residue, and yielding a small quantity of an acid sublimate. (Lerch.)

The α-rhodizonates are red, and are produced from the hydrocarboxylates (iii. 189) and from carboxide of potassium by assumption of water and oxygen (Lerch). The *potassium-salt* is obtained by treating the "black mass" of the potassium preparation repeatedly with strong alcohol, then with dilute alcohol, mixed towards the end of the process with a little acetic acid, and finally washing the residue with dilute alcohol. It is at first of an unctuous consistence and light yellowish-red colour, but acquires a crimson colour by exposure to the air, and remains unaltered after drying. It is insoluble in alcohol, dissolves slowly in about 150 pts. of cold water, much more easily in hot water, forming a neutral reddish-yellow solution. (Will.)

Rhodizonate of potassium dried at ordinary temperatures has, according to Will's analysis, the composition $C^5H^2K^2O^6.H^2O$; it gives off its water at 120°—130°, leaving the anhydrous salt $C^5H^2K^2O^6$. The hydrated salt is isomeric with croconate of potassium, $C^5K^2O^5.2H^2O$, but differs from the latter in giving off only half as much water when heated (ii. 111).—The neutral solution scarcely absorbs any oxygen from the air, but if mixed with free potash it quickly turns yellow, absorbs a considerable quantity of oxygen, and then leaves on evaporation a mixture of croconate and oxalate of potassium. The croconic acid is formed from the rhodizonic acid by addition of the elements of water: its formation does not, however, take place immediately, but only on evaporation. The oxalic acid, the proportion of which is not constant, appears to be formed, not from rhodizonic acid, but from a brown substance mixed with it, probably a product of the oxidation of rock-oil not completely removed from the "black mass" by washing with alcohol. (Will.)

Rhodizonate of barium, $C^5H^2Ba''O^6.H^2O$ (vacuum-dried), is obtained, by precipitating the potassium-salt with chloride of barium, as a dark-red precipitate, which becomes dark-brown when dried, acquires a greenish-yellow lustre when pressed, and gives off its water at 100° (Will). The *triplumbic salt*, $C^{10}H^2Pb^3O^{12}.2H^2O$ (vacuum-dried), is obtained, by precipitating the potassium-salt with neutral acetate of lead, as a dark-red flocculent precipitate (the supernatant liquid acquiring an acid reaction), which becomes blue-black when dry, and gives off its water at 100°—120° (Will). Lerch, by precipitating the aqueous acid with neutral acetate of lead, obtained a dark-red basic lead-salt, $C^{10}H^2Pb^3O^{12}.2PbH^2O^2$.—The *triargentic salt*, $C^5HAg^3O^6$, is a purple-red precipitate, metallic-green when dry, slightly soluble in water. (Will.)

β-Rhodizonic acid, $C^{10}H^6O^8$.—This acid is not known in the free state (*i.e.*, as a hydrogen-salt). Its *potassium-salt*, $C^{10}K^6O^8$, discovered by Brodie, remains undissolved when pure carboxide of potassium is treated with absolute alcohol (iv. 696). It is distinguished from the α-rhodizonate by the great facility with which it absorbs oxygen on exposure to air and moisture, and is converted into croconate of potassium:

$$C^{10}K^6O^8 + H^2O + O^3 = 2C^5K^2O^5 + 2KHO \text{ (Brodie).}$$

The α-rhodizonate is probably formed from it in a similar manner by the assumption of a larger quantity of water, thus:

$$C^{10}K^6O^8 + 3H^2O + O^3 = 2C^5H^2K^2O^6 + 2KHO;$$

but this latter reaction has not been actually observed (Will). The conversion of the β-rhodizonate into croconate is not accompanied by the formation of oxalic acid. (Brodie.)

Pure β-rhodizonate of potassium dissolves with pale red colour in dilute acetic acid, and the solution yields, with acetate of barium, a shining red precipitate, which quickly changes colour, even during washing. (Brodie.)

RHODOCHROME. A variety of Kæmmererite from the Ural (iv. 770).

RHODOCHROSITE. Native carbonate of manganese. (See CARBONATES, i. 789.)

RHODONITE. *Siliceous Manganese, Manganese spar, Bustamite, Pajsbergite, Bisilicate of Manganese, rother Mangankiesel, Kieselmangan.*—A mineral consisting mainly of silicate of manganese, but containing also iron, magnesium, and calcium. It usually occurs massive, but sometimes in monoclinic crystals, like angite, having the angle $\infty P : \infty P = 87°7'$, and exhibiting the faces ∞P, $\infty P \infty$, $[\infty P \infty]$, oP. Cleavage perfect parallel to ∞P, imperfect parallel to oP. Hardness = 5·5 to 6·5. Specific gravity = 3·4 to 3·68. It has a vitreous lustre, light brownish-red or flesh-red colour, sometimes greenish or yellowish when impure; streak white. Transparent to opaque. Fracture conchoïdal to uneven. Brittle. Melts to a black bead before the blowpipe, and gives conspicuously with fluxes the reactions of manganese.

Analyses: *a*. From Långhansbyttan in Sweden (Berzelius, Schw. J. xxi. 254).—*b*. St. Marcel in Piedmont (Ebelmin, Ann. Min. [4], vii. 8).—*c*. *Bustamite*, from the Real Minas de Fetela, Mexico: α. by Dumas (Bull. des sc. Nat. 1826, Oct. 163); β. by Ebelmin (*loc. cit.*).—*d*. Algeria: rose-red, granular (Ebelmin).—*e*. *Pajsbergite*, from the Pajsberg iron-mine near Philipstadt in Wermeland, Sweden: rose-red; specific gravity = 3·63. (Igelström, J. pr. Chem. xxiii. 278.)

	a.	*b*.	*c*.		*d*.	*e*.

	100·38	99·23	100·34	99·89	98·63	100·69

These analyses show that—

a. consists of 12 $MnSiO^3.CaSiO^3$
b. „ „ 7 $MnSiO^3.CaSiO^3$
c. „ „ 2 $MnSiO^3.CaSiO^3$
d. „ „ 6 $MnSiO^3.CaSiO^3.FeSiO^3.MgSiO^3$
e. „ „ 24 $MnSiO^3.6CaSiO^3.2FeSiO^3.MgSiO^3$

Fowlerite, from Franklin, New Jersey, where it occurs with Franklinite, is a crystallised manganous silicate resembling the preceding, but likewise containing zinc. Specific gravity = 3·63. The following analyses—*a*. by Hermann (J. pr. Chem. xlvii. 5); *b*. by Rammelsberg (*Mineralchemie*, p. 459)—lead to the formula $7MnSiO^3. 2FeSiO^3. 2CaSiO^3. MgSiO^3. ZnSiO^3$:—

	SiO^2	MnO	FeO	ZnO	CaO	MgO	Loss by ignition.		
a.	46·48	31·52	7·23	5·85	4·50	3·09	1·00	=	99·67
b.	46·70	31·20	8·35	5·10	6·30	2·81	0·28	=	100·74

Manganous silicate is often mixed with manganous carbonate, manganous oxide, or quartz, as in the several varieties of siliceous manganese from Elbingerode in the Hartz, known as *Allagite*, *Photizite*, *Corneous Manganese*, &c. Rhodonite likewise becomes altered by the tendency of manganous oxide to pass to a higher state of oxidation, accompanied by absorption of water, the red colour of the mineral changing to brown or black, and indefinite compounds or mixtures resulting, which may consist either partly of silicates, or wholly of an oxide of manganese. *Marceline* or *Heterocline* from St. Marcel is a mineral of this kind; also *Stratopeite*, a black amorphous mineral of specific gravity 2·64, from the Pajsberg mine in Philipstadt, in which Igelström found 35·43 per cent. silica, 32·41 manganic oxide, 10·37 ferric oxide, 8·04 magnesia, and 13·75 water.

[For analyses of these indefinite varieties of siliceous manganese, see Rammelsberg's *Mineralchemie*, pp. 460—462.]

RHODOPHYLLITE. Syn. with RHODOCHROME.

RHODOTANNIC ACID, or **RHODOXANTHIN.** Tannic acid from the leaves of the *Rhododendron ferrugineum*. (R. Schwarz, Wien. Akad. Ber. ix. 298; Gm. xv. 530.)

RHOMB-SPAR. Syn. with Magnesite or native carbonate of magnesium (i. 787).

RHUBARB. *Rheum*. Many species of rhubarb—*Rheum palmatum*, *Rh. undulatum*, *Rh. compactum*, *Rh. australe*, *Rh. hybridum*, &c.—grow wild on the high lands of Central Asia, and some of them are cultivated in various parts of Europe. The roots are much used for their purgative properties; several kinds occur in commerce, the most esteemed being the Turkey rhubarb. In this country the waved garden rhubarb, *Rheum undulatum*, and the large garden rhubarb, *Rh. hybridum*, are much cultivated for the sake of their juicy stems, which have a pleasant acid taste, and are used for making pastry. The juice of the stems contains oxalic, citric, and malic acids, the latter sometimes in considerable quantity. Dessaignes (J. Pharm. [3] xxv. 23) obtained from a litre of the juice of *Rh. compactum* (after removing the oxalic acid by chloride of calcium), 15 grms. of acid calcic malate; *Rh. Rhaponticum*, on the other hand, yielded only 7 grms.

The root of rhubarb has been made the subject of numerous investigations, the most important of which are those of Schlossberger and Döpping (Ann. Ch. Pharm. l. 196), and of De la Rue and Müller (Chem. Soc. Qu. J. x. 298). Schlossberger and Döpping found, in the alcoholic tincture of rhubarb, a number of substances, which were afterwards found also by De la Rue and Müller in the deposit which separates from the tincture after long standing. These are:—1. *Chrysophanic acid*, which separates to the amount of about 4 per cent. from the alcoholic decoction of the precipitate; 2. *Erythroretin*, contained in the mother-liquor of the chrysophanic acid, and obtained from it by repeated precipitation with ether and solution in alcohol; 3. *Phæoretin*, the portion of the alcoholic decoction which is insoluble in ether; and 4. *Aporetin*, in the portion of the original deposit insoluble in boiling alcohol. (See these several substances.) By exhausting the pulverised root with benzene, or with light coal-tar oil, to extract the chrysophanic acid (which is the best mode of preparing that substance, i. 958), then distilling off the greater part of the solvent, pressing out the liquid from the nearly solid residue, and repeated solution in hot benzene, De la Rue and Müller likewise obtained a reddish-yellow crystalline substance, *emodin*, insoluble in benzene (ii. 485).

For the older investigations of rhubarb-root, which were made chiefly with the view of extracting an active medicinal principle from it, but did not lead to any definite result, see *Handwörterbuch der Chemie*, vi. 819. Schlossberger and Döpping are of opinion that the physiological action of the root cannot be attributed to any one of its constituents in particular.

The ash of the stems and leaves of rhubarb [what species?] has been analysed by Th. Richardson (Jahresb. 1847–48; Tafel C zu S. 1074), with the following results:—

	K^2O	Na^2O	CaO	MgO	SO^3	SiO^2	P^2O^5	$Fe'''PO^4$	$NaCl$		
Stems . .	59·59	0·46	10·04	. .	1·89	2·77	12·83	2·77	8·84	=	99·19
Leaves . .	14·47	31·77	3·95	5·59	9·52	2·33	30·04	2·33	trace	=	100·00

The stems [fresh or dry?] yielded 0·41 per cent., and the leaves 1·23 per cent. ash.

R. Brandes (Jahresb. 1853, p. 581) has examined the inorganic constituents of four kinds of rhubarb-root. A Russian species gave 5·03 per cent. water and 18·2 ash; a Chinese species 8·22 water and 8·82 ash; an older Austrian species, 9·0 water and 5·8 ash; a younger Austrian species (both cultivated at Bilitz), 11·2 water and 5·54 ash.

The ash from 100 pts. of the dried roots contained:—

	Soluble in water.					Insoluble in water.								
	KCl	K^2O	CaO	MgO	SO^3	Fe^2O^3	Al^2O^3	CaO	MgO	MnO	P^2O^5	SiO^2

Tip (Jahresb. 1854, p. 657) found in 100 parts of rhubarb-root dried at 100° (I. Russian, II. Chinese, III. Root of *Rheum palmatum*, IV. *a* the tap-root, and IV. *b* the branch-roots of *Rh. undulatum*), the following quantites of ash and calcic carbonate:—

	I.	II.	III.	IV. *a*.	IV. *b*.
Ash . . .	17·0	23·0	3·6	11·6	10·0
$CaCO^3$ therein .	15·5	22·3	1·7	11·5	8·4

RHUBARBARIC ACID. }
RHUBARBARIN. } Syn. with CHRYSOPHANIC ACID.

RHUS. *Sumach.* Many species of this genus are very rich in tannic acid, which in *Rhus Coriaria*, *Rh. glabra*, and *Rh. typhina*, exists in all parts of the plant. The tannic acid of the sumachs, like gallotannic acid, yields gallic acid when treated with sulphuric acid. (Stenhouse.)

The leaves of *Rh. copallina* and *Rh. glabra* contain a considerable quantity of acid malate of calcium. *Rh. Metopium* exudes a yellow, emetic, purgative resin; the wood is rich in tannin. *Rh. succedanea* is said by some authorities to yield Chinese wax; according to others, this substance is produced by an insect living on the plant.

The juice of the leaves of *Rhus Toxicodendron* contains gallic acid (Aschoff). Khittel (Jahresb. 1858, p. 530) found in these leaves, besides the usual plant-constituents, an iron-greening tannin and a volatile alkaloïd, which is the poisonous principle. *Rh. venenata* and *Rh. juglandifolia* also contain poisonous principles.

Rh. vernicifera contains a juice which blackens in the air, and is used for the preparation of Japan-varnish; the seeds contain a sebaceous oil. The milky juices of *Rh. Toxicodendron* and *Rh. venenata* likewise blacken on exposure to the air. (Rochleder's *Phytochemie*, pp. 30, 31.)

The air-dried leaves of *Rh. Toxicodendron* yield, according to Khittel, 7·30 per cent., the leaves dried at 100°, 7·91 per cent. ash, containing, in 100 pts.: 25·81 per cent. K^2O, 0·04 Na^2O, 21·59 CaO, 6·45 MgO, 0·49 Al^2O^3, 2·35 Fe^2O^3, 1·54 Cl, 3·98 SO^3, 11·57 P^2O^5, 6·86 SiO^2, 18·43 CO^2 (= 99·11).

The heart-wood of *Rhus pentaphyllum* yields, according to Comaille (J. Pharm. [3] xliii. 269; Jahresb. 1863, p. 616), 0·9 per cent. ash, containing in 100 pts.: 0·25 K^2O and Na^2O, 49·54 CaO, 0·27 MgO, 0·37 Al^2O^3, 8·20 Fe^2O^3, 0·14 Cl, 1·81 SO^3, 2·57 SiO^2, and 36·66 CO^2.

RICINELAÏDAMIDE. $C^{18}H^{35}NO^2$.—A product obtained by the action of alcoholic ammonia on ricinelaïdin. It closely resembles elaïdamide, melts at 91°—93°, and solidifies at 89°. (Rowney, Chem. Gaz. 1855, p. 361.)

RICINELAÏDIC ACID. $C^{18}H^{34}O^3$. *Palmic acid.* (Boudet, Ann. Ch. Pharm. iv. 16.—Playfair, *ibid.* lx. 322.—Bouis, Ann. Ch. Phys. [3], xliv. 82.—Gm. xvii. 135.)—An acid isomeric with ricinoleic acid, produced by the action of nitrous acid on the latter; also by saponifying ricinelaïdin with caustic potash, salting out the resulting soap, and decomposing it with hydrochloric acid. It crystallises in tufts of white silky needles, melting at 50° (Boudet, Bouis), and solidifying to a crystalline mass at 48·5°. Reddens litmus strongly; dissolves easily in alcohol and ether; decomposes alkaline carbonates. Decomposed by distillation, and by heating with soda, in the same manner as ricinoleic acid. The ricinelaïdates of the alkali-metals are soluble in water.—The *barium-salt*, $C^{36}H^{66}Ba''O^6$, obtained by precipitation, is a white powder unctuous to the touch.—The *silver-salt*, $C^{18}H^{33}AgO^3$, is a light white powder, soluble in ammonia, but insoluble in water, alcohol, and ether.

Ricinelaïdate of Ethyl, $C^{20}H^{38}O^3 = C^{18}H^{33}(C^2H^5)O^3$, formed by the action of hydrochloric acid gas on an alcoholic solution of the acid, is a crystalline mass, which melts at 16°, dissolves slightly in cold, very freely in hot alcohol. (Playfair.)

RICINELAÏDIN. $C^{39}H^{72}O^7$?—A solid fatty body produced by the action of nitric peroxide on castor-oil. When purified by washing with water and crystallisation from alcohol, it forms small white nodules melting at 43° (Playfair), at 45° (Bouis), at 62°—66° (Boudet). It solidifies slowly, after remaining pasty for a long time. It is very soluble in alcohol and ether. Caustic potash at the boiling heat converts it into glycerin and ricinelaïdate of potassium. When submitted to dry distillation, it behaves like castor-oil, yielding a dark brown-red, spongy residue, and a distillate of œnanthol (Bertagnini, Ann. Ch. Pharm. lxxxv. 282); and if the œnanthol be driven off by steam, there remains a solid acid, containing 73·8 per cent. carbon and 11·21 hydrogen (Bouis). With care the distillation may be continued to the end without formation of the spongy residue, in which case a large quantity of acrolein and solid hydrocarbons pass over, whilst a little carbon remains behind (Bouis). By distillation with excess of *potash*, ricinelaïdin yields octylic alcohol, sebate of potassium, and two other acids. (Bouis.)

RICINIC ACID. A fatty acid, containing 73·6 per cent. carbon, 9·9 hydrogen, and 16·5 oxygen, said by Bussy and Lecanu to be obtained, together with others, by the saponification, and by the distillation, of castor-oil. (*Gmelin's Handbook*, xvii. 140.)

RICININE. (Tuson, Chem. Soc. J. xvii. 195.)—An alkaloïd contained in the seeds of the castor-oil plant (*Ricinus communis*). The seeds of *Croton Tiglium* contain a similar or perhaps the same base. To prepare it, bruised castor-seeds are exhausted by repeated boiling with water; the decoction is strained, and, after separating the oil as completely as possible, evaporated to an extract, which is boiled with alcohol and filtered. After standing 24 hours, the tincture is separated from the deposited resin, and the alcohol is distilled off. The residue, on standing, deposits crystals of ricinine, which are purified by recrystallisation from alcohol, with the help of charcoal.

Ricinine forms colourless rectangular prisms and laminæ, having a slight taste of bitter almonds, insoluble in water, soluble in alcohol, nearly insoluble in ether and in benzene. When heated, it melts to a colourless liquid, which solidifies in crystalline needles. Sublimes unchanged between two watch-glasses. Contains nitrogen.

When strongly heated on platinum-foil, it burns with a luminous smoky flame. Dissolves in *oil of vitriol* without coloration; the solution is coloured green by chromate of potassium.—Dissolves in *nitric acid* without evolving red fumes, and on evaporation leaves colourless needles, which turn white in water.

Ricinine is insoluble in *water*.—It forms with *hydrochloric acid* a compound, which is decomposed by evaporating the solution.—Its solution mixed with *mercuric chloride*, solidifies after some minutes to a crystalline mass of fine needles.—The hydrochloric acid solution, when evaporated with *chloride of platinum*, yields orange-coloured octahedrons of the double salt.

RICINOLEAMIDE. $C^{18}H^{35}NO^2 = \left.\begin{matrix}C^{18}H^{33}O^2\\H^2\end{matrix}\right\}N$. (Boullay, J. Pharm. [3], v. 329.—Bouis, Ann. Ch. Phys. [3] xliv. 96.)—Produced by saturating an alcoholic solution of castor-oil with ammonia-gas, and leaving it to stand for three or four months, or heating it for a few days in a salt-bath. When purified by crystallisation from alcohol, it forms white crystalline needles, melting at 66°, and solidifying to an opaque brittle mass. It is insoluble in water, soluble in alcohol and ether, and is resolved by acids and alkalis into ammonia and ricinoleic acid.

RICINOLEIC ACID. $C^{18}H^{34}O^3 = \left.\begin{matrix}C^{18}H^{33}O^2\\H\end{matrix}\right\}O$. (Bussy and Lecanu, J. Pharm. xiii. 70.—Saalmüller, Ann. Ch. Pharm. lxiv. 108.—Svanberg and Kolmodin, J. pr. Chem. xlv. 431.—Bouis, Ann. Ch. Phys. [3] xliv. 103, and xlviii. 99.—Petersen, Ann. Ch. Pharm. cxviii. 69.—Gm. xvii. 131.)—A fatty acid produced by saponification of castor-oil and of the oil of *Jatropha Curcas*.

Preparation.—Castor-oil is saponified with potash or soda-ley; the soap is salted out and decomposed by hydrochloric acid; and the oily mixture of ricinoleic acid with a small quantity of solid fatty acids is cooled to −10° or −12° with ½ its volume of alcohol: the solid acids then crystallise out, and are removed. After driving off the alcohol, the ricinoleic acid is digested with excess of lead-oxide, and the lead-salt formed is dissolved in ether, and decomposed by hydrochloric acid and water. The ricinoleic acid, which is left on evaporating the ethereal layer, is purified by dissolving it in aqueous ammonia, precipitating with chloride of barium, and crystallising the barium-salt from alcohol. From the barium-salt the acid is obtained by decomposition with aqueous hydrochloric acid.

Properties.—Ricinoleic acid is a pale wine-yellow syrupy oil, colourless in thin layers. Specific gravity, 0·94 at 15°. Solidifies completely, at − 6° to − 10°, to a granular mass. Inodorous. Has a very disagreeable, persistent, harsh taste. It mixes in all proportions with alcohol and ether. The alcoholic solution has an acid reaction, and decomposes carbonates with effervescence.

Decompositions.—1. Ricinoleic acid, subjected to distillation, yields at first a limpid and afterwards a thick and repulsive-smelling distillate, free from sebacic acid (Saalmüller).—2. It does not absorb oxygen from the air, or even on long exposure to the gas, and does not form carbonic acid (Saalmüller).—3. It absorbs a little sulphurous acid gas, without becoming solid or otherwise altered. (Saalmüller.)

4. By the dry distillation of ricinoleates of the alkali-metals, various products are obtained, according as the neutral salt is distilled alone, or with an excess of alkali:

a. By cautiously distilling the *neutral sodium-salt* until the residue begins to froth up, a distillate of œnanthol (iv. 174) is obtained, the residue containing the sodium-salt of the same acid that is formed by the dry distillation of castor-oil. The sodium-salt and the glyceride of ricinoleic acid are therefore decomposed in the same manner by distillation (Städeler). According to Bouis, the neutral ricinoleates of the alkali-metals yield, by dry distillation, octylic aldehyde (xiii. 187), and a peculiar acid:

$$C^{18}H^{34}O^3 = C^8H^{16}O + C^{10}H^{18}O^2.$$

b. A mixture of potassic or sodic ricinoleate with excess of the caustic alkali froths up when heated, emitting an odour like that of mushrooms; then thickens, gives off at 250° a large quantity of hydrogen gas (no carbonic anhydride or gaseous hydrocarbon) and a volatile oil, and leaves a white spongy residue, consisting of sebate of potassium, together with a neutral oil, which yields a white soap by saponification, and deposits crystals of palmitic acid when cooled (Bouis). The volatile oil is a mixture of methyl-œnanthyl with heptylic or octylic alcohol, or both. (See ALCOHOLS, i. 98; HEPTYLIC ALCOHOL, iii. 145; OCTYLIC ALCOHOL, iv. 170).—According to E. T. Chapman (Chem. Soc. Qu. J. xviii. 290), sometimes the one, sometimes the other alcohol is produced.—The same products are obtained by heating castor-oil with excess of caustic soda. (Bouis.)

Ricinoleates.—Ricinoleic acid is monobasic, the general formula of its salts being

$C^{18}H^{33}MO^2$, or $C^{36}H^{66}M''O^6$. These salts are all soluble in alcohol, most of them also in ether, and crystallisable. They do not alter by keeping, or absorb oxygen from the air.

The *barium-salt*, $C^{36}H^{66}Ba''O^6$, prepared as above (p. 110), crystallises from alcohol in soft scales, slightly soluble in water.—The *strontium-salt*, $C^{36}H^{66}Sr''O^6$, obtained by precipitating the ammonium-salt with chloride of strontium, crystallises from alcohol in small grains.—The *calcium-salt*, $C^{36}H^{66}Ca''O^6$ (at 100°), prepared in like manner, forms scales, which melt at 80° to a yellow mass, brittle and friable after cooling.—The *magnesium-salt*, $C^{36}H^{66}Mg''O^6$, is very soluble in alcohol, and crystallises therefrom in slender needles.—The *zinc-salt* forms small granules.

Lead-salt, $C^{36}H^{66}Pb''O^6$.—The acid heated with excess of lead-oxide loses 2·9 to 3·6 per cent. of water (1 at. = 3·02 per cent.), and forms a solid compound, the ethereal solution of which, evaporated over oil of vitriol, leaves the lead-salt as a transparent crystalline mass, melting at 100° to a light-brown viscid liquid, and solidifying to an easily pulverisable mass. It is very soluble in ether; dissolves in cold, and not much more freely in hot alcohol.—By precipitating ammoniacal ricinoleic acid with neutral acetate of lead, a curdy precipitate of variable composition is obtained. (Saalmüller.)

Silver-salt, $C^{18}H^{33}AgO^3$.—Nitrate of silver throws down from the ammonium-salt a curdy precipitate, which, when treated with alcohol or ether, partially dissolves, but for the most part blackens and remains undissolved. It softens at 100°, melts at higher temperatures to a black mass, and burns with evolution of disagreeably-smelling vapours; dissolves easily in hot alcohol, and slightly in cold alcohol and ether.

Ricinoleate of Ethyl, $C^{20}H^{38}O^3 = C^{18}H^{33}(C\ H^5)O^3$, is prepared by passing hydrochloric acid gas into a solution of the acid in absolute alcohol, and purified by washing with water and carbonate of sodium. It is a yellowish oil, which cannot be distilled without decomposition. (Saalmüller.)

RICINO-MARGARITIC and **RICINO-STEARIC ACIDS.** Names applied by Bussy and Lecanu to certain fatty acids of doubtful composition, obtained from castor-oil: probably mixtures of stearic and palmitic acid. (See CASTOR-OIL, i. 815; also *Gmelin's Handbook*, xvii. 140.)

RIEMANNITE. Syn. with ALLOPHANE (i. 132).

RINMANN'S GREEN. See COBALT-GREEN (i. 1057).

RIOLITE. A selenide of silver, occurring in small lead-grey hexagonal tables, at Tasco in Mexico. Contains, according to Del Rio, 57·7 per cent. silver and 42·34 selenium, whence the formula AgSe. Requires further examination. (Dana, ii. 502.)

RIPIDOLITE. A mineral resembling chlorite in many respects, and allied to it in chemical composition. It occurs in crystals commonly referred to the hexagonal system, with very distinct cleavage parallel to the base. Crystals from the Tyrol exhibit the form of double six-sided pyramids, having the angles of the terminal edges = 132°40′, of the basal edges = 106°30′ (Descloizeaux). According to later observations by Descloizeaux (Ann. Min. [5], xi. 261), however, the crystals have two optic axes inclined to one another at an angle of 20°: hence it would appear probable that the mineral is monoclinic, like chlorite (i. 913).

Hardness = 1—2. Specific gravity = 2·78—2·96. Translucent to nearly transparent, with pearly lustre and green colour, but red across the axis by transmitted light. Streak uncoloured or greenish. Laminæ flexible, not elastic. Before the blowpipe it behaves like chlorite.

Analyses: *a*, *b*. From Greiner in the Zillerthal (v. Kobell, Ann. Ch. Pharm. xl. 244).—*c*. Gumuchdagh, in Asia Minor (Smith, Ann. Min. [4], xviii. 304).—*d*. Mont des Sept-Lacs, Dauphiné (Marignac, Ann. Ch. Phys. [3], xiv. 56).—*e*. Rauris, in the Pinzgau (v. Kobell).—*f*. St. Gotthardt (Varrentrapp, Pogg. Ann. xlviii. 185).—*g*. From the same (Rammelsberg, *ibid.* lxxvii. 414).—*h*. St. Christophe, Dauphiné, (Marignac):—

	a.	*b.*	*c.*	*d.*	*e.*	*f.*	*g.*	*h.*

* With 0·47 manganous oxide.
† With 0·62 " "

These results may be represented by the formula $4M''SiO^3.\ \overset{=}{M}{}^3\overline{\overline{Al}}{}^2O^6.\ 6H^2O$, the numbers of atoms of ferrous oxide and magnesia being in *b.* as 1 : 3, in *d.* as 5 : 6, in *e. f.* as 1 : 1, in *g.* as 5 : 7, and in *h.* as 6 : 5.

Ripidolite occurs also in Scotland.

RISIGALLO. Syn. with REALGAR.

RITTINGERITE. A mineral from the Joachimsthal, occurring in small blackish monoclinic crystals, which behave before the blowpipe like pyrargyrite. According to Breithaupt, it is identical with **xanthocone** (*q.v.*).

RIVULIN. A mucilaginous substance obtained from a freshwater alga, *Rivula tuberosa*. (**Braconnot**, Ann. Ch. Phys. [2] lxx. 206.)

ROBINIC ACID. An acid existing, according to **Reinsch** (Répert. Pharm. [2] xxxix. 198), in the root of the false acacia (*Robinia pseudacacia*). The infusion of the root, evaporated to a syrup, and left in a cool place, deposits rhomboïdal crystals of robinate of ammonium. The free acid is a syrupy mass, which becomes crystalline in contact with absolute alcohol.

ROBINIIN. A yellow colouring matter existing, according to **Kümmell** (N. Br. Arch. xciii. 295), in the wood of *Robinia pseudacacia*, from which it is obtained by precipitating the aqueous decoction with basic acetate of lead, and decomposing the precipitate with sulphydric acid.

ROBININ. $C^{25}H^{30}O^{16}$. (**Zwenger** and **Dronke**, Ann. Ch. Pharm. Suppl. i. 257; Jahresb. 1861, p. 774; 1862, p. 498.)—A yellow substance contained in the blossoms of *Robinia pseudacacia*. To prepare it, the recently gathered flowers are boiled in water, and the decoction is again boiled six or eight times with fresh flowers; it is then evaporated to a syrup, which is repeatedly exhausted with boiling alcohol; the alcohol is distilled off, and the residue is set aside to crystallise; the crystals are pressed and washed with cold alcohol, to remove the greater part of the mother-liquor, and dissolved in boiling water; and neutral acetate of lead is added to the solution, whereby foreign substances are precipitated, while the robinin remains dissolved. The filtrate is freed from lead by sulphydric acid and evaporated, and the robinin is purified by recrystallisation from water.

Robinin thus prepared forms very delicate straw-yellow crystals, having a somewhat silky lustre, and containing $2C^{25}H^{30}O^{16}.11H^2O$. They give off their water (14·45 per cent.) at 100°, leaving anhydrous robinin, which melts to a yellow liquid at 195°, and solidifies to an amorphous mass on cooling. Anhydrous robinin gave by analysis 50·98 per cent. C, and 5·51 H (calc. 51·19 C, 5·10 H, 43·71 O); the hydrate gave 43·50 C and 6·33 H (calc. 43·79 C, 5·98 H, 50·23 O).

Robinin is neutral, tasteless in the solid form, slightly styptic in aqueous solution. Water and alcohol dissolve it slightly in the cold, more freely at the boiling heat; it is insoluble in ether. It dissolves quickly in alkalis and alkaline carbonates, forming golden-yellow solutions; the ammoniacal solution turns brown on standing. The aqueous solution does not precipitate metallic salts; it colours ferric chloride dark-brown or greenish, but does not affect ferrous chloride. The alcoholic solution precipitates neutral and basic acetate of lead. It reduces cupric oxide in a boiling alkaline solution; is not altered by emulsin.

By dry distillation, robinin yields a yellow distillate, containing quercetin in solution. When heated above its melting point, it burns with a smoky flame and a smell of burnt sugar, and leaves charcoal. It is decomposed by concentrated *nitric acid* (with peculiar facility by the fuming acid), with formation of oxalic acid and a large quantity of picric acid. When heated with *dilute acids*, it splits up very readily into quercetin and robinin-sugar:

$$C^{25}H^{30}O^{16} + 2H^2O = C^{13}H^{10}O^6 + 2C^6H^{12}O^6.*$$

100 parts of crystallised robinin yield 37·96 parts of quercetin, dried at 100° (by calculation 38·25 parts).

Robinin-sugar does not crystallise, but is obtained as a sweet brown syrup, which smells like caramel when heated, and yields with nitric acid a large quantity of picric acid, together with traces of oxalic acid. It reduces *cuprate of potassium* in the cold; does not undergo fermentation with beer-yeast.

ROCCELLANILIDE, or *Phenyl-roccellamide*, $C^{29}H^{42}N^2O^2 = \left.\begin{matrix}(C^{17}H^{30}O^2)''\\(C^6H^5)^2\\H^2\end{matrix}\right\}N^2$. — When roccellic acid is heated with excess of aniline to 180°—200°, water and aniline distil over, and a black pitchy residue is left, which when drenched with alcohol yields crystals after a few days. These are collected and purified by repeated crystallisation from boiling alcohol, with help of animal charcoal. Roccellanilide thus obtained, forms beautiful colourless laminæ, which melt to a colourless liquid at 53·3°, and solidify partially at 52°. Neutral. At a somewhat elevated temperature, it yields a colourless distillate, without any carbonaceous residue. It is insoluble in water, aqueous ammonia, and hydrochloric acid; not coloured by hypochlorite of sodium. The alcoholic solution does not precipitate alcoholic neutral acetate of lead.

---

* It will be observed that the formula of robinin is related to that assigned toquercetin by Zwenger and Dronke (p. 4).

ROCCELLIC ACID. $C^{17}H^{32}O^4 = \left.\begin{matrix}(C^{17}H^{30}O^2)''\\ H^2\end{matrix}\right\} O^2$.—A kind of fatty acid existing in *Roccella tinctoria* and other species of the same genus; also, according to Heeren, in *Lecanora tartarea*. It was discovered in 1830 by Heeren (Schw. J. lix. 346), and has been examined by Liebig (Pogg. Ann. xxi. 31), Schunck (Ann. Ch. Pharm. xxxviii. 459), and Hesse (*ibid.* cxvii. 332).

Preparation.—1. *Roccella tinctoria* is exhausted with aqueous ammonia; the filtrate is precipitated by chloride of calcium; the well-washed precipitate is decomposed by hydrochloric acid; and the acid thus separated is purified by solution in ether (Heeren). The liquid filtered from the roccellate of calcium retains erythric acid (ii. 502) in solution.—2. The lichen is freed from erythric acid by milk of lime; the residue is boiled with dilute hydrochloric acid; the acid solution is removed; and the residue warmed with dilute soda-ley. From the greenish-brown solution, hydrochloric acid throws down green flocks, which must be suspended in water and treated for a short time with chlorine gas, which chiefly removes the green substances. The acid, after being treated with chlorine, is washed with water, and purified by recrystallisation from boiling alcohol, with help of animal charcoal (Hesse). The acid obtained by method 1 may also be purified in this manner, or by passing chlorine into the alkaline solution (Hesse).—3. The lichens are exhausted with ether in a percolator; the ether is distilled off; and the greenish-white crystalline residue is dissolved in the smallest possible quantity of borax-solution, a portion then separating out as the liquid cools. The rest is precipitated by hydrochloric acid, and purified by re-solution in boiling aqueous borax; then, together with the portion of acid first obtained, by recrystallisation from ether, with help of animal charcoal (Hesse). Schunck treats the lichen exhausted with boiling water, and thereby freed from erythric acid [and picroerythrin (ii. 503)], with boiling alcohol; separates the green flocks, which fall down as the tincture cools; and evaporates the filtrate to dryness. From the residue, boiling water extracts a small quantity of picroerythrin; the solution then prepared with cold alcohol deposits, on addition of alcoholic neutral acetate of lead, greenish-white flocks of roccellate of lead, which are decomposed by nitric acid; and the acid thus separated is purified by recrystallisation from boiling alcohol, with help of animal charcoal.

Properties.—Roccellic acid forms delicate, white, rectangular, four-sided plates, having a silvery lustre; from alcohol it separates in short needles. Melts at 132° to a colourless liquid, which solidifies in the crystalline form at about 108°. At a temperature somewhat below 200°, a portion volatilises, while another portion is converted into an anhydride (Hesse). It is tasteless and scentless; the alcoholic solution has an acid reaction. It is perfectly insoluble in water, dissolves in 1·81 pt. of boiling alcohol of specific gravity 0·819, easily in *ether* (Heeren); slightly in warm *benzene*. (Hesse.)

Decompositions.—The acid heated to between 220° and 280° gives off water, turns brown, and leaves roccellic anhydride, $C^{17}H^{30}O^3$ (Hesse). By dry distillation it yields sharp-tasting products similar to those obtained from the fats (Heeren); according to Schunck, a distillate which solidifies in the crystalline form, and after repeated distillation. remains oily, leaving little or no residue. Roccellic acid is but little affected by reagents. It is not decomposed by bromine, sulphuric acid, or hydrochloric acid, and is but slowly oxidised by boiling with hydrochloric acid and chlorate of potassium. When boiled for a long time with fuming nitric acid, it gives off volatile acids having the odour of butyric acid, but does not yield any crystallisable non-volatile acids. It is but slightly altered by fusion with hydrate of potassium; heated with aniline, it forms roccellanilide. (Hesse.)

Roccellates.—Roccellic acid decomposes carbonates. The roccellates of the alkali-metals are soluble in water; the other salts have for the most part the composition $C^{17}H^{30}M''O^4$.—The *barium-salt*, $C^{17}H^{30}Ba''O^4$, obtained by precipitating the ammonium-salt with chloride of barium, is a bulky white precipitate, somewhat soluble in boiling water, insoluble in pure alcohol, but easily soluble in alcohol containing acetic acid.—The *calcium-salt*, $C^{17}H^{30}Ca''O^4.H^2O$, is a white amorphous precipitate, which gives off 48 per cent. water at 160°, and decomposes at a higher temperature, giving off acrolein and a combustible gas (Hesse).—A *basic lead-salt*, $2C^{17}H^{30}Pb''O^4.Pb''H^2O^2.2H^2O$, is obtained by precipitating alcoholic roccellic acid with a warm alcoholic solution of neutral lead-acetate, as a white powder which gives off a small quantity of water at [illegible] then 1·9 per cent. at 125° and melts at a higher temperature (Hesse).—The [illegible] H^4Ag^2 [illegible] obtained by precipitation, is a white amorphous mass, which turns grey on exposure to light. (Hesse.)

[illegible] obtained by passing hydrochloric acid gas into a warm alcoholic solution of the acid, is a pale-yellow oil, having a [illegible] heavier than water, insoluble in water and in aqueous ammonia, and not decomposed either by aqueous or by alcoholic ammonia even after several months' contact, or when heated to [illegible]. It is easily soluble in alcohol, less soluble in ether. (Hesse.)

ROCCELLIC ANHYDRIDE. [illegible].—Obtained by heating roccellic acid to at least 200°, treating the fused brown mass with dilute soda-ley, then agitating it with ether, and evaporating the decanted ethereal solution. It is a colourless or faintly yellow neutral oil, having a fatty odour, makes grease-spots on paper; dissolves sparingly in cold, more easily in hot alcohol and in ether. Boiling soda-ley converts it into roccellic acid. The [illegible] mixed with hydrochloric acid, deposits white flocks [illegible] in alcohol, and remaining, when the alcohol is evaporated, as a semi-crystalline acid oil having a burning taste: probably a mixture of roccellic and roccellamic acids. (Hesse.)

ROCCELLIC ETHER. ([illegible])

ROCCELLININ. [illegible] (Stenhouse, Ann. Ch. Pharm. lxviii. 69.)—A crystalline substance obtained, together with β-orsellic acid (iv. 235), from *Roccella tinctoria*. To prepare it, the gelatinous mass obtained by precipitating the lime-extract of the lichen with hydrochloric acid is boiled with alcohol, whereby the β-orsellic acid is transformed into orsellinate of ethyl (iv. 236), while the roccellinin remains unaltered. The product is treated with boiling water, which dissolves out all the ethylic orsellinate, leaving the roccellinin undissolved.

Roccellinin crystallises from boiling alcohol in silky needles, nearly insoluble in cold alcohol and ether. It gives by analysis 62·44—62·67 per cent. carbon, and 4·65—4·90 hydrogen, the formula [illegible] requiring 62·8 C., 4·7 H. and 32·5 O. It is easily dissolved by ammonia and the fixed alkalis: the solutions do dot become coloured on exposure to the air. It is not attacked by baryta or by boiling potash. It does not precipitate metallic solutions. Hot nitric acid converts it into oxalic acid.

ROCHELLE-SALT. Sodio-potassic tartrate. (See TARTARIC ACID.)

ROCHLANDITE. Syn. with SERPENTINE.

ROCK-CORK. A variety of asbestos (i. 415).

ROCK-CRYSTAL. Pure crystallised silica. (See QUARTZ.)

ROCK-MILK, or *Agaric Mineral.* A loose friable variety of limestone (iii. 696).

ROCK-SALT. See SODIUM, CHLORIDE OF.

ROCK-SOAP. A variety of bole.

RŒMERITE. A hydrated ferroso-ferric sulphate, occurring on the Rammelsberg, near Goslar, in monoclinic crystals, accompanied and interpenetrated by ferrous and ferric sulphates. (*Rammelsberg's Mineralchemie*, p. 292.)

RŒSSLERITE. A hydrated arsenate of magnesium, occurring, together with pharmacolite and cobalt-bloom, in the cupriferous shale of Biber, near Hanau. It forms thin fibrous or laminar plates, or dentiform and vermicular masses, apparently cleavable in one direction; hardness (of the unaltered mineral) = 2 to 3. Translucent to transparent, colourless or white, with vitreous lustre. On exposure to the air it becomes opaque, dull, and less hard, apparently from loss of water. Before the blowpipe it gives up its water and melts to a white enamel. Dissolves easily in hydrochloric acid (Blum, Jahresb. 1861, p. 1031). Contains, according to Delffs, 40·16 As^2O^5, 14·22 MgO, with trace of cobalt, and 45·62 water (= 100), whence the formula $2Mg''O.As^2O^5.15H^2O$.

RŒTTISITE. A mineral, consisting essentially of hydrated nickel-silicate, occurring, together with conarite (hydrated nickel-phosphate), in the Hans-Georg mine near Röttis, in the Saxon Voigtland. It forms thick lenticular and wedge-shaped masses, sometimes weighing several pounds; is of an emerald-green colour, rarely passing into apple-green; usually dull and opaque, but translucent on the edges; sometimes brittle, and splits with moderate facility. Fracture conchoïdal to earthy. Streak, dark apple-green. Hardness = 2 to 3. Specific gravity = 2·356 to 2·370. A. Winckler found in lumps translucent on the edges:

NiO	CoO	CuO	Fe^2O^3	Al^2O^3	SiO^2	P^2O^5	As^2O^5	SO^3	H^2O		
35·87	0·67	0·40	0·81	4·68	39·15	2·70	0·80	trace	11·17	=	95·55

Hence the mineral appears to consist essentially of $3(3Ni''O.SiO^2).4H^2O$. (Breithaupt, Jahresb. 1859, p. 791.)

ROMANZOVITE. A brownish lime-garnet from Kimito in Finland.

ROMEINE, or **ROMEITE.** A mineral found at St. Marcel in Piedmont, in groups of minute crystals in the gangue which accompanies manganese. The crystals are dimetric octahedrons, having the basal angle = 110° 50′—111° 20′, and the angle over the summit 68° 10′—69° 10′ (Dufrénoy). It scratches glass. Specific gravity in grains = 4·714; in powder = 4·675. Colour, hyacinth or honey-yellow. Contains 15·82 per cent. oxygen, 62·18 antimony, 1·31 iron, 1·21 manganous oxide, 16·29 lime, 0·96 soluble silica, and 1·90 insoluble silica = 99·67 (or 40·79 Sb^2O^5, 36·82 Sb^2O^3, 1·70 FeO, 1·21 MnO); and may be represented by the formula $3M''O.Sb^2O^3.Sb^2O^5$. (Damour, Ann. Min. [3] xx. 247; [5] iii. 179.)

ROSANILINE. *Aniline-red.* See PHENYLAMINES (iv 468). Nitrous acid converts it into rosolic acid. (Wanklyn and Caro, p. 117.)

Hydrocyan-rosaniline, $C^{21}H^{20}N^4 = C^{20}H^{19}N^3.HCy$. (Hugo Müller, Zeitschr. Ch. Pharm 1866.)—A base produced by addition of the elements of hydrocyanic acid to rosaniline, analogous therefore in composition to hydrocyanharmaline (iii. 8). It has a great resemblance to leucaniline, the base formed from rosaniline by addition of hydrogen (iii. 574). It is prepared by treating a finely pulverised rosaniline-salt with alcohol and cyanide of potassium (the latter being added in the proportion of about ⅛, if acetate of rosaniline is used); the resulting yellowish white powder is washed on a filter with alcohol, then dissolved in dilute hydrochloric acid; the solution is warmed and mixed with dilute alcohol; and the base is precipitated by ammonia, mixed with a little cyanide of potassium or hydrocyanic acid, in case the solution should still exhibit a red colour from unaltered rosaniline. A white or yellowish-white bulky precipitate is thus obtained, which becomes crystalline after a while, and then quickly settles down. If it is coloured, it may be purified by resolution and reprecipitation; or the hydrochloric acid solution may be decolorised by treatment with animal charcoal.

Hydrocyan-rosaniline precipitated from the aqueous hydrochlorate by ammonia, forms a dazzling white opaque crystalline powder. From a warm alcoholic solution, it separates in small transparent monoclinic crystals, having a splendid diamond lustre. Alkalis added to a very dilute aqueous solution of one of its salts, separate the base either as a milky turbidity or a curdy precipitate resembling chloride of silver. It is permanent in the dark, but becomes rose-red on the surface when exposed to sunlight. It is decomposed by fusion with potash, apparently with reproduction of rosaniline.

Hydrocyan-rosaniline dissolves very easily in hydrochloric, nitric, and sulphuric acids, forming colourless crystallisable salts. The *hydrochlorate* separates from a very concentrated solution, in large apparently monoclinic crystals, permanent in the air, and very soluble in alcohol. The *nitrate* and *sulphate* are also very soluble, but more difficult to crystallise, the solutions having a great tendency to dry up to gummy masses. The solution of the hydrochlorate is not precipitated by chloride of platinum, but on evaporation, the *chloroplatinate* separates as a heavy resinous body. A solution of potassic *picrate* forms, even in very dilute solutions of the salts, a yellow flocculent precipitate, which at a gentle heat cakes together to a dark-yellow resin.

ROSE, OIL OF. A volatile oil, extracted chiefly in Persia, India, and the State of Tunis, from several species of very odoriferous roses, especially *Rosa centifolia*, *R. damascena*, *R. moschata*. It is a thick yellow liquid, solidifying at low temperatures to a buttery mass of transparent, colourless, shining laminæ, which does not liquefy completely again below 28°—30°. The scent of the oil is very fragrant when much diluted; but in the concentrated state it causes headache. The oil is a mixture, in variable proportions, of a camphor or stearoptene, and an oxygenated oil which has not been analysed. Specific gravity of the crude oil = 0·87 (Chardin, Ann. Ch Pharm. vii. 154); 0·8912 at 15·5° (Gladstone and Dale, Chem. Soc. Qu. J. xvii. 1). Index of refraction at 25° = 1·4567 for the line A, 1·4627 for D, 1·4835 for H. Molecular rotatory power = 7°. (Gladstone and Dale.)

Rose-camphor is very slightly soluble in alcohol, but very freely in ether and essential oils. It forms laminæ, melting at 35°, and boiling between 280° and 300°. It is a hydrocarbon having the composition of ethylene (Saussure, Blanchet, and Sell). It is soluble in caustic potash and acetic acid; very slightly attacked by hydrochloric and nitric acid.

Oil of roses is often adulterated with oil of geranium. According to Guibourt (J. Pharm. xv. 345), the adulteration may be detected, either by means of strong *sulphuric acid*, which does not impair the purity and sweetness of rose-oil, but developes in geranium-oil a strong disagreeable odour, even with very small quantities; or by exposing the oil to *iodine-vapour*, which does not alter the colour of rose-oil, but colours geranium-oil a very deep brown; or by exposing it to *nitrous acid*, which colours rose-oil deep yellow, and geranium-oil apple-green.

ROSEINE. Syn. with Rosaniline (iv. 468).—D. S. Price (Rep. Pat. Invent. 1860, p. 159; Jahresb. 1859, p. 760) applies the term especially to the red dye obtained by treating sulphate of aniline with peroxide of lead.

ROSELITE. An arsenate of cobalt, occurring in small quantity, on quartz, at Schneeberg in Saxony, in trimetric crystals, having the angle $\infty P : \infty P = 132° 48'$; $oP : \bar{P}\infty = 158° 2'$. Cleavage distinct and brilliant, parallel to $\infty \bar{P}\infty$. Hardness = 3. Colour deep rose-red. (Levy, *Dana's Mineralogy*, ii. 417.)

ROSELLAN, or **ROSITE.** A variety of anorthite, from Aker in Södermanland, Sweden, having a rose-red colour and granular structure. When heated, it gives off water and becomes colourless; melts easily before the blowpipe. Contains, according to Svanberg, 44·90 per cent. silica, 34·50 alumina, 0·69 ferric oxide, 0·19 manganic oxide, 3·59 lime, 2·45 magnesia, 6·63 potash, and 6·53 water. (*Rammelsberg's Mineralchemie*, p. 592.)

ROSEMARY, OIL OF. Obtained by distilling the fresh leaves and flowers of *Rosmarinus officinalis* with water. It is transparent, colourless or yellow, of specific gravity 0·88 to 0·91 (Zeller), 0·9080 at 15·5° (Gladstone and Dale). Boils at 165°—168° (Kane); neutral; has a camphorous taste, and the odour of the plant. Index of refraction at 16·5° = 1·4632 for A; 1·4688 for D; 1·4867 for H. Optical rotatory power = —17° (Gladstone and Dale). According to Lallemand, on the contrary, it is dextrorotatory.

Oil of rosemary is blackened by strong sulphuric acid; the mixture saturated with lime yields the calcium-salt of a peculiar acid (Unverdorben). The mixture of rosemary-oil and sulphuric acid yields by distillation an empyreumatic oil (Kane's *rosmarine*) having the alliaceous odour of mesitylene, a specific gravity of 0·807, boiling at 173°, and isomeric with turpentine-oil. (See *Gmelin's Handbook*, xiv. 396.)

According to Lallemand (Ann. Ch. Phys. [3] lvii. 404), oil of rosemary may be separated by fractional distillation into two oils, one boiling at 165°, the other between 200° and 210°.—*a.* The former is a mobile hydrocarbon, which turns the plane of polarisation to the left; it unites with *hydrochloric acid*, the combination being attended with rise of temperature, and forms a compound, which remains liquid if left to itself, but when treated with nitric acid, yields a considerable quantity of a crystalline hydrochlorate, apparently identical with hydrochlorate of turpentine-oil, or artificial camphor, $C^{10}H^{16}.HCl$. The same oil quickly absorbs moist oxygen in sunshine, forming crystals, which are similar to those produced in like manner from oil of turpentine, but disappear if subjected to the further action of oxygen, yielding a brown acid soluble in water.

b. The portion boiling between 200° and 210° deposits, at low temperatures, a large quantity of camphor, resembling common camphor in all respects, excepting that it has rather less dextrorotatory power. An additional quantity of it may be obtained by treating the mother-liquor with dilute nitric acid.

ROSENITE. Syn. with Plagionite.

ROSEO-CHROMIC SALTS. See Chromium (i. 951).

ROSEO-COBALTIC SALTS. See Cobalt-bases, Ammoniacal (i. 1052). For Braun's view of the constitution of these and other ammoniacal cobalt-compounds, see Ann. Ch. Pharm. cxxxii. 33; Jahresb. 1864, p. 273.

ROSE QUARTZ. See Quartz (p. 1).

ROSETTE-COPPER. See Copper (ii. 33).

ROSEWOOD, OIL OF. *Oleum ligni rhodii.*—A volatile oil obtained from rosewood (*Convolvulus scoparius*), by distillation with water. It is pale-yellow, somewhat viscid, and consists, to about $\frac{4}{5}$, of a hydrocarbon, $C^{10}H^{16}$, which boils at 249°, and smells like roses and sandalwood. Specific gravity of the crude oil = 0·9064 at 15·5°. Index of refraction at 17° = 1·4843 for A; 1·4903 for D; 1·5113 for H. Optical rotatory power = —16° (Gladstone and Dale). Rosewood-oil is sometimes used for adulterating oil of roses, which thereby loses its buttery consistence.

ROSITE. Syn. with Rosellan.

ROSOLIC ACID. A compound produced by the oxidation of phenol in presence of alkalis. It was discovered by Runge (Pogg. Ann. xxxi. 70), amongst the products obtained by treating coal-tar oil with milk of lime. When the mixture of phenol, rosolic acid and brunolic acid (i. 684), thus obtained, is distilled with water, phenol passes over, and a pitchy residue is left, containing rosolic and brunolic acids. This residue, dissolved in alcohol and mixed with milk of lime, yields a rose-coloured solution of calcic rosolate, and a brown precipitate of calcic brunolate. The solution evaporated to a syrup, and mixed with a third of its volume of alcohol, deposits, after a few days, rose-coloured crystals of calcic rosolate, from which the rosolic acid may be separated by acetic acid (Runge). To obtain the rosolic acid pure, the treatment with lime and alcohol, and the decomposition of the calcium-salt by acetic acid, must be repeated several times; and finally, the alcoholic solution of the acid, which is still not quite free from lime, must be mixed with a little hydrochloric acid, and diluted with a large quantity of water: the rosolic acid then separates out pure. (Hugo Müller, Chem. Soc. Qu. J. xi. 1: see also Tschelnitz. J. pr. Chem. lxxi. 416; Jahresb. 1857, p. 447.)

Rosolic acid is more easily prepared by heating phenol with certain metallic oxides in presence of an alkali. R. Angus Smith (Chem. Gaz. p. 20), obtained it by heating phenol with soda and peroxide of manganese; but it is difficult to free the product from the manganate of sodium formed at the same time. An easier process is that given by Jourdin (Rép. Chim. app. iii. 217), who uses mercuric oxide instead of manganic peroxide. The action, which takes place below 150°, is complete in about ten minutes, and the solution decanted from the reduced mercury contains pure rosolate of sodium. Rosolic acid is likewise produced, with evolution of hydrochloric acid, by heating phenol with mercuric chloride (Jourdin); also, according to Schützenberger and Sengenwald (iv. 394), by heating di-iodophenol in contact with the air.*

According to Wanklyn and Caro, rosolic acid is closely related to rosaniline (iv. 468), and may be produced by adding a solution of a nitrite to any salt of rosaniline, and boiling the solution. During the boiling, a copious evolution of nitrogen occurs, and the rosolic acid gradually separates out in the form of a pitch, with a cantharides-like lustre. The reaction probably takes place by two stages, as follows:—

$$\underset{\text{Rosaniline.}}{C^{20}H^{19}N^{3}} + 3HNO^{2} = \underset{\text{Azorosaniline.}}{C^{20}(H^{10}N'''^{3})N^{3}} + 6H^{2}O.$$

$$\underset{\text{Azorosaniline.}}{C^{20}H^{10}N^{6}} + 4H^{2}O = \underset{\text{Rosolic acid.}}{C^{20}H^{18}O^{4}} + 3N^{2}$$

Rosolic acid is a dark-coloured amorphous substance, having a greenish lustre, and yielding a red powder; in thin films it exhibits a red colour by transmitted light. It bakes together at about 60°, and melts in boiling water to a dark-green, nearly black liquid. It is not volatile, and not easily combustible. It dissolves readily, with brownish-yellow colour, in alcohol and ether; also in phenol, in wood-creosote, in strong acetic, hydrochloric, and sulphuric acids, and is not quite insoluble in water; chloroform, benzene, and sulphide of carbon do not dissolve it (Hugo Müller). Its composition has not been fixed with certainty. According to the mean of Müller's analyses, rosolic acid dried over oil of vitriol contains 75·92 per cent. carbon and 5·83 hydrogen, agreeing nearly with the empirical formula $C^{23}H^{22}O^{4}$, which requires 76·27 C, 6·05 H, and 17·68 O. Angus Smith proposed the formula $C^{12}H^{12}O^{3}$ (requiring 70·6 per cent. carbon), and Dusart (Rép. Chim. app. i. 207), from his own analysis (not given), deduces the formula $C^{6}H^{6}O^{2}$, requiring 65·4 per cent. carbon. According to Wanklyn and Caro, the true formula is probably $C^{20}H^{18}O^{4}$ (*vid. sup.*).

Rosolic acid distilled over excess of soda-lime yields phenol, a portion, however, suffering further decomposition (Dusart). According to Wanklyn and Caro, it yields phenol by distillation *per se.* It is easily attacked in alcoholic solution by chlorine and bromine, also by nitric acid when heated, forming a light-yellow substance, which dissolves in caustic alkalis, but not with red colour. It is not acted upon by a solution of glucose in caustic potash (Müller), and is not decolorised by sulphurous acid (Dusart). When boiled with aniline and little benzoic acid, it forms a splendid and very permanent blue dye, the reaction not being attended with evolution of ammonia, but apparently with separation of water. (Wanklyn and Caro.)

Rosolates.—Rosolic acid is a very weak acid, weaker even than carbonic acid. It unites with ammonia, the fixed alkalis, and the alkaline earths, forming dark-red compounds, soluble in water and alcohol, and very easily decomposed by exposure to light and air, being partly converted into carbonates, and losing their colour.—The carmine-red solution of rosolic acid in alkalis is decolorised by boiling with zinc-powder, but the colour is restored by addition of ferricyanide of potassium. (Wanklyn and Caro.)

The *calcium-salt* separates on carefully evaporating its solution in a vacuum over lime, as a granular or crystalline powder, which when pressed resembles carthamin.—The *magnesium-salt* is the most stable of the rosolates. The soluble rosolates do not form precipitates with the salts of the heavy metals, not even with basic acetate of lead; neither does rosolic acid combine with alumina. (H. Müller.)

---

* Communication from Prof. Wanklyn.

ROTHOFFKITE. A name of garnet.

ROTTLERA. The fruit of *Rottlera tinctoria*, a tree growing in all parts of India, is covered with stellate hairs and glands, which, when brushed off, form a brick-red sandy powder, used in India as a dye, and lately introduced into medicine, under the name of *Kamala*, as a remedy for tapeworm. It has an aromatic odour, is but slowly wetted by water, and yields but little to boiling water, colouring it only a pale-yellow; but alkaline carbonates and caustic alkalis, especially the latter, extract the colouring matter, forming deep red solutions. The extract prepared with soda imparts to silk a fine and durable fiery-orange colour, without further addition or the use of mordants; with cotton, on the other hand, it does not produce a good colour. The natural dye-stuff contains 3·49 per cent. water, 78·19 resinous colouring-matters, 7·34 albuminous substances, 7·14 cellulose, and 3·84 ash, besides small quantities of volatile oil and a volatile colouring matter. (The liquid distilled from the alcoholic extract has a yellow colour, and the odour of the original substance). The concentrated ethereal extract of the colouring matter deposits a yellow crystalline substance called *Rottlerin* (vid. inf.). The extract prepared with boiling alcohol deposits, on cooling, non-crystalline flocks of a substance having the composition of $C^{30}H^{34}O^{4}$. It may be obtained, nearly colourless, by repeated solution and separation; is sparingly soluble in ether and in cold alcohol, insoluble in water; not precipitated by lead- or silver-salts. The alcoholic solution separated from these flocks leaves a dark-red resin, $C^{30}H^{30}O^{7}$, soluble in all proportions in alcohol and ether, insoluble in water, melting at 100°, and forming with acetate of lead, a deep orange-coloured precipitate of variable composition. (**Anderson**, Edinb. New Phil. Journ. new series, i. 300; Jahresb. 1855, p. 669.)

G. **Leube**, Jun. (Vierteljahrschr. pr. Pharm. ix. 321; Jahresb. 1860, p. 562) has also examined the red colouring matter of *Rottlera tinctoria*, but with very different [and doubtful] results, not having even succeeded in preparing the crystallised substance rottlerin. He found in the deep red powder 47·6 per cent. resinous substances, 19·7 of other constituents extractable by solvents (extractive matter, oxalic acid, albumin, ulmic acid, and inorganic salts), 7·7 fibrin, and 25·0 [insoluble] mineral substances. The resinous substance extracted by ether was resolved by treatment with cold alcohol into two resins, one easily soluble, the other sparingly soluble, in that liquid. The former, melting at 80°, contains $C^{15}H^{18}O^{4}$; the latter, melting at 191°, contains $C^{8}H^{12}O^{5}$. Both are brittle, reddish-yellow, dissolve with fine red colour in cold potash-ley, alkaline carbonates, and ammonia, and are separated therefrom by acids without alteration; they are not altered by boiling with dilute sulphuric acid, but nitric acid decomposes them, with formation of oxalic acid. The ash, amounting to 28·85 per cent. of the red substance, was found to contain 0·9 per cent. potash and soda, 0·2 magnesia, 4·1 lime, 0·7 manganic oxide, 8·5 ferric oxide, 1·2 soluble silica, 83·8 insoluble silica [it was probably mixed with sand], and traces of chlorine and sulphuric acid.

ROTTLERIN. $C^{11}H^{10}O^{3}$. (**Anderson**, *loc. cit.*)—This substance separates from the ethereal extract of the colouring matter of *Rottlera tinctoria*, in yellow silky crystals, which are insoluble in water, sparingly soluble in cold, more easily in boiling alcohol, melt when heated, and then decompose. It dissolves in alkalis with deep red colour. Its alcoholic solution is not precipitated by acetate of lead. With bromine it forms a colourless substitution-product: with nitric acid, first a yellow resin, and then oxalic acid; with cold concentrated sulphuric acid, a yellow solution, which when heated becomes darker and gives off sulphurous acid.

ROUCOU. Syn. with Annotto (i. 307).

RUBEANHYDRIC ACID. The name given by Berzelius to the compound $C^{2}N^{2}H^{4}S^{2}$ or $Cy^{2}.2H^{2}S$. (See Cyanogen, Sulphydrates of, ii. 285.)

RUBELLAN. An altered biotite (iii. 1013), occurring in small hexagonal forms, of a red colour, in a kind of wacke. (**Dana**, ii. 226.)

RUBELLITE. Red tourmaline.

RUBERYTHRIC ACID. A yellow substance existing, according to **Rochleder** (Ann. Ch. Pharm. lxxx. 321; lxxxii. 205), in madder-root. To prepare it, the aqueous decoction of the root is precipitated by neutral acetate of lead; the precipitate (which serves for the preparation of alizarin and purpurin), is collected on a filter; and the filtrate is mixed with basic acetate of lead, not in excess, which throws down a dark, flesh-coloured, nearly brick-red precipitate, containing ruberythric and rubichloric acids, with small quantities of citric and phosphoric acids. This precipitate is suspended in water, and decomposed by sulphydric acid; the solution, chiefly containing rubichloric acid, is filtered from the sulphide of lead; and the ruberythric acid, which remains attached to this lead-precipitate, is extracted from it, after washing for a short time, by boiling with alcohol. The alcoholic solution evaporated to one-third, then mixed with water and a small quantity of baryta-water, deposits a scanty white precipitate; and the filtrate, treated with a larger quantity of baryta-water, yields ruberythrate of barium in dark cherry-red flocks. These are collected and dissolved in dilute acetic acid; and the solution is nearly neutralised with ammonia, and precipitated by basic acetate of lead, whereby a cinnabar-coloured lead-salt is obtained, which must be washed with dilute alcohol, and decomposed under alcohol by sulphydric acid. The liquid heated to the boiling-point with the sulphide of lead, then filtered hot and evaporated, deposits light-yellow crystals of ruberythric acid, which may be purified by pressure and recrystallisation from a small quantity of boiling water.—25lbs. madder yield 1 gramme of the acid; Levantine more than European madder.

Ruberythric acid forms yellow prisms having a silky lustre. It has a faint taste; dissolves sparingly in cold, easily in hot water; with gold-yellow colour in alcohol and ether, with blood-red colour in aqueous alkalis; forms red precipitates with baryta-water, with alum-solution after addition of ammonia, and with basic acetate of lead, after addition of a little alcohol. Boiling aqueous ferric chloride dissolves it, forming a dark brown-red solution, which is precipitated by alcohol.

Ruberythric acid contains, according to Rochleder's analysis, 54·48 per cent. carbon and 5·16 hydrogen, agreeing nearly with the formula $C^{36}H^{40}O^{20}$ (calc. 54·54 C, 5·05 H, and 40·41 O), or with $C^{36}H^{42}O^{21}$ (calc. 54·64 C, 5·04 H, and 40·32 O). The percentage composition is nearly the same as that of rubian (p. 123); in fact, Rochleder regards rubian as merely impure ruberythric acid. Schunck, on the contrary, did not find ruberythric acid in madder, and is of opinion that, in the preparation above described, products of the decomposition of rubian must have been obtained.

Ruberythric acid heated in aqueous solution with hydrochloric acid is resolved into alizarin and glucose. The reaction may be represented, according to Rochleder, by either of the equations:

$$\underset{\text{Ruberythric acid.}}{C^{36}H^{40}O^{20}} = \underset{\text{Alizarin.}}{3C^{10}H^{6}O^{3}} + \underset{\text{Glucose.}}{C^{6}H^{12}O^{6}} + 5H^{2}O.$$

or:

$$3C^{36}H^{42}O^{21} = 12C^{10}H^{6}O^{3} + 8C^{6}H^{12}O^{6} + 9H^{2}O.$$

The aqueous solution boiled with alkalis also deposits alizarin on addition of an acid. (Rochleder.)

RUBIA. See MADDER (iii. 740).

RUBIACIC ACID. An acid produced, according to Schunck (Ann. Ch. Pharm. lxvi. 201; lxxxvii. 344), by boiling rubiacin or rubiafin, or the brown flocks thrown down by hydrochloric acid from spent madder-liquor, with ferric nitrate or chloride. The resulting brown-red solution, mixed with hydrochloric acid, deposits brown flocks of impure rubiacic acid, which may be purified by solution in boiling aqueous carbonate of potassium, and reprecipitation with an acid. It is a lemon-yellow amorphous powder, slightly soluble in boiling water, and converted by sulphuric acid, first into rubiacin, then into rubiafin. Contains, according to Schunck, 57·6 per cent. C, 2·9 H, and 39 5 O, which he represents by the formula $C^{32}H^{9}O^{17}$ or $C^{32}H^{18}O^{17}$, requiring 57·0 C, 2·7H, and 40·3 O. The potassium-salt forms brick-red needles or prisms, containing 13·04 per cent. potash, the formula $C^{32}H^{8}KO^{17}$ requiring 12·58 per cent.

RUBIACIN. *Madder-orange. Krapp-orange.* (Runge, J. pr. Chem. v. 367; Robiquet, Ann. Ch. Phys. lxiii. 311; Higgin, Phil. Mag. [3] xxxiii. 232; Schunck, *Gmelin's Handbook*, xvi. 47.)—A yellow, crystallisable colouring-matter, discovered by Runge. It exists in madder-root, probably as a calcium-compound, from which it separates as the extract turns sour. It is also produced by the action of alkaline hydrosulphates on rubiacic acid (Schunck), and by heating Higgins' xanthin (*q. v.*) with strong sulphuric acid, and by the spontaneous decomposition of that substance which takes place when an aqueous extract of madder is left to itself. Rubiacin is found partly in the precipitate produced by acids in the decoction of madder, partly in the residue left after exhausting the root with water, and may be obtained in the pure state by conversion into rubiacic acid and subsequent reduction of that compound. (Schunck). It may also be prepared from the madder-liquor of the dye-houses, by mixing the liquid with hydrochloric acid, treating the resulting precipitate with boiling alcohol, redissolving the orange-yellow powder which separates on cooling, in boiling alcohol, and adding stannous oxide to the solution. The hot filtrate deposits rubiacin, or cooling, in splendid light-yellow plates and needles, having a strong reddish-green lustre like iodide of lead. When heated, it sublimes completely in yellow scales (Schunck). It is slightly soluble in boiling water, more soluble in boiling alcohol. It contains 67·1 per cent. carbon and 4·0 hydrogen, whence Schunck deduces the formula $C^{32}H^{22}O^{10}$ (calc. 67·8 C, 3·9 H, 28·3 O).

Rubiacin dissolves in strong sulphuric acid, forming a yellow liquid, which may be heated without decomposition. Strong nitric acid attacks it at the boiling heat. It dissolves in ferric chloride or nitrate, forming a brown solution, which on addition of an acid, turns yellow and deposits flocks of rubiacic acid. It dissolves in alkalis, forming purple solutions, from which acids throw down yellow flocks. The ammoniacal solution forms dingy-red precipitates with the chlorides of barium and calcium.

Hydrate of aluminium introduced into an alcoholic solution of rubiacin acquires an orange tint, and decolorises the liquid. The alumina-precipitate dissolves easily in caustic potash, forming a purple solution. A piece of mordanted calico is scarcely coloured by rubiacin suspended in boiling water. (Schunck.)

RUBIADIN. $C^{16}H^{14}O^{5}$. (Schunck, Phil. Mag. [4] v. 410, 495; xii. 200, 270.)—A body produced, together with glucose, by the action of alkalis on rubiacin (respecting its mode of formation, see MADDER, iii. 746); also in the decomposition of rubihydran or rubidehydran by dilute hydrochloric or sulphuric acid.

Preparation: 1. When rubian is boiled for some time with caustic soda, a precipitate is formed, consisting chiefly of the soda-compound of alizarin (i. 114); and the alkaline mother-liquor, mixed with dilute sulphuric acid and a large quantity of water, deposits yellow flocks containing alizarin, rubiretin, verantin, and rubiadin, while glucose remains in solution. The flocks are treated with boiling alcohol, which dissolves them, leaving only a brown substance formed from the sugar; and the filtered liquid is treated with acetate of aluminium, whereby the alumina-compound of alizarin is precipitated, together with a small quantity of verantin.

The mother-liquor is then mixed with acetate of lead, which throws down rubiretin and verantin as a brownish-purple precipitate (see RUBIRETIN), while rubiadin remains in solution, still mixed, however, with a small quantity of rubiretin. By precipitating the solution with a large quantity of water, dissolving the yellow flocks thereby obtained in the exact quantity of boiling alcohol required, and digesting with hydrate of lead (or stannous hydrate), the rubiretin is removed, and the hot-filtered solution deposits rubiadin on cooling; an additional quantity of that substance, but in an impure state, is obtained by evaporating the mother-liquor. This latter product may be purified by sublimation.

2. An aqueous solution of rubihydran (p. 131) is boiled with hydrochloric or sulphuric acid till it becomes colourless, and no longer deposits yellow flocks or a brown resin. These flocks are a mixture of rubiretin, verantin, and rubiadin, with a small quantity of alizarin; the alizarin may be separated by acetate of aluminium, and then the rubiadin, in the same manner as from the mixture of these bodies obtained by the first method.

Rubiadin crystallises in yellow needles, or in rectangular plates, which are sublimable, insoluble in water, more soluble in alcohol than rubianin. Strong sulphuric acid dissolves it, with yellow colour; aqueous ammonia and carbonate of sodium dissolve it at the boiling heat, with blood-red colour. It is precipitated by chloride of barium, chloride of calcium, and cupric acetate, not by acetate of of lead; does not dissolve in ferric chloride.

Rubiadin gives by analysis 69·6 per cent. carbon and 5·1 hydrogen, whence Schunck deduces the formula $C^{32}H^{13}O^{9}$ (calc. 69·3 C, 4·7 H, and 26·0 O). It is more probably $C^{32}H^{14}O^{10}$ or $C^{16}H^{14}O^{5}$.

Chlororubiadin, $C^{16}H^{13}ClO^{5}$. (Schunck, Phil. Mag. [4] xii. 270.)—Produced by boiling chlororubian (p. 124), with dilute sulphuric or hydrochloric acid. It is insoluble in water, but soluble in alcohol, whence it crystallises in broad shining needles or laminæ. The alcoholic solution reddens litmus. The compound dissolves in caustic soda with purple, and in alkaline carbonates with blood-red colour. It gives by analysis 60·6 to 61·7 C, 4·2 to 4·3 H, and 11·2 to 11.0 Cl, which Schunck represents by the formula $C^{32}H^{12}ClO^{9}$, requiring 61·65 C, 3·85 H, 11·36 Cl, and 23·14 O. The formula $C^{16}H^{13}ClO^{5}$ requires 59·5 C, 4·0 H, and 11·1 Cl. An ammoniacal solution of chlororubiadin mixed wtth chloride of barium, filtered from the flocks which separate at first and left to itself in a closed vessel, deposits long red needles, which when dried at 100° contain 15·65 per cent. Ba″O, and may be represented by the formula $C^{32}H^{24}Ba''Cl^{2}O^{10}.2Ba''O$.

RUBIADIPIN. $C^{30}H^{24}O^{6}$? (Schunck, J. pr. Chem. lix. 474.)—A compound formed, together with many others, by the fermentation of madder.

Erythrozym is added to aqueous rubian, and the liquid is allowed to stand in a moderately warm place, until it has become tasteless and colourless, owing to the deposition of a brown jelly. If this deposit should not take place in 24 hours, more erythrozym must be added. Or madder is stirred up with cold or warm water, and left in a warm place till a jelly is formed. In both cases the mass is mixed with a little water, and the jelly is collected on a filter and washed with a small quantity of water. It contains alizarin, rubiretin, verantin, rubiafin, rubiagin, and rubiadipin, which are separated as follows:—

The mass is well boiled with alcohol as long as the liquid acquires a yellow colour, and acetate of aluminium is added to the filtrate, whereby alizarin, verantin, and rubiafin are precipitated in combination with alumina, but only partially. The whole is then filtered (for the further treatment of the precipitate, see below), and sulphuric acid and a large quantity of water are added to the dark brownish-red filtrate, whereby the whole of the dissolved substances are precipitated as a yellow powder, which, having been thoroughly washed with water, is redissolved in boiling alcohol, and mixed with excess of acetate of lead. The dark purple-red lead-precipitate, which is to be filtered boiling, contains alizarin, rubiretin, verantin, and rubiafin; the dark-yellow filtrate, rubiagin and rubiadipin.

On mixing this filtrate with a large quantity of water, a faintly orange-coloured precipitate is formed, consisting of the lead-compounds of rubiagin and rubiadipin; this precipitate is to be collected and decomposed by boiling dilute sulphuric acid. The undissolved portion washed with water, then boiled with alcohol, yields to the latter, rubiagin and rubiadipin, both of which remain, after evaporation of the alcohol, as a soft, dark-brown, fatty mass, and may be separated by cold alcohol, which dissolves chiefly the rubiadipin; the undissolved rubiagin may be purified by recrystallisation from hot alcohol.

Rubiadipin is a semifluid, yellowish-brown, fatty substance, which does not harden even when heated for a long time. In boiling water it melts to oily drops, which rise to the surface. It is insoluble in water, soluble in alcohol and in alkalis, forming with the latter a blood-red soapy liquid. The alcoholic solution forms, with neutral acetate of lead, a blood-red precipitate containing 31·35 per cent. lead-oxide, whence Schunck deduces the formula $C^{30}H^{24}O^{5}.PbO$.

RUBIAFIN. $C^{32}H^{13}O^{9}$? (Schunck, J. pr. Chem. lix. 465.)—A compound isomeric with rubiadin, produced, as already mentioned, in the fermentation of rubian. The lead-precipitate, containing alizarin, rubiretin, verantin, and rubiafin, obtained as described in the preceding article, is decomposed by boiling hydrochloric acid; and the precipitated yellow flakes are washed and covered with cold alcohol, which extracts rubiretin, leaving alizarin, rubiafin, and verantin. On the other hand, the above-mentioned precipitate produced by acetate of aluminium, is decomposed by boiling hydrochloric acid, whereby orange flakes are separated; and these are added to the residue of alizarin, rubiafin, and verantin, which was left undissolved by cold alcohol, and the whole is subjected to the following treatment:—The mixture is dissolved in boiling alcohol and mixed with acetate of copper, which forms a purple precipitate containing rubiafite and verantite, with a small quantity of alizarite of copper, while alizarin alone remains in solution. The purple copper-precipitate, decomposed by hydrochloric acid, deposits insoluble red flakes, which, after washing, are dissolved in boiling alcohol, and treated with hydrated stannous oxide; whereupon only *rubiafin* remains dissolved, and crystallises from the filtrate in brilliant needles and laminæ, while verantin, together with a small quantity of alizarin, is precipitated as a stannous oxide lake (Schunck). See VERANTIN.

Rubiafin forms yellow shining plates and needles, sometimes star- or fan-shaped masses, which behave like rubiacin when heated with water, sulphuric acid, nitric acid, neutral acetate of lead, and cupric acetate, and likewise form rubiacic acid when treated with ferric nitrate: in fact, rubiafin differs from rubiacin only in composition. It contains, according to Schunck, 69·3 per cent. carbon and 4·6 hydrogen (calc. 69·3 C, 4·7 H, and 26·0 O).

RUBIAGIN. (Schunck, J. pr. Chem. lix. 471.)—This is another of the compounds produced by the fermentation of rubian. For the mode of preparing it, see RUBIADIPIN (p. 120). It forms small yellow spherical granules, or concentrically grouped needles. It is insoluble in boiling water, dissolves in boiling alcohol more easily than rubiadin or rubianin, and with yellow colour in acetic acid, from which it crystallises on cooling. Alkalis, baryta-water, and lime-water dissolve it with blood-red colour. It dissolves in cold oil of vitriol, with dark brown-red colour, and in boiling nitric acid, forming a yellow liquid, which deposits shining crystals as it cools. When boiled with ferric chloride, it assumes a darker colour, but does not become purple-brown, like rubiafin and rubiacin. The alcoholic solution mixed with neutral acetate of lead turns yellow, and then throws down orange-coloured grains, which dissolve sparingly in boiling alcohol, easily in an alcoholic solution of neutral lead-acetate. This property distinguishes rubiagin from rubiacin, rubiadin, and rubiafin. With cupric acetate, the alcoholic solution of rubiagin forms an orange-coloured precipitate.

The composition of rubiagin is very uncertain, as it has not been obtained pure. Schunck found it to contain 68·10 per cent. C and 5·14 H. The formula $C^{16}H^{14}O^{5}$, which requires 67·12 C, 4·89 H, and 27·99 O, would explain its formation from rubian, as follows:—

$$\underset{\text{Rubian.}}{C^{28}H^{34}O^{15}} + 2H^2O = \underset{\text{Rubiagin.}}{C^{16}H^{14}O^5} + \underset{\text{Glucose.}}{2C^6H^{12}O^6}.$$

RUBIAN. $C^{28}H^{34}O^{15}$.—A glucoside existing in madder-root, and yielding, under the influence of acids, alkalis, or erythrozym (madder-ferment)—on the one hand, glucose, and on the other, alizarin, together with rubiretin, verantin, and other products, varying according to the nature of the decomposing compound. It was discovered by Schunck in 1847. (For references to his memoirs, see *Gmelin's Handbook*, xvi. 32.)

Preparation.—It is difficult to obtain this substance pure, inasmuch as it alters very quickly, and does not precipitate any metallic solution excepting basic acetate of lead, which when added to madder-extract, throws down othor substances at the same time. The best results are obtained by taking advantage of the great affinity of rubian for porous bodies, especially for animal charcoal.

One pound of Avignon-madder is exhausted on a cloth strainer, by pouring four or five quarts of boiling water upon it; the dark yellowish-brown, still hot filtrate is mixed with an ounce of bone-charcoal, stirred, and left to settle; the still brown liquid is decanted; and the residue is collected and washed with cold water, till the liquid which runs off becomes green when boiled with hydrochloric acid (from the presence of chlorogenin). The washed bone-charoal, if boiled with alcohol, as long as it colours the liquid yellow, yields to it the rubian which it has carried down; and on evaporating the alcoholic solution, the rubian is left behind, but still impure, containing chlorogenin. To remove the latter, the impure rubian, obtained in the manner just described, is again precipitated in the same manner on the previously used charcoal, which now takes up only the rubian, and again extracted by boiling alcohol, this series of operations being repeated a third time with the same bone-charcoal, in case the alcoholic solution still contains chlorogenin.* On evaporating the alcoholic solutions, the rubian remains behind, still retaining a small quantity of a decomposition-product formed by the action of heat. This is separated, either—*a.* By evaporating the greater part of the alcohol, mixing the solution when cold with dilute sulphuric acid (which throws down the decomposition-product in brown resinous drops), removing the sulphuric acid by carbonate of lead, then filtering, and evaporating over the water-bath; or—*b.* By precipitating the solution with neutral acetate of lead, filtering from the brown-red flocks which separate, and adding basic acetate of lead, whereby a compound of rubian with lead-oxide is precipitated, which must be washed with alcohol, and decomposed by sulphydric or dilute sulphuric acid. In the latter case, the excess of sulphuric acid must be removed, as in *a.*—One cwt. of madder yields 1,000 grammes of rubian.

The following process serves at the same time for the preparation of alizarin, rubiacin, rubiretin, and verantin:—Coarsely pulverised madder-root is well boiled with water (1lb. of the root to 16 quarts of water); the liquid, after several hours' boiling, is strained through calico (the residue, exhausted with water, still contains alizarin and rubiacin); and the liquid is precipitated with dilute sulphuric (or hydrochloric) acid. A dark-brown precipitate is thus obtained, which, when separated by decantation and filtration, and freed from excess of acid by washing with a quantity of cold water just sufficient for the purpose (a larger quantity dissolves rubiacin), contains seven substances, —viz. rubian, alizarin, rubiacin, rubiretin, verantin, pectic acid, and a dark-brown product of the decomposition of extractive matters. (The filtrate retains chlorogenin and a small quantity of sugar). The precipitate, while still moist, is boiled with alcohol, as long as the alcohol acquires a yellow colour, and the liquid is filtered hot. (In the residue there remains pectic acid and oxidised extractive matter). The dark-brown decoction, on cooling, frequently deposits *verantin* as a dark-brown resinous powder, which must be separated by filtration. The alcoholic solution, after being again heated to the boiling-point, is mixed and digested with recently precipitated hydrate of aluminium, till the solution is nearly decolorised, whereby alizarin, rubian, rubiacin, and part of the rubiretin and verantin are precipitated, while another portion of the two last-mentioned substances remains dissolved in alcohol.

a. Separation of Alizarin.—The alumina-precipitate, after being washed with alcohol, is added to a concentrated boiling solution of potassic carbonate; the deep red solution, containing all the other substances, is filtered from the undissolved compound of alizarin and alumina; this substance is repeatedly boiled with aqueous potassic carbonate, till the liquid, which runs off on filtration, exhibits only a faint purple colour; the residue is decomposed by boiling hydrochloric acid; and the alizarin thus separated is crystallised from alcohol.

---

* As fresh bone-charcoal precipitates both rubian and chlorogenin, whereas charcoal, which has once been used for this purpose and boiled out with alcohol, precipitates only the former, or at least gives up only the former to boiling alcohol, it is best not to extract, for the purpose of purification, the first portion of rubian taken up by fresh bone-charcoal, but to use this charcoal for the preparation of purer rubian.

β. Of Rubian.—The deep red alkaline liquid, filtered from the compound of alizarin and alumina, still retains in solution, rubian, rubiacin, rubiretin, and verantin, which may all be precipitated by hydrochloric acid, then collected and washed with cold water, till the liquid which runs off is free from acid. As soon as this point is attained, the rubian, which is insoluble in acidulated water, begins to dissolve in the pure water, imparting to that which runs off a yellow colour and bitter taste; so that at length it is completely dissolved, and may be obtained as a yellow extract, by evaporating the filtrate. It still, however, retains pectic acid, which remains behind on dissolving the extract in alcohol, and from 5 to 8 per cent. ash, from which it cannot be separated.

γ. Of Rubiacin, Rubiretin, and Verantin.—The residue left after the rubian has been washed out, is mixed with that which remains on evaporating the alcoholic liquid above mentioned, containing verantin and rubiretin, and the mixture is treated with a boiling solution of ferric chloride or nitrate. Rubiretin and rubiacin then dissolve (the latter partly as such, partly converted, with assumption of oxygen, into ferric rubiacate, p. 119), while verantin remains behind in combination with ferric oxide. The deep red-brown solution is filtered after boiling for some time; the residue is kept for the preparation of verantin; the rubiacin, rubiacic acid, and rubiretin are thrown down from the filtrate as a yellow precipitate, turning brown during washing; and this precipitate, while still moist, is dissolved in boiling alcohol, which takes up the rubiacin and rubiretin, and deposits the former, on cooling, in small lemon-yellow crystals. (The rubiacic acid which remains in solution is purified in the manner already described, p. 119,—the crystallised rubiacin by converting it into rubiacic acid, from which it may be again obtained as rubiacin). By further evaporation of the alcohol, a mixture of rubiacin and rubiretin is obtained as a dark-brown-red residue, which, when boiled with water, deposits dark brown drops of rubiretin; whilst rubiacin remains suspended as a light powder, and may be removed by decantation. After boiling several times with water, as long as any yellow powder remains, and then decanting, rubiretin ultimately remains in the form of a dark red-brown mass.

Properties.—Rubian is a hard, dry, brittle, perfectly amorphous mass, resembling dried varnish or gum-arabic, not at all deliquescent, transparent, and deep yellow in thin layers, dark-brown in thicker masses. It is very soluble in *water*, somewhat less soluble in *alcohol*, and insoluble in *ether*, which precipitates it from the alcoholic solution in brown drops. The solutions are very bitter.

Rubian dried at 100° (after deduction of 5·30—7·69 per cent. ash, consisting chiefly of calcic carbonate), contains, according to Schunck, 54·85 per cent. carbon, 5·57 hydrogen, and 39·58 oxygen, whence he deduces the formula $C^{28}H^{34}O^{15}$, requiring 55·08 C, 5·57 H, and 39·35 O. This formula serves to account for the several transformations of rubian observed by Schunck, supposing that the formulæ assigned to the several products, alizarin, rubiretin, rubiadin, &c., are correct. This, however, is very doubtful, especially with regard to the most important and best-defined of these products, viz. alizarin, to which Schunck assigns the formula $C^{14}H^{10}O^{4}$, representing its formation from rubian by the equation:

$$C^{28}H^{34}O^{15} = 2C^{14}H^{10}O^{4} + 7H^{2}O.$$

Other chemists, however, represent alizarin by the formula $C^{10}H^{6}O^{3}$, which agrees nearly as well with the results of analysis, and gives a clearer view of the other chemical relations of alizarin, especially to phthalic acid (i. 114). Hence Gerhardt (*Traité*, iii. 492) suggested for rubian (dried at 100°) the formula $C^{16}H^{16}O^{8}.\frac{1}{2}H^{2}O$, (requiring 55·87 C, 4·94 H, and 39·25 O), according to which the formation of alizarin is represented by the equation:

$$\underset{\text{Rubian.}}{C^{16}H^{16}O^{8}} + H^{2}O = \underset{\text{Alizarin.}}{C^{10}H^{6}O^{3}} + \underset{\text{Glucose.}}{C^{6}H^{12}O^{6}}$$

It is not very easy to explain the formation of the other derivatives of rubian by Gerhardt's formula, especially that of rubianic acid; but, as already observed, the formulæ assigned by Schunck to these compounds are very doubtful, many of them being founded on analyses evidently made upon impure preparations. The whole subject therefore requires further investigation.

Decompositions.—1. Rubian heated in a test-tube decomposes, and gives off water at 130°; at a higher temperature, it emits orange-coloured vapours, chiefly consisting of alizarin, and leaves much charcoal.

2. Heated on platinum-foil, it melts, swells up, burns with flame, and leaves a mixture of charcoal and ash.

3. Aqueous rubian, evaporated by heat in contact with the *air*, deposits dark-brown

resinous drops, the quantity of which increases on pouring water upon the residue, and again evaporating. The drops of resin melt in boiling water, become brittle on cooling, yield, when heated in a test-tube, a copious, yellow, transparent sublimate, resembling rubiacin, and behaving in a similar manner to ferric chloride; they are probably, therefore, a mixture of rubiretin and rubiacin.

4. *Chlorine* passed into aqueous rubian throws down yellow flocks of chlororubian, while glucose remains in solution:

$$\underset{\text{Rubian.}}{C^{28}H^{34}O^{15}} + 3H^2O + Cl^2 = \underset{\text{Hydrochlorate of chlororubian.}}{C^{22}H^{27}ClO^{12}.HCl} + C^6H^{12}O^6.$$

The continued action of the chlorine ultimately produces perchlororubian. *Chloride of lime* converts rubian into phthalate of calcium.

5. Aqueous rubian is not altered by cold *nitric acid*, but at the boiling heat red fumes are evolved; and the rubian is completely converted into phthalic acid, without formation of oxalic acid or any insoluble residue.

6. *Oil of vitriol* dissolves rubian, with blood-red colour, and blackens it on boiling, with evolution of sulphurous acid.

7. When aqueous rubian is boiled with dilute *sulphuric* or *hydrochloric acid*, the solution first becomes opalescent, and then deposits orange-coloured flocks, containing alizarin, rubiretin, verantin, and rubianin, while sugar remains in solution. [For the equations representing the formation of these products, see MADDER, iii. 746.]

8. In contact with aqueous *alkalis*, *alkaline earths*, or the *acid carbonates of the alkaline earth-metals*, and *air*, rubian takes up oxygen, and is converted into rubianic acid, rubidehydran, and rubihydran,—small quantities of acetic acid, rubiadin, and sugar being formed at the same time.

a. Formation of rubianic acid:

$$\underset{\text{Rubian.}}{C^{28}H^{34}O^{15}} + O^5 = \underset{\text{Rubianic acid.}}{C^{26}H^{30}O^{14}} + 2CO^2 + 2H^2O$$

or

$$\underset{\text{Rubian.}}{C^{28}H^{34}O^{15}} + O = \underset{\text{Rubianic acid.}}{C^{26}H^{30}O^{14}} + \underset{\text{Acetic acid.}}{C^2H^4O^2}.$$

β. Of rubidehydran:

$$C^{28}H^{34}O^{15} = C^{28}H^{32}O^{14} + H^2O.$$

γ. Of rubihydran:

$$C^{28}H^{34}O^{15} + 3H^2O = C^{28}H^{40}O^{18}.$$

9. Rubian boiled with excess of *caustic potash*, or *soda*, dissolves with blood-red colour, changing to purple-red; and by continued boiling is completely resolved into alizarin, rubiretin, verantin, and rubiadin, which are precipitable by acids, and sugar, which remains in solution. The same products are formed, though more slowly, by boiling with caustic *baryta*. [MADDER, iii. 746.]

Ammonia colours aqueous rubian blood-red, but does not decompose it, even at t boiling heat.

Magnesia colours aqueous rubian blood-red; the carbonates of calcium and barium do not act upon it; aluminic, ferric, and cupric hydrates extract all the rubian from it.

The alkaline solutions of rubian reduce *gold-salts*, but not silver or copper-salts.

10. *Erythrozym*, added to an aqueous solution of rubian, diffuses itself through the liquid without dissolving, rendering it turbid and gummy, and converting it, after standing for some time in a moderately warm place, into a brown jelly, like coagulated blood, containing yellow striæ and flocks formed of long capillary crystals, till finally (more erythrozym being added if necessary) the liquid becomes tasteless and colourless, and a gelatinous mass separates, consisting of alizarin, verantin, rubiretin, rubiafin, rubiagin, and rubiadipin (iii. 746; v. 120). The solution retains sugar and pectic acid. During the fermentation, the liquid remains neutral, neither absorbing nor giving off gases: access of air is likewise unnecessary.

Derivatives of Rubian.

Chlororubian, $C^{22}H^{27}ClO^{12}$. (Schunck, Phil. Mag. [4] xii. 200, 270.)—A compound formed, together with glucose, by the action of chlorine on aqueous rubian. To prepare it, an aqueous extract of madder is precipitated with neutral acetate of lead, the filtrate precipitated with ammonia, the resulting red precipitate decomposed by sulphuric acid, and chlorine gas passed into the filtrate. The dirty yellow flocks of an easily fusible resin, which are precipitated by the first action of the chlorine, are separated by filtration; and the pure yellow flocks of chlororubian, precipitated on continuing the passage of the chlorine, are collected and crystallised from hot alcohol.

When crystallised from dilute alcoholic solution, it forms light orange-yellow needles, having a bitter taste; precipitated from concentrated alcoholic or hot aqueous solution, it forms granular amorphous spherules. It is neutral; dissolves with yellow colour in boiling water, also in alcohol; does not dye mordanted tissues. It gives by analysis 51·18 per cent. C, 4·93 H, and 6·38 Cl, the formula requiring 50·92 C, 6·82 H, 5·20 Cl, and 37·51 O.

Chlorine-water gradually converts chlororubian into perchlororubian. By boiling dilute *sulphuric* or *hydrochloric acid*, it is resolved into chlororubiadin (p. 120) and glucose:

$$C^{22}H^{27}ClO^{12} = C^{16}H^{11}ClO^{4} + C^{6}H^{12}O^{6} + 2H^{2}O.$$

With caustic *soda* it forms a blood-red solution, which after being heated for some time deposits dark red-brown flocks of oxyrubian, while sugar and its products of decomposition, together with verantin, rubiretin, and rubiadin, remain in solution.

Oxyrubian, after boiling with hydrochloric acid, washing with boiling alcohol, and drying, is a yellowish-brown powder, which if free from chlorine, yields, when heated in a test-tube, a yellow crystalline sublimate, easily soluble in alkalis. It is not altered by sulphide of ammonium, but alkalis turn it red-brown. It contains, according to Schunck, 70·7 C, 3·9 H, and 25·4 O, which may be represented by the formula $C^{22}H^{14}O^{6}$; its formation may take place according to the equation:

$$C^{22}H^{27}ClO^{12} + NaHO = C^{22}H^{14}O^{6} + NaCl + 7H^{2}O.$$

Perchlororubian, $C^{44}H^{18}Cl^{18}O^{18}$. (Schunck, *loc. cit.*)—This compound, recrystallised from boiling alcohol, forms colourless transparent four-sided plates, having a splendid iridescence. It is neutral, sublimes in micaceous scales when cautiously heated, is insoluble in water, soluble in alcohol and ether; gives by analysis 37·05 C, 1·51 H, 44·40 Cl, the formula requiring 37·09 C, 1·26 H, 44·47 Cl, and 16·88 O.

RUBIANIC ACID. $C^{26}H^{30}O^{14}$? (Schunck, Phil. Mag. [4] xii. 200, 270.)—An acid, produced, together with rubihydran and rubidehydran, by the oxidation of rubian in contact with alkalis (iii. 746).

Preparation: 1. *From Rubian.*—Carbonic acid gas is passed into a solution of rubian mixed with excess of baryta-water, till the baryta is converted into acid carbonate, and the filtrate is left to stand in contact with the air. The liquid, after some time, becomes covered with thin scarlet films, presenting a crystalline appearance under the microscope (compounds of baryta with rubianic acid and rubidehydran), more of which are obtained after longer standing, and again on evaporating the liquid, finally in the form of red flocks, whilst rubihydran remains dissolved in the brownish-yellow liquid (sometimes also sugar resulting from a secondary decomposition). The collected films and flocks are decomposed with dilute sulphuric acid; the excess of that acid is precipitated by carbonate of lead; the precipitate is repeatedly boiled with water, till it exhibits only a faint reddish tint (in which state it contains no impurity except a small quantity of rubiadin, produced by secondary decomposition), and the solution is filtered and evaporated; a yellow-brown mass then remains, mixed with yellow needles, from which cold water extracts rubidehydran, leaving rubianic acid in the form of a yellow powder. This product is washed with cold water, and recrystallised from boiling water, if necessary with aid of animal charcoal.

2. *From Madder, without previous preparation of Rubian.*—Extract of madder prepared with hot water is precipitated with neutral acetate of lead, then the filtrate with basic acetate; and the latter precipitate, containing rubian and chlorogenin, is decomposed by cold dilute sulphuric acid, digested with carbonate of lead, and filtered. The filtrate, treated with baryta-water, then with carbonic acid, as in the first method, deposits, after standing for some time in contact with the air, rubianate of barium and the barium-compound of rubidehydran, to be treated as in 1, while rubidehydran and chlorogenin remain in solution.

Properties.—Rubianic acid forms lemon-yellow silky needles; in the impure state, granules and a crystalline mass. Tastes somewhat bitter. Reddens litmus.

It gives by analysis 55·5 to 56·6 per cent. C, and 5·4 to 5·6 H, whence Schunck deduces the formula $C^{52}H^{56}O^{27}$ (calc. 56·0 C, 5·2 H, 38·8 O). The formula $C^{26}H^{30}O^{14}$ requires 55·1 C, 5·3 H, and 39·6 O.

Rubianic acid dissolves more easily in boiling than in cold water; also in alcohol, but not in ether; does not dye mordanted fabrics. It dissolves without decomposition in hot aqueous *phosphoric*, *acetic*, *oxalic*, and *tartaric acids*. Its salts are red; those of the *alkali-metals* are easily soluble; the rest are formed by precipitation.

Rubianic acid when strongly heated yields a sublimate of alizarin, and a residue of charcoal; by boiling with dilute sulphuric acid it is resolved into alizarin and glucose:

$$C^{26}H^{30}O^{14} + 2H^{2}O = C^{14}H^{10}O^{4} + 2C^{6}H^{12}O^{6}.$$

RUBIANIN. A body obtained, together with alizarin, rubiretin, and verantin, by boiling aqueous rubian (or the extract of madder prepared with boiling water) with dilute sulphuric acid. The orange-yellow flocks thereby deposited, which contain the four substances, are dissolved in boiling alcohol, the reddish-yellow solution is filtered boiling, and the residue is boiled with fresh alcohol as long as the latter acquires a dark-yellow colour. The yellow or brownish-yellow crystalline mass left in the residue is chiefly rubianin, which, however, may also be dissolved by frequent treatment with boiling alcohol, whence it crystallises on cooling, as well as from the first extracts. The solutions are left to cool, and the crystals of rubianin containing verantin are separated from the mother-liquid (which, however, still contains a little rubianin), and dissolved in boiling alcohol; the verantin is precipitated by acetate of lead, and the filtrate is left to cool, whereupon it deposits crystals of rubianin. (See further *Gmelin's Handbook*, xiv. 133, 134.)

Rubianin crystallises in lemon-yellow needles having a silky lustre, and lighter in colour than rubiacin. It contains (at 100°) 57·6 per cent. C and 5·42 H, whence Schunck deduces the formula $C^{32}H^{38}O^{15}$ (requiring 58·0 C, 5·7 H. and 36·3 O. Gerhardt (*Traité*, iii. 493) suggested the formula $C^{10}H^{10}O^{5} = C^{10}H^{6}O^{3}$ (alizarin) + $2H^{2}O$ (calc. 57·1 C, 4·8 H).

Rubianin is more soluble in boiling water than rubiacin, less soluble in alcohol than rubiretin or verantin. Chlorine converts it into perchlororubian (?). It dissolves with yellow colour in cold oil of vitriol, and without decomposition in hot, strong, nitric acid. It is insoluble in the cold in ammonia, carbonate of potassium, and carbonate of sodium, but dissolves at the boiling heat, forming a blood-red solution, whence it crystallises after standing for some time.—The ammoniacal solution forms red precipitates with chloride of barium and chloride of calcium. The alcoholic solution does not precipitate neutral acetate of lead. Rubianin dissolves with dark-brown colour in a strong solution of ferric chloride, without forming rubiacic acid.

RUBICHLORIC ACID. (Rochleder, Ann. Ch. Pharm. lxxx. 327; R. Schwarz, *ibid.* lxxx. 333; Willigk. *ibid.* lxxxii. 339.)—This acid, perhaps identical with Schunck's chlorogenin (i. 921), is contained, according to Rochleder, in the root, according to Willigk, in the leaves, of *Rubia tinctorum*; also, according to Schwarz, in the herb of *Asperula odorata*, *Galium verum*, and *G. aparine*. It is found in traces in the precipitate formed by neutral acetate of lead in the aqueous extracts of the plants just mentioned; in somewhat larger quantity in the precipitate produced in the filtrate by basic acetate of lead; and chiefly in the precipitate thrown down by ammonia in the liquid filtered from the preceding precipitates, and still containing lead. It is separated therefrom by sulphydric acid. (For the details of the preparation, see *Gmelin's Handbook*, xvi. 67.)

Rubichloric acid is a colourless or slightly yellow mass, having no odour, but a faint nauseous taste; easily soluble in water and alcohol, insoluble in ether, coloured yellow by alkalis, not precipitated by baryta-water. Its *lead-salt*, obtained by precipitating the ammoniacal solution with neutral acetate of lead, is a yellow transparent mass. The results obtained by its analysis are so discordant that it is useless to quote them. The acid itself has not been analysed.

Rubichloric acid heated with hydrochloric acid turns blue, then green, and deposits dark-green flocks of chlororubin, with simultaneous production of formic acid; perhaps thus:—

$$\underset{\text{Rubichloric acid.}}{C^{14}H^{16}O^{9}} = \underset{\text{Chlororubin.}}{C^{12}H^{8}O^{3}} + \underset{\text{Formic acid.}}{2CH^{2}O^{2}} + 2H^{2}O.$$

Chlororubin.—This body is likewise produced by boiling chlorogenin with acids (Schunck). According to Jessen (Wien. Akad. Ber. xiv. 294), it is contained in Chinese yellow pods, the fruit of *Gardenia grandiflora*, and may be prepared therefrom by distilling the alcoholic decoction in a stream of carbonic anhydride, to remove the alcohol, passing the liquid through a wet filter to free it from oil, and treating the filtrate with neutral acetate of lead, which throws down colouring matters and tannic acid. On gently warming the filtrate with hydrochloric acid and heating it to the boiling-point, after removing the brown flocks which separate at first, chlororubin is deposited in dark-green flocks, which may be washed with water and dried in a vacuum. It then forms a blue-green, grass-green, or black-green powder, containing variable quantities of water. It is insoluble in water and in alcohol, but dissolves in alkalis, forming a blood-red solution, which is turned green by acids. It gives by analysis: (*a*) 63·8 per cent. C, 5·0 H (Debus); (*b*) 68·6 C, 4·4 H (Rochleder); (*c*) 61·17 C, 5·1 H (Schwarz).

According to Rochleder, anhydrous chlororubin contains $C^{12}H^{8}O^{3}$, and it is associated in *a* with $\frac{3}{2}$ at., in *b* with $\frac{1}{2}$ at., and in *c* with 2 at. water. According to v. Orth

(Wien. Akad. Ber. xiii. 510), it contains, after deduction of 5·9 per cent. ash, 74·8 C and 6·46 H, whence he deduces the formula $C^{48}H^{50}O^{9}$.

RUBIDEHYDRAN. $C^{28}H^{32}O^{14}$. (Schunck, Phil. Mag. [4] xii. 200.)—Obtained in aqueous solution in the preparation of rubianic acid, and partly purified by evaporation, solution in cold water, and precipitation with alcohol. It forms a reddish-yellow, transparent, non-deliquescent, bitter gum, yielding with water a yellowish solution, from which it is not precipitated by any metallic salt, except basic acetate of lead. It gave by analysis 56·50 C and 5·65 H; the above formula, which is that of rubian *minus* 1 at. water, requires 56·75 C, 5·40 H, and 38·87 O.

RUBIDINE. $C^{11}H^{17}N$. (G. Thenius, Rép. Chim. app. iv. 181; Jahresb. 1861, p. 500.)—An organic base belonging to the pyridine series, $C^{n}H^{2n-5}N$, and contained, together with several other members of that series, in coal-tar. The method adopted by Thenius for obtaining these bases from coal-tar oil, and separating them one from the other, is similar to that given by Greville Williams under PICOLINE (iv. 636); consisting in combining the bases with sulphuric acid, liberating them by caustic soda, dehydrating them with caustic potash, and separating them by fractional distillation, or by fractional precipitation as platinum-salts.

Rubidine, so called from the tendency of most of its salts to assume a reddish tint on exposure to the air, is a colourless liquid, having a faint odour and oily consistence. It is heavier than water (specific gravity = 1·017), slightly soluble therein, soluble in all proportions in alcohol, ether, and volatile oils. At 17° it thickens, but does not solidify. Boils at 230°.—With *chloride of lime* it produces a red colour, which does not entirely disappear on addition of acids. Fir-wood moistened with hydrochloric acid is also coloured red by it. The base precipitates alumina, chromic oxide, and ferric oxide from solutions of their salts, but not lime, baryta, or magnesia.

The solutions of rubidine in acids leave, when evaporated over the water-bath, gummy masses, which solidify in the crystalline form on standing over chloride of calcium. The *hydrochlorate* forms, with *mercuric chloride*, a double-salt which melts at 32°, and crystallises from hot water in needles, turning somewhat reddish in contact with the air. The *platinum-salt*, $2C^{22}H^{18}NCl.Pt^{iv}Cl^{4}$, is a reddish crystalline powder, insoluble in water, alcohol, and ether. With *chloride of gold*, the solution of the base in hydrochloric acid forms a yellowish-red, sparingly soluble double salt.

RUBIDIUM. *Symbol*, Rb.; *Atomic Weight*, 85·4.—A metal, belonging to the group of elements which likewise includes lithium, sodium, potassium, and cæsium. It was discovered by Kirchhoff and Bunsen in 1860, by the method of spectral analysis. Its spectrum is chiefly distinguished by two bright red lines, situated beyond the line A: hence the name of the metal (*ρυβιδος*, dark-red).

Rubidium was first detected, together with cæsium, in the mineral water of Dürckheim, in which it exists to the amount of 2 pts. in ten million. It has since been found in larger quantity, together with cæsium and lithium, in several other saline waters (see CÆSIUM, i. 1113), and most abundantly in that of Bourbonne-les-Bains, a litre of which contains 0·034 grm. chloride of potassium, 0·032 grm. chloride of cæsium, and 0·019 grm. chloride of rubidium (Grandeau, Ann. Ch. Phys. [3] lxvii. 155); and in that of Nauheim, the mother-liquor of which yields a residue containing in a pound, 2 drachms 9 grains of the chlorides of rubidium and cæsium. (Böttger, Ann. Ch. Pharm. cxxvii. 368; cxxviii. 240.)

Rubidium is also found in several lepidolites; that of Rozena, in Moravia, contains 0·24 per cent. rubidium, with only a trace of cæsium; that of Hebron, in the State of Maine, 0·24 per cent. rubidium and 0·3 per cent. cæsium. The two metals likewise occur, though in smaller quantity, in the lepidolite of Prague, the petalite of Utö in Finland, the lithia-mica of Zinnwald in Bohemia, triphylline, and other lithia minerals. The melaphyre of Norheim, in which the mineral waters of Dürckheim and Kreuznach take their rise, contains, according to Laspeyres (Bull. Soc. Chim. 1866, i. 356) 0·00038 per cent. oxide of cæsium, and 0·000298 per cent. oxide of rubidium.

Lastly, rubidium has been found in the ashes of many plants, and in the salin or crude potash obtained from the residue of the beetroot sugar manufacture (iv. 713). According to Grandeau, the salin of the North of France contains 1·8 grm. rubidium-chloride in a kilogramme. The quantity of this salt annually abstracted from the soil amounts to about 260 grms. per hectare, although the proportion of rubidium existing in the soil is too small to be detected, even by spectral analysis. Rubidium has also been found in tobacco-leaves, in coffee, tea, cocoa, and crude tartar. In minerals and mineral-waters, rubidium and cæsium are always associated with lithium, and generally also with potassium and sodium; but plants have the power of assimilating two or three of these metals, to the exclusion of the rest: thus tea, coffee, and the salin of beetroot contain potassium, sodium, and rubidium, but not a trace of lithium.

Preparation.—The best source of rubidium, according to Bunsen, is the saline residue obtained in the preparation of lithia from Saxon lepidolites, and consisting of the chlorides of sodium, potassium, and rubidium, with small quantities of chloride of cæsium, and traces of chloride of strontium. The rubidium is precipitated, together with potassium and cæsium, by platinic chloride, and separated from potassium by the inferior solubility of its chloroplatinate (i. 1114). One kilogramme of the saline mixture is dissolved in 2·5 kilogrms. of water, and the cold liquid is precipitated by a solution of about 30 grms. platinum in nitromuriatic acid. After the precipitate has completely settled down, the supernatant liquid is decanted, and the precipitate is boiled 25 times in succession with small quantities of water (about 1·5 kilogrm. in all), each portion being then poured into the original liquid decanted from the precipitate. A fresh precipitation of platinum-salt is thereby produced, and the liquid decanted therefrom is to be evaporated down to nearly its original bulk (2·5 kilogrammes). If now the precipitated chloroplatinate be decomposed by hydrogen, and the reduced platinum washed, redissolved in nitromuriatic acid, and added to the liquid, a new precipitate will be formed, related to the solution in the same manner as at the beginning of the process. The precipitate and liquid may therefore be again treated as before.

By repeating this operation seven or eight times, the greater part of the rubidium-chloride contained in a kilogramme of the same material will be extracted. Each of the precipitates thus obtained is dried over the water-bath, the whole reduced by hydrogen, and the alkaline chlorides dissolved out by water. The product thus obtained consists of 125 grms. chloride of rubidium, mixed with 3 or 4 per cent. chloride of potassium, and a very small quantity of chloride of cæsium. To remove these impurities, the boiling solutions of 36 grms. of the mixed chlorides, and of the platinic chloride produced by dissolving 30 grms. platinum in nitromuriatic acid, are mixed together, and the yellow sandy precipitate, which separates on cooling to 40°, is washed by decantation with water at 40°—50°. The washed precipitate is reduced by hydrogen at as low and regular a temperature as possible, and the same treatment is repeated till the precipitate, when examined by the spectroscope, no longer exhibits the red ray peculiar to potassium (Bunsen, Ann. Ch. Pharm. cxxii. 351). The chloride of rubidium thus purified no longer contains any foreign metal except cæsium, from which it may be separated by the processes already described (i. 1113, 1114).

The same process may of course be applied to other mother-liquors and residues containing cæsium and rubidium. Böttger (*loc. cit.*) recommends the saline residue obtained by evaporating the mother-liquor of the Nauheim water as the cheapest and most productive source of these metals.

A modification of the preceding process is given by Heintz. (J. pr. Chem. lxxxvii. 310; Jahresb. 1862, p. 121; further, Ann. Ch. Pharm. cxxxiv. 129; Bull. Soc. Chim. 1865, ii. 354.)

The following process, applicable on the large scale, for extracting the alkali-metals from lepidolite is given by Schrötter (Wien. Akad. Ber. i. [2] 268; Bull. Soc. Chim. 1865, ii. 106; Jahresb. 1864, p. 186):—The mineral is first heated to redness, without the addition of any flux. It then melts with considerable tumefaction, and when subsequently thrown into cold water, solidifies to a vitreous transparent mass, which must be pulverised and washed. (The wash-waters contain small quantities of the alkali-metals, and may be used for the treatment of another portion of the mineral). The washed mass is boiled with hydrochloric acid (2 pts. of acid of specific gravity 1·10 to 1 pt. of lepidolite) for several hours, whereby the greater part of the silica is separated; and the solution, after addition of ferric nitrate, is mixed with carbonate of sodium, which precipitates iron, aluminium, calcium, magnesium, and manganese, the liquid being sufficiently diluted to prevent the simultaneous precipitation of carbonate of lithium. The filtered liquid deposits on evaporation a small additional quantity of magnesium-carbonate, and then retains nothing but the alkaline chlorides and a small quantity of silica. It is saturated with hydrochloric acid, and mixed with an aqueous solution of potassic chloroplatinate in sufficient quantity (determined by previous trial) to precipitate the whole of the rubidium, cæsium, and thallium. The filtered liquid, containing the excess of platinum and lithium, is precipitated by sulphydric acid to separate the platinum; then concentrated, and treated with carbonate of sodium, which throws down the lithium as carbonate.

The platinum-precipitate containing rubidium, cæsium, and thallium, is reduced by hydrogen at as low a temperature as possible; the ignited mass is washed with water, to remove the chlorides of cæsium and rubidium; then treated with sulphuric acid, and again washed with water, to dissolve out the thallium-salt. Lastly, the cæsium and rubidium are separated by the processes already mentioned.

This process, according to Schrötter, may be applied to all minerals containing lithium: 1000 pts. of lepidolite thus treated yield 78 pts. carbonate of lithium, 6·5 pts. chlorides of cæsium and rubidium, and 0·6 pt. thallium—supposing the preparation to be continuously carried on. (For remarks on Schrötter's process, see v. Hauer, Bull. Soc. Chim. 1865, ii. 352.)

According to Redtenbacher (Bull. Soc. Chim. 1865, ii. 201), potassium, cæsium, and rubidium may be separated by the different solubilities of their alums at 17°, 100 pts. of water at that temperature dissolving 13·5 pts. of potassium-alum, but only 2·27 pts. of rubidium-alum, and 0·619 pt. of cæsium-alum.

Metallic Rubidium was first obtained by electrolysis of the fused chloride, the positive pole being formed of graphite, the negative pole of an iron wire; but the metal, as fast as it was isolated, rose to the surface of the fused mass, and burnt with a reddish flame. By using, instead of pure rubidium-chloride, a mixture of the chlorides of rubidium and calcium in equivalent qantities, and heating it to a temperature a little below redness, a fused mass is obtained at the negative pole, which, when thrown into water, causes a brisk evolution of hydrogen—the gas carrying with it small globules of metal, which burn on the surface of the water. This method, however, does not yield the metal in sufficient quantity to allow of an examination of its properties. On the other hand, an amalgam of rubidium is easily formed by electrolysing a strong neutral aqueous solution of rubidium-chloride, using mercury as the negative and a platinum-wire as the positive pole of the battery. The mercury then takes up the rubidium, becoming heated at the same time, and the resulting amalgam forms on cooling a brittle, crystalline, silver-white mass. It decomposes water at common temperatures, and oxidises in the air, becoming covered with a crust of rubidic hydrate.

Rubidium is obtained in larger quantity by heating a mixture of 89·55 pts. acid tartrate of rubidium, 8·46 neutral tartrate of calcium, and 1·99 soot from oil of turpentine, in a furnace similar to that used for the reduction of potassium (iv. 693), and collecting the volatilised metal in a receiver containing mineral naphtha: 75 grms. of the acid tartrate thus treated yield 5 grms. of rubidium.

Properties.—Rubidium is a white metal, with a tinge of yellow, and a silvery lustre. Specific gravity = 1·52. It is as soft as wax, even at −10°, melts at 38·5°, and is converted, even below a red heat, into a greenish-blue vapour. When exposed to the air, it instantly becomes covered with a blue-grey film of suboxide, and takes fire in a few minutes even more easily than potassium. It is decidedly more electropositive than potassium, when formed into a circuit with the latter in acidulated water. When thrown on water it takes fire, with violent evolution of hydrogen, and burns with a flame exactly like that of potassium. It burns with vivid incandescence in the vapour of chlorine, bromine, iodine, sulphur, and arsenic, and acts as a reducing agent in the same manner as potassium. (Bunsen, Ann. Ch. Pharm. cxxv. 367; Jahresb. 1863, p. 185.)

RUBIDIUM, BROMIDE OF. RbBr.—Prepared by dissolving the carbonate in hydrobromic acid; crystallises in permanent shining cubes with subordinate octahedral faces and cubic cleavage; soluble in 104·8 pts. water at 16°, and in 5·98 pts. at 100°. (Reissig, Ann. Ch. Pharm. cxxvii. 33; Jahresb. 1863, p. 186.)

RUBIDIUM, CHLORIDE OF. RbCl.—The hot solution of the hydrate or carbonate in hydrochloric acid yields, by cooling or rapid evaporation, confused crystals; by slow evaporation, cubic crystals having a vitreous lustre and easily cleavable. They are anhydrous, permanent in the air, decrepitate when heated. The chloride melts at an incipient red heat, and volatilises perfectly in the blowpipe flame on platinum-wire. 100 pts. of water dissolve 76·38 pts. rubidium-chloride at 1°, and 82·89 pts. at 7°. (Bunsen, Jahresb. 1861, p. 176.)

Chloroplatinate of Rubidium, $2RbCl.Pt^{iv}Cl^4$, is obtained by precipitation as a light-yellow, sandy, anhydrous powder, consisting of microscopic regular octahedrons, insoluble in alcohol, and much less soluble in water than chloroplatinate of potassium. (See Table of Solubilities given under CÆSIUM, i. 1114.)

RUBIDIUM, CYANIDE OF. Small cubic crystals, which decompose very easily (Reissig).—The *ferrocyanide*, $Rb^4Fe''Cy^6.2H^2O$, is obtained by boiling ferrocyanide of iron free from potash (prepared by precipitating ferrous acetate with prussic acid, and exposing the washed precipitate to the air), with hydrate of rubidium, filtering, neutralising with acetic acid, and precipitating with alcohol. The light-yellow crystals, deposited from a hot solution on cooling, appear to be triclinic. (Piccard, Rép. Chim. pure, v. 254: Jahresb. 1862, p. 125.)

RUBIDIUM, DETECTION AND ESTIMATION OF. The compounds of rubidium so closely resemble the corresponding compounds of potassium and cæsium, that they cannot be distinguished therefrom by ordinary analytical methods; but by spectral analysis, very minute quantities may be detected. The spectrum of rubidium is continuous in the middle part, like that of potassium, but somewhat less bright; it is especially characterised by two strong red lines, Rbα and Rbβ, situated beyond Fraunhofer's line A, and the two others, γ and δ, less distinct, and likewise situated beyond A. These lines are most distinctly seen with the nitrate, chlorate, perchlorate, and chloride of rubidium, on account of the facility with which these salts are decomposed by heat. A drop of water weighing 4 milligrammes, and holding in solution only 0·002 milligrm. of the chloride, shows the lines α and β very distinctly. The sulphate also gives a fine spectrum, and even with the silicate and phosphate, all parts of the spectrum may be distinctly seen. (Bunsen and Kirchhoff.)

Estimation and Separation.—In a solution not containing potassium or cæsium, rubidium may be estimated in the same manner as potassium. The separation of rubidium from potassium is effected, as already described, by the inferior solubility of its chloroplatinate (p. 128). Heintz (J. pr. Chem. lxxxvii. 320; Jahresb. 1862, p. 121) has observed, that when a mixture of the chlorides of sodium, potassium, and rubidium is treated with a quantity of platinic chloride more than sufficient to convert all the rubidium into chloroplatinates, and then boiled down to a small bulk, the supernatant liquid retains only a trace of rubidium. If, on the contrary, the platinic chloride be added in quantity less than sufficient to precipitate the whole of the rubidium, and the liquid be kept for some time at a suitable temperature, the precipitate will consist wholly of chloroplatinate of rubidium.

For quantitative estimation, however, it is best to resort to indirect methods. Bunsen (Ann. Ch. Pharm. cxxii. 347) gives the following:—

α. The two metals are precipitated together by platinic chloride, and the amount of platinum in the precipitate is determined by the loss of weight consequent on reduction by hydrogen, and subsequent washing. Let A be the weight of the precipitate, B the loss of weight caused by reduction, &c., x the weight of the potassic chloroplatinate ($KPtCl^3$)* in the precipitate, y that of the corresponding rubidium-salt; then

$$x + y = A,$$

$$\frac{2Cl}{Pt + K + 3Cl}x + \frac{2Cl}{Pt + Rb + 3Cl}y = B;$$

whence x and y may be calculated.

As, however, commercial platinum often contains impurities, which may render its atomic weight incorrect by several hundredths, it is more exact: β. To weigh the mixture of the chlorides of potassium and rubidium obtained by washing the reduced precipitate, and determine the quantity of chlorine contained therein by precipitation with nitrate of silver.

Let x be the weight of potassium-chloride, y that of rubidium-chloride, A the weight of the mixture found by experiment, B that of the precipitated chloride of silver: then

$$x + y = A;$$

$$\frac{Ag + Cl}{K + Cl}x + \frac{Ag + Cl}{Rb + Cl}y = B.$$

$$\text{whence, if } \frac{Ag + Cl}{K + Cl} = a; \quad \frac{Ag + Cl}{Rb + Cl}y = b,$$

we find:

$$x = \frac{bA - B}{b - a}; \qquad y = A - x.$$

Atomic Weight of Rubidium.—Determined in the same manner as that of potassium. According to the mean of Bunsen's experiments, it is 85·36; according to Piccard, 85·41: hence 85·4 may be regarded as correct.

RUBIDIUM, FERROCYANIDE OF. (See page 129.)

RUBIDIUM, HYDRATE OF. $RbHO$, or $Rb^2O.H^2O$. Obtained by gradually adding baryta-water to a solution of the sulphate in 100 pts. water deprived of air by boiling. If the liquid be kept near the boiling point at the time of adding the baryta-water, and agitated, the precipitated barium-sulphate settles down in a few minutes, and the filtrate evaporated in a silver retort, yields hydrate of rubidium in the form of a white porous mass, with slightly greyish reflex. It melts at a heat below redness, without loss of water, and forms on cooling a brittle, slightly friable, amorphous mass, having a lamellar fracture. It volatilises completely in the blowpipe flame, dissolves in water with great rise of temperature, deliquesces rapidly on exposure to the air, forming a syrupy liquid, which is greasy to the touch, corrodes the skin, and, on continued exposure to the air, is gradually transformed into acid carbonate of rubidium, In short, hydrate of rubidium possesses alkaline and caustic properties as powerful as those of hydrate of potassium. It dissolves in alcohol, like caustic potash. It cannot be fused in platinum-vessels because it attacks them.

---

* $Pt = 98·7$.

RUBIDIUM, IODIDE OF. RbI.—Obtained like the bromide, which it resembles in form. (Reissig.)

RUBIDIUM, OXYGEN-SALTS OF. The *acetate*, $C^2H^3RbO^2$, crystallises in nacreous laminæ (Grandeau). The *borate*, $Rb^2O.2B^2O^3.6H^2O$, separates from a hot solution of 2 at. boric acid and 1 at. rubidium-carbonate, at 6°, in small tabular rhombic crystals, exhibiting the combination $oP \,.\, \infty P \,.\, \infty\breve{P}\infty$, and having the angle $\infty P : \infty P = 82° 23'$; $\infty P : \infty\breve{P}\infty = 131° 4'$. It is permanent in the air, more soluble in hot than in cold water, and has an alkaline taste. (Reissig, Ann. Ch. Pharm. cxxvii. 33.)

Carbonates.—The *neutral salt*, Rb^2CO^3, is prepared by precipitating the sulphate with baryta-water, adding carbonate of ammonium to the filtrate, evaporating to dryness, and exhausting the residue with water. The solution yields, on evaporation, indistinct crystals of the hydrated salt, $Rb^2CO^3.H^2O$, soluble in alcohol, and having a strong alkaline reaction. The crystals, when heated, give off their water, and leave the anhydrous carbonate as a sandy powder, which melts at a higher temperature. On exposure to the air, it deliquesces, and is converted into the *acid carbonate*, $RbHCO^3$, which forms glassy prismatic crystals, permanent in the air, having a very faint alkaline reaction, a cooling, not caustic taste, and easily converted by heat into the neutral carbonate. (Bunsen and Kirchhoff.)

Chlorate, $RbClO^3$.—Prepared by mixing sulphate of rubidium and chlorate of barium in equivalent proportions. It forms very small white prisms, having the taste of chlorate of potassium, soluble in water to the amount of 2·8 per cent. at 4·7°, and 1 per cent. at 195°. (Reissig).

Perchlorate, $RbClO^4$.—Obtained by decomposing the carbonate with perchloric acid, and purified by repeated crystallisation from boiling water. It forms a sandy powder, composed of hard shining microscopic crystals. The crystals obtained by evaporation over oil of vitriol appear to be trimetric and isomorphous with perchlorate of potassium. They are anhydrous, permanent in the air, less soluble than perchlorate of potassium, and have a disagreeable, slightly saline taste. They melt easily, and decompose at a red heat into oxygen and chloride of rubidium. (Louguinine, *Traité de Chimie par Pelouze et Frémy*, 3^me ed. iii. 1419.)

Chromates.—The *neutral salt*, Rb^2CrO^4 or $Rb^2O.CrO^3$, is obtained by adding carbonate of rubidium to a solution of the dichromate. If is isomorphous with chromate of potassium, has an alkaline reaction, and forms a solution of a fine yellow colour.

The *acid chromate* or *dichromate*, $Rb^2O.2CrO^3$, forms hard, rather bulky crystals, exactly like the corresponding potassium-salt. It is easily prepared, either by supersaturating a hot solution of the carbonate with chromic acid, or by fusing the nitrate or carbonate with oxide of chromium, lixiviating, and evaporating. The mother-liquor ultimately deposits crystals of the neutral salt. (Grandeau, Ann. Ch. Phys. [3] lxvii. 155; Jahresb. 1863, p. 184.)

The *nitrate* and *oxalates* of rubidium have been already described. The *sulphates* and *tartrates* will be described under the respective acids.

RUBIHYDRAN. (Schunck, Phil. Mag. [4] xii. 200, 270.)—A substance having the composition of hydrated rubian, produced, together with rubianic acid and rubidehydran, by treating rubian with acid carbonate of barium. The brown-yellow filtrate, obtained as described at p. 125, is again mixed with baryta-water to separate any still undecomposed rubian; carbonic acid is once more passed into it, and the red flocks which separate on evaporation are removed. The filtrate mixed with basic acetate of lead, yields a red precipitate, which is to be washed, decomposed by cold dilute sulphuric acid, and treated with carbonate of lead to remove the excess of that acid. The precipitates are then removed; sulphydric acid is passed into the liquid; the sulphide of lead is separated by filtration; and the filtrate is evaporated.

Rubihydran is a brown-yellow, transparent gum, having a bitter taste, and becoming soft and moist on exposure to the air. It gives up its water only after prolonged heating over the water-bath, and then gives by analysis, 51·1 per cent. C and 6·0 H, agreeing approximately with the formula $C^{56}H^{78}O^{35} = 2C^{28}H^{34}O^{15}.5H^2O$. In other experiments, Schunck obtained numbers agreeing with the formulæ $C^{56}H^{78}O^{35}.3H^2O$ and $C^{56}H^{78}O^{35}.6H^2O$.

Rubihydran dissolves easily in water, but is not very soluble in alcohol. It is not altered by boiling phosphoric, oxalic, acetic, or tartaric acid; neither is it precipitated by any metallic salt except basic acetate of lead. With acids, alkalis, and chlorine, it yields the same products as rubian.

RUBINDENIC ACID. Syn. with Isamic Acid (iii. 403).

RUBINIC ACID. Also called *Rufocatechuic acid* (Svanberg, Ann. Ch. Pharm. xxiv. 215). When a solution of catechin in an alkaline carbonate is exposed to the air, the liquid gradually assumes a dark red colour, and then yields with hydrochloric acid, red, non-crystalline flocks of rubinic acid, which, however, is so unstable that it blackens even during washing and drying. When dried in a vacuum, and already altered, it gave by analysis 61·04 per cent. carbon and 4·21 per cent. hydrogen.

The rubinates are red and slightly soluble: their solutions blacken during evaporation. The *potassium-salt* may be isolated by saturating the red solution of catechin in potassic carbonate with acetic acid, till the rubinic acid begins to separate, adding alcohol to the filtrate, and drying the precipitated salt in a vacuum. It is very soluble in water; its solution forms red precipitates with metallic salts.

RUBIRETIN. $C^7H^6O^2$.—A substance, isomeric with benzoic acid, existing in madder-root, and obtained as a bye-product in the preparation of rubian (p. 123); in the decomposition of rubian by acids and by erythrozym (p. 124; also *Gmelin's Handbook*, xiv. 133, 135), and in the preparation 1 of rubiadin (p. 120); in the last case as a lead-compound. It is also produced by boiling chlororubian with alkalis.

The mixture of the lead-compounds of rubiretin and verantin, obtained in the preparation of rubiadin, yields, when decomposed by boiling hydrochloric acid, a brown powder, from which the rubiretin may be dissolved out by cold alcohol, the greater part of the verantin remaining behind. The alcoholic solution, when evaporated, leaves the rubiretin, which, if it does not melt in boiling water, must be purified by re-solution in cold alcohol and evaporation of the filtrate. A similar mode of purifying may be applied to rubiretin obtained as a secondary product under other circumstances.

Properties.—Rubiretin is a dark reddish-brown resin, brittle and friable in the cold, soft at 65°, melting, at about 100°, to dark-brown drops. It gives by analysis, 68·41 per cent. C, and 5·22 H (calc. 68·85 C, 4·91 H, 26·24 O).

Rubiretin dissolves sparingly in boiling *water*, but softens therein, and on cooling deposits yellow flocks, which increase on the addition of an acid. It is easily soluble in *alcohol*. It dissolves with dark orange colour in *oil of vitriol*, and is precipitated by water. It dissolves in *ammonia*, in the *pure fixed alkalis*, and in *alkaline carbonates*, forming brown-red solutions, from which it is precipitated by acids. The ammoniacal solution forms purple precipitates with *chloride of barium* and *chloride of calcium*, dirty red with *alum* and *nitrate of silver*. It dissolves in aqueous *ferric chloride*, with dark red-brown colour, and is precipitated by acids. When free from alizarin, it does not dye mordanted fabrics.

When heated in a test-tube, it generally yields a scanty sublimate of alizarin, together with a brown oil. It is decomposed by hot *oil of vitriol*. Boiling *nitric acid* converts it into a yellow substance, which no longer softens in boiling water, and is scarcely soluble in alcohol. *Chlorine* passed into the alcoholic solution of rubiretin, decolorises it, and renders it no longer precipitable by acids. (Schunck.)

RUBITANNIC ACID. Tannic acid from the leaves of *Rubia tinctorum*. (Willigk, Ann. Ch. Pharm. lxxxii. 340; Gm. xv. 532.)

RUBRINITRIC ACID, or *Nitro-hæmatic acid*. See Picramic Acid under Phenol (iv. 406).

RUBY. The Oriental ruby is a red variety of corundum (ii. 86); see also *Dana's Mineralogy* (ii. 111). The red varieties of spinel are sometimes called *Spinel ruby*, *Balas ruby*, or *Alamandin ruby*. (See Spinel.)

RUE, OIL OF. The essential oil obtained by distilling garden rue (*Ruta graveolens*) with water. When purified by a few rectifications, it is somewhat viscid; has a specific gravity of 0·837 at 18°; a strong disagreeable odour, like that of the plant; a slightly bitter aromatic taste; boils at 228°—230°; and solidifies, between + 1° and − 2°, to shining crystalline laminæ, resembling those obtained from anise-oil.

Oil of rue is chiefly a mixture of a hydrocarbon with an aldehyde or ketone belonging to the series $C^nH^{2n}O$. This compound, separable by alkaline bisulphites, was formerly regarded, according to the investigations of Gerhardt (Compt. rend. xxvi. 225, 361; *Traité*, ii. 773), and of Cahours (Compt. rend. xxvi. 262), as capric or rutic aldehyde, $C^{10}H^{20}O$. But Greville Williams (Phil. Trans. 1858, [1] 99; Jahresb. 1858, p. 443) has shown that the crude oil contains two such compounds, viz., $C^{11}H^{22}O$ and $C^{12}H^{24}O$, the latter in comparatively small quantity; and this result has been confirmed by Harbordt. (Ann. Ch. Pharm. cxxiii. 293; Jahresb. 1862, p. 250.)

Williams, by subjecting crude oil of rue to repeated fractional distillation, obtained distillates having boiling-points between 160° and 238°. The portion boiling between 160° and 188°, give, with alkaline bisulphites, scarcely traces of a crystalline compound; but the fractions of higher boiling-point yield crystalline compounds when thus treated (best with the ammonium-salt); and the portions boiling above 210° solidify, after a few hours' contact with the acid sulphite, to a crystalline mass, from which, after washing with the solution of the sulphite, pressure, &c., the aldehyde or ketone may be separated by distillation with potash.

The product thus obtained from the portion of the oil boiling between 210° and 232° is a colourless liquid, having a fruity odour quite different from that of rue. Specific gravity = 0·8497 at 15°. When cooled to + 7° and shaken, it solidifies to a white mass resembling camphor. Boils at 213° (oxidising at the same time unless kept in an atmosphere of hydrogen). Gives by analysis, 77·71 per cent. C and 13·07 H, agreeing with the formula $C^{11}H^{22}O$, which requires 77·65 C, 12·94 H, and 9·41 O. Vapour density, obs. = 5·870; calc. = 5·874. Williams regards this compound as euodic aldehyde or hydride of euodyl, $C^{11}H^{21}O.H$, the name being suggested by its fragrant odour. See also Hallwachs (Jahresb. 1859, p 506).

The higher fractions of crude oil of rue, yielded also by similar treatment a small quantity of a liquid boiling at 232°, and having nearly the composition of lauric aldehyde, $C^{12}H^{24}O$; anal. 78·1 per cent. C, 12·9 H; calc. 78·3 C, 13·0 H, and 8·7 O. Vapour-density, obs. = 6·182; calc. = 6·366.

According to Harbordt (*loc. cit.*), the compound $C^{11}H^{22}O$, which forms the chief constituent of rue-oil, is not euodic aldehyde, but a ketone, viz., methyl-caprinol = $C^{10}H^{19}O.CH^3$. The portion of the crude oil boiling at 228°, yielded by analysis numbers agreeing with the formula of lauric aldehyde, $C^{12}H^{24}O$; but the compound obtained therefrom with acid ammonium-sulphite, gave by distillation with carbonate of sodium, a body agreeing nearly in composition and vapour-density (obs. 6·03) with the formula $C^{11}H^{22}O$. This 11-carbon compound yielded by oxidation (together with oxalic acid), capric acid, caprylic acid, and lower members of the acetic acid series, but no acid containing 11 at. carbon.

The portion of rue-oil which does not combine with alkaline bisulphites, is separable into a more volatile portion, having the composition of turpentine oil, and a less volatile portion, which appears to be isomeric with borneol, but boils at a lower temperature. (Gr. Williams.)

RUFIGALLIC ACID. $C^7H^4O^4.H^2O$. *Para-ellagic acid.* (Robiquet, Ann. Ch. Pharm. xix. 204.)—This acid, which, in the dry state, contains the elements of gallic acid *minus* 1 at. water, is produced by gently heating gallic acid to 140° with 5 pts. of strong sulphuric acid, and pouring the sticky mass when cold into cold water, drop by drop. An abundant red-brown precipitate is then formed, partly flocculent, partly crystalline, and the crystalline portion, which amounts to 50 or even 70 per cent. of the gallic acid employed, may be separated by levigation.

Rufigallic acid thus obtained forms kermes-brown crystalline grains, which at 120° give off 10·6 per cent. (1 at.) water, and lose their lustre. When strongly heated in the air, it carbonises in great part, becoming covered with small cinnabar-coloured prisms. It dissolves in 3,500 pts. of water, easily in potash, the solution, when exposed to the air, depositing coloured crystals after a long time. On boiling the acid with stuffs mordanted with alum or an iron-salt, dyes are obtained similar to those produced by madder, but less bright.

RUFIMORIC ACID. (Wagner, J. pr. Chem. li. 82.)—An acid obtained, in the form of a dark brick-red precipitate, when a solution of morintannic acid in cold strong sulphuric acid, or that produced by boiling morintannic acid with dilute hydrochloric acid, is left to itself for some time. When purified by washing with cold water, solution in alcohol, reprecipitation with water, and drying, it forms a dark-red amorphous powder, very soluble in alcohol, less soluble in water, very slightly soluble in ether. A very small quantity of ammonia suffices to render it soluble in water, in all proportions. Its solutions have an acid reaction. Its composition, as determined by analysis (54·4 per cent. C, 4·4 H), is very near to that of morintannic acid; and as the latter can be reproduced by the action of alkalis on rufimoric acid, it is probable that the two acids are either isomeric, or differ only by the elements of water.

Rufimoric acid may be heated without decomposition to 130°; but above that temperature, it gives off vapours which condense to a crystalline mass, exhibiting all the characters of pyrocatechin. It dissolves with red colour in strong sulphuric acid without alteration, also in hydrochloric acid. Nitric acid converts it into oxalic acid and a nitrogenised acid. With caustic alkalis and their carbonates, it forms crimson solutions, which lose their colour but slowly. An alcoholic solution of the acid forms with alcoholic potash a dark-red viscous precipitate. Rufimoric acid, boiled with potash or baryta, is reconverted into morintannic acid.

The aqueous solution of rufimoric acid (containing a trace of ammonia), does not precipitate alum; but on adding more ammonia, a dark-red lake is thrown down. The same reaction is produced with stannous chloride and chloride of barium. Neutral acetate of lead, cupric acetate, and mercurous nitrate form red or brown precipitates. Nitrate of silver and sulphate of zinc are not precipitated.

Chlorine decomposes the solution of rumiforic acid, throwing down red flocks.

RUFIN. $C^{21}H^{20}O^{8}$. (Mulder, Rev. scientif. iii. 50.)—A compound produced by the action of heat on phlorizin, and differing therefrom by the elements of 2 at. water: $C^{21}H^{24}O^{10} = C^{21}H^{20}O^{8} + 2H^{2}O$. It is a resinous substance of a red colour, very friable, dissolving in alcohol with deep orange colour, nearly insoluble in ether. Water dissolves it at the boiling heat, and decolorises it instantly; the solution becomes milky on cooling. Rufin dissolves in strong sulphuric acid, producing a fine red solution, which is decolorised by water. It is insoluble in hydrochloric acid; decomposed by hot nitric acid. It dissolves with red colour in potash and ammonia, and is precipitated therefrom by acids.

RUM. A spirituous liquor distilled in the West Indies from molasses. (See *Ure's Dictionary of Arts, &c.* iii. 606.)

RUMICIN. Syn. with CHRYSOPHANIC ACID (i. 958). This substance exists in the roots of various species of *Rumex*, viz., *Rumex patientia*, *R. palustris*, *R. acutus*, *R. aquaticus*, and *R. Hydrolapathum*, as well as in rhubarb and wall-lichen.

RUSIOCHINE. A red substance produced by the action of chlorine-water and ammonia on quinine (p. 18).

RUTAMIDE. Syn. with CAPRAMIDE.

RUTHENHYPERIC ACID. See RUTHENIUM, OXIDES OF (p. 137).

RUTHENIOCYANIDES. See CYANIDES OF RUTHENIUM (ii. 271).

RUTHENIUM. *Atomic weight*, 104. *Symbol*, Ru.—This metal, discovered by Claus in 1846, occurs in platinum-ore, and chiefly in osmiridium, which sometimes contains it to the amount of 3 to 6 per cent. Its properties and combinations have been examined chiefly by Claus (Pogg. Ann. lxiv. 192, 624; lxv. 200; Ann. Ch. Pharm. lvi. 257; lix. 234; lxiii. 259), Frémy (*Traité de Chimie par Pelouze et Frémy*, 3^{me} ed. iii. 1334), and Deville and Debray (Ann. Ch. Phys. [3] lvi. 385; Jahresb. 1859, p. 233).

Extraction: 1. Pulverised osmiridium, mixed with about half its weight of common salt, is heated to low redness in a current of moist chlorine; the disintegrated mass is digested in cold water; and the concentrated solution, which is brown-red and almost opaque, is mixed with a few drops of ammonia and gently heated, whereupon it deposits a copious black-brown precipitate, consisting of sesquioxide of ruthenium and dioxide of osmium. This precipitate, after being washed with nitric acid, is heated in a retort, till the osmium is expelled in the form of osmic tetroxide. The residue is then ignited for an hour in a silver crucible with caustic potash free from silica, and the ignited mass is softened and dissolved by cold distilled water. The solution is left in a corked bottle for two hours to clarify; after which the perfectly transparent orange-coloured liquid is separated by a siphon, and neutralised with nitric acid. It then deposits velvet-black sesquioxide of ruthenium, which, when washed, dried, and ignited in an atmosphere of hydrogen, yields the pure metal. (Claus; see also PLATINUM-ORE, iv. 681).

2. Pulverised osmiridium is heated with 3 pts. peroxide and 1 pt. nitrate of barium; the mass is treated in the manner described under IRIDIUM (iii. 315, No. 5); and the orange-yellow solution of ruthenate of potassium, ultimately obtained by fusing the mixture of iridium and ruthenium with nitre and caustic potash, and lixiviating with water, is treated with carbonic or nitric acid till it becomes colourless; it then deposits oxide of ruthenium, slightly contaminated with silica. This oxide, strongly calcined in a graphite crucible, yields metallic ruthenium, which is then fused in the oxyhydrogen furnace (iv. 313). The ruthenium thus obtained still requires to be purified by one or more fusions with nitre and potash, till its density is brought up to 11·3. (Deville and Debray.)

3. Scaly osmiridium, consisting almost entirely of osmium, iridium, and ruthenium, is heated to bright redness in a porcelain tube, through which a current of air (freed from carbonic acid by passing through potash, and from organic matter by passing through oil of vitriol) is drawn by means of an aspirator. The osmium and ruthenium are thereby oxidised, the former being carried forward as tetroxide and condensed in caustic potash solution, while the oxide of ruthenium remains behind, together with iridium; and by fusing this residue with hydrate of potassium, and treating the

mass with water, a solution of potassic rutheniate is obtained as above (Frémy). According to Deville and Debray, the ruthenium thus obtained is still contaminated with small quantities of osmium, rhodium, and iridium.

Properties.—Ruthenium obtained by calcining one of its ammoniacal chlorides, is a white spongy mass; when separated from its oxides by reduction with hydrogen, it forms porous fragments, very much resembling iridium, and moderately easy to pulverise. It is the most refractory of all metals except osmium. Deville and Debray have, however, fused it by placing it in the hottest part of the oxyhydrogen flame at about 2 millimetres from the orifice of the jet. After fusion, it has a density of 11 to 11·4; that of the porous metal is only 8·6.

Ruthenium is scarcely attacked by nitromuriatic acid. It is, however, more easily oxidised than platinum, or even than silver (Frémy). When pure it is easily oxidised by fusion with hydrate of potassium, still more easily on addition of a small quantity of nitrate or chlorate, producing rutheniate of potassium, which dissolves in water, with orange-yellow colour.

RUTHENIUM, ALLOYS OF. Zinc forms with ruthenium an alloy, which crystallises in regular hexagonal prisms, takes fire when heated in the air, and burns with faint deflagration.

An alloy of tin and ruthenium, $RuSn^2$, is easily obtained by heating ruthenium to redness in a graphite crucible, with 10 to 15 times its weight of tin, and dissolving out the excess of tin from the cooled mass with hydrochloric acid. The alloy then remains in magnificent cubic crystals, like those of melted bismuth. (Deville and Debray.)

RUTHENIUM, CHLORIDES OF. Ruthenium forms three chlorides, viz., $RuCl^2$, $RuCl^3$, and $RuCl^4$; the last, however, is known only in combination.

The *dichloride*, $RuCl^2$, is produced, together with the trichloride, by igniting pulverised ruthenium in a stream of chlorine, the trichloride then volatilising; while the dichloride remains in the form of a black crystalline powder, insoluble in water and in all acids, even nitromuriatic acid, and only partially decomposed by alkalis. A soluble dichloride is formed by passing sulphydric acid gas into a solution of the trichloride. A brown sulphide is then precipitated, and the solution acquires a fine blue colour. If the excess of sulphydric acid be expelled by a current of air, a pure solution of the dichloride will be obtained, which becomes green by strong concentration, and yields with ammonia a green precipitate of the soluble dichloride (? hydrated). Both the blue and the green dichloride are converted into trichloride when heated with nitric acid.

Trichloride or *Ruthenious Chloride*, $RuCl^3$. Prepared by precipitating a solution of potassic rutheniate with an acid, dissolving the precipitated black oxide in hydrochloric acid, and evaporating. It is a yellow-brown, crystalline, very deliquescent mass, becoming dark-green and blue at certain points when strongly heated. It dissolves easily in water and in alcohol, leaving a small quantity of a yellow insoluble salt.

The concentrated solution of ruthenious chloride, mixed with concentrated solutions of the chlorides of potassium and ammonium, yields the double salts $K^2Ru'''Cl^5 = 2KCl.RuCl^3$ and $(NH^4)^2Ru'''Cl^5$, in the form of crystalline precipitates, with violet iridescence, very slightly soluble in water, insoluble in alcohol. The solution of the potassium-salt, left for some time in contact with water, becomes turbid and black, and deposits a black oxychloride of ruthenium; the same decomposition takes place immediately on heating the solution.

Tetrachloride of Ruthenium or *Ruthenic Chloride*, $RuCl^4$, is known only in its double salts. The *potassium-salt*, $K^2Ru^{iv}Cl^6 = 2KCl.RuCl^4$, is prepared by mixing a solution of ruthenic hydrate in hydrochloric acid with chloride of potassium, and evaporating to the crystallising point. It is brown, with rose-coloured iridescence, very soluble in water, but insoluble in alcohol. It appears to be dimorphous, inasmuch as, when deposited from a solution containing several other salts, it crystallises in microscopic six-sided prisms, but, under other circumstances, in regular transparent octahedrons, being then isomorphous with the corresponding salts of platinum, palladium, osmium, and iridium.

The *ammonium-salt*, $2NH^4Cl.RuCl^4$, is obtained like the potassium-salt, which it resembles closely.

RUTHENIUM, CYANIDES OF. (See CYANIDES, ii. 271.)

RUTHENIUM, DETECTION AND ESTIMATION OF. Ruthenium is most frequently met with in solution in the form of trichloride. This solution, which is of an orange-yellow colour, is distinguished by its character of decomposing, when heated, into hydrochloric acid and blackish-brown sesquioxide of ruthenium. The same solution exhibits with reagents the following characters:—

Sulphydric acid partly precipitates the ruthenium in the form of a black sulphide, but at the same time reduces the trichloride to dichloride, the reduction being attended with a change of colour from orange-yellow to a fine azure-blue: this reaction is extremely delicate, and very characteristic of ruthenium. *Zinc* effects the same reduction. *Sulphydrate of ammonium* throws down the greater part of the ruthenium, in the form of a black-brown sulphide, not perceptibly soluble in excess.—The *caustic alkalis, alkaline carbonates*, and *phosphate of sodium* precipitate the black sesquioxide, insoluble in excess of the reagent.—*Borax* forms no precipitate at first, but, on heating the solution, the hydrated sesquioxide is thrown down.—*Sulphurous acid, oxalic acid*, and *formate of sodium* do not precipitate the metal, but merely decolorise the solution. —*Ferrocyanide of potassium* decolorises the solution at first, but afterwards turns it bluish-green.—*Sulphocyanate of potassium* produces, after awhile, a red coloration passing to deep red-purple, and changing to a fine violet on heating the liquid. This is one of the most characteristic reactions of ruthenium, inasmuch as soluble sulphocyanates do not exhibit any very decided character with the other metals of the platinum group; for its distinct production, however, it is necessary that the solution be free from other platinum-metals.—*Acetate of lead* forms a purple-red precipitate, inclining to black.—*Cyanide of mercury* colours the solution blue, and throws down a blue precipitate.—*Nitrate of silver* forms a black precipitate, which is a mixture of chloride of silver and sesquioxide of ruthenium; the oxide dissolves, after a while, in the nitric acid, leaving a white residue of chloride of silver; and if ammonia be then added in excess, the chloride of silver dissolves, and the sesquioxide of ruthenium is reprecipitated: this is also a very delicate reaction.—The *chlorides of potassium* and *ammonium* throw down, from concentrated solutions, crystalline precipitates of double chlorides, exhibiting a play of colours inclining to violet.—The *nitrites of the alkali-metals* form with ruthenious solutions, double salts $[3MNO^2.Ru'''(NO^2)^3]$, which dissolve readily in excess of the alkaline nitrite, forming solutions, which, when treated with a small quantity of yellow sulphide of ammonium, assume a splendid dark-red colour, changing to brown without precipitation of sulphide. This reaction is recommended by Gibbs and by Claus (Jahresb. 1863, p. 697) for the detection of nitrites.

The solution of chlororutheniate of potassium, $2KCl.RuCl^4$, exhibits the following reactions:—With *sulphydric acid*, no reaction at first; but after a while, or on heating, a brown precipitate of disulphide, RuS^2. a considerable quantity of ruthenium, however, remaining in solution.—Yellow *sulphydrate of ammonium* immediately throws down part of the ruthenium, in the form of a brown-yellow sulphide; the reaction is complete on the addition of an acid.—*Potash* and *alkaline carbonates* form no precipitate in the cold; a deposition of oxide takes place on heating the liquid, but a considerable portion still remains dissolved.—*Nitrate of silver* forms a rose-coloured, mercurous *nitrate*, a light-yellow, and *stannous chloride* a yellow precipitate.

The compounds of ruthenium may readily be distinguished from those of the other platinum-metals, by fusing a few milligrammes of the substance in a platinum-spoon, with a large excess of nitre, leaving it to cool when it ceases to froth, and dissolving the cooled mass in a little distilled water. An orange-yellow solution of potassic rutheniate is thus formed, which, on addition of a drop or two of nitric acid, yields a bulky black precipitate; and on adding hydrochloric acid to the liquid, with the precipitate still in it, and heating it in a porcelain crucible, the oxide dissolves, forming a solution which has a fine orange-yellow when concentrated, and when treated with sulphydric acid till it becomes nearly black, yields a filtrate of a splendid sky-blue colour. Characteristic reactions are also obtained with sulphocyanate of potassium and acetate of lead.

Metallic ruthenium may be distinguished from the other platinum-metals by mixing it with common salt, and igniting the mixture in a current of chlorine. The resulting black mass dissolves in water, with a fine orange-yellow colour, which of itself is sufficient to distinguish ruthenium from rhodium and iridium (the former of which yields under similar circumstances a rose-coloured, and the latter a black-brown solution). It may be further distinguished by the black precipitate which it yields with ammonia, and by the reactions with sulphydric acid, &c., above mentioned.

Estimation and Separation.—Ruthenium is precipitated from its solutions in the form of oxide, and generally as sesquioxide, viz., from a solution of the sesquichloride, either by alkalis or by simply heating the solution, and from a solution of rutheniate of potassium by nitric acid. The precipitated oxide is reduced to the metallic state by ignition in an atmosphere of hydrogen. As, however, the precipitate generally contains alkali, which cannot be removed by washing, the reduced mass must be treated with water; the liquid filtered from the ruthenium; and the metal, before weighing, must be again ignited, and left to cool in an atmosphere of hydrogen, as it oxidises when heated in the air.

Ruthenium has hitherto been found only associated with the metals of the platinum-residues, and from these it is separated by the methods already described (p. 134; see also PLATINUM-ORE, iv. 681).

The following methods of separating ruthenium from platinum, rhodium, and iridium, are given by Gibbs (Sill. Am. J. [2] xxxiv. 341; Jahresb. 1863, p. 292):—

1. From *Platinum.*—The mixture of the double chlorides, K^2PtCl^6 and K^2RuCl^6, is treated with a cold solution of chloride of potassium; the resulting solution, which contains chiefly the ruthenium-salts, is heated with nitrite of potassium, and evaporated to dryness; and the residue is treated with hot absolute alcohol, which leaves chloroplatinate of potassium undissolved. The alcoholic solution containing the chlororutheniate of potassium (together with traces of platinum) is evaporated; the residue is heated with hydrochloric acid; the deep rose-coloured solution of the potassic chlororutheniate is repeatedly evaporated to dryness with sal-ammoniac; and the hot aqueous solution of the resulting chlororutheniate of ammonium is converted, by evaporation with ammonia, into the yellow ammonio-chloride, $4NH^3.RuCl^2.3H^2O$. The latter, when dissolved in hot water, yields with mercuric chloride a yellow crystalline precipitate of the salt, $4NH^3.RuCl^2.Hg''Cl^2$, which may be freed from platinum by recrystallisation, and yields by ignition silver-white ruthenium.

2. A similar method serves for the separation of ruthenium from *rhodium*, the latter metal remaining undissolved as chlororhodiate of potassium, when the solution of the two double chlorides is treated with nitrite of potassium, and the evaporated residue with alcohol. The chlororhodiate of potassium is then either converted into metallic rhodium by ignition with sal-ammoniac, or dissolved in hot hydrochloric acid, supersaturated with ammonia, and precipitated as sulphide by sulphydric acid. (Gibbs.)

3. From *Iridium.*—The best mode of proceeding is to heat the solution of the two metals with an excess of nitrite and carbonate of sodium till a light orange-yellow is produced; then add sulphide of sodium by small portions, till part of the precipitated sulphide of ruthenium is redissolved; boil for a few minutes; and mix the liquid, after cooling, with a slight excess of hydrochloric acid. The precipitated sulphide of ruthenium is washed with hot water, dissolved in nitromuriatic acid, and converted, first into chlororutheniate of ammonium, then into the above-mentioned mercury-compound. The solution filtered from the sulphide of ruthenium, and evaporated with hydrochloric acid and sal-ammoniac, yields pure chloriridiate of ammonium.—The tetrachlorides of iridium and ruthenium may also be separated by heating with nitrite and carbonate of potassium, evaporating to dryness, and treating the residue with absolute alcohol. The ruthenium-salt then dissolves, whilst the iridium-salt remains, and may be easily converted into chloriridiate of ammonium.

According to Gibbs, the separation of iridium and ruthenium by ignition with nitre and potash does not yield good results, inasmuch as part of the ruthenium always remains unattacked, and a small quantity of the iridium dissolves, together with the rutheniate of potassium.

On the separation of ruthenium and the other platinum-metals, see further Gibbs (Sill. Am. J. [2] xxxvii. 57; Jahresb. 1864, p. 288; Bull. Soc. Chim. 1864, ii. 38), Carey-Lea (Sill. Am. J. [2] xxxviii. 31; Jahresb. 1864, p. 290).

Atomic Weight of Ruthenium.—Claus (J. pr. Chem. xxxiv. 173, 420; Ann. Ch. Pharm. lvi. 257), by the analysis of chlororuthenite of potassium, $2KCl.RuCl^3$, found that the atomic weight of the metal was 104·22, which is nearly the same as that of rhodium. Other experiments gave higher numbers, but the above determination is generally regarded as nearest to the truth.

RUTHENIUM, OXIDES OF. Ruthenium forms five oxides, viz. RuO, Ru^2O^3, RuO^2, RuO^3, and RuO^4, the fourth, however, being known only in combination.

The *protoxide*, RuO, obtained by calcining the dichloride with carbonate of sodium in a current of carbonic anhydride, and washing the residue with water, has a dark-grey colour and metallic lustre, is not acted upon by acids, but is reduced by hydrogen at ordinary temperatures.

Sesquioxide, or *Ruthenious Oxide*, Ru^2O^3.—Pulverised ruthenium, heated in contact with the air, rapidly absorbs 48 per cent. oxygen, and is afterwards slowly converted into the anhydrous sesquioxide, which has a deep blue colour, is insoluble in acids, and is reduced when heated into hydrogen gas.

The hydrated sesquioxide, $Ru^2O^3.3H^2O = RuH^3O^3$, is obtained as a blackish-brown precipitate, when a solution of ruthenious chloride is treated with an alkaline carbonate. This hydrate, after prolonged washing, still retains 3 or 4 per cent. of alkali; it dissolves with yellow colour in acids, but is not dissolved by water or by alkalis. When strongly heated in an atmosphere of carbonic anhydride, it gives off its water, and becomes insoluble in acids.

The *dioxide* or *ruthenic oxide*, RuO^2, is formed by roasting the disulphide, or by strongly igniting ruthenic sulphate, RuS^2O^8 or $RuO^2.2SO^3$. The former method yields a black-blue powder with a tinge of green; the latter, grey particles with metallic lustre, and bluish or greenish iridescence.

The *hydrate*, $RuH^4O^4 = RuO^2.2H^2O$, is obtained as a gelatinous precipitate, by decomposing chlororutheniate of potassium with carbonate of sodium, or ruthenic sulphate with caustic potash or soda; in the latter case, however, the solution must be evaporated, as it retains a considerable quantity of the hydrate. Ruthenic hydrate, when dried and heated in a platinum spoon, deflagrates with vivid incandescence, and is scattered about. It dissolves in acids, forming yellow solutions. The solution in hydrochloric acid turns red when evaporated, and ultimately leaves red-brown ruthenic chloride. The hydrate dissolves also with light-yellow colour in alkalis.

The *trioxide*, RuO^3, commonly called *ruthenic acid*, is known only in the form of a potassium-salt, which is obtained by igniting ruthenium with a mixture of potash and nitrate or chlorate of potassium. It dissolves in water, forming an orange-yellow solution, which has an astringent taste, colours organic substances black by coating them with oxide, and is decomposed by acids, yielding a precipitate of the sesquioxide.

Tetroxide of Ruthenium, RuO^4. *Ruthenic tetroxide. Perruthenic acid. Ruthenhypersäure.*—This volatile oxide, analogous to osmic tetroxide, is obtained by heating to dull redness, in a silver crucible, a mixture of 3 grammes of ruthenium with 24 grms. caustic potash and 8 grms. nitre, dissolving the fused mass in 48 grms. of water, introducing the solution into a tubulated retort connected by a long condensing tube with a flask containing caustic potash, and passing chlorine into the liquid. The liquid becomes hot, and the tetroxide passes over, condensing in the neck of the retort and the tube, as a golden-yellow crystalline crust, which melts between 50° and 60°. Part of it, however, remains in the liquid, and may be separated by distillation. To purify it from adhering water and chlorine, it is melted in a tube under a layer of water; it then crystallises on cooling, and may be pressed between paper.

Ruthenic tetroxide is a golden-yellow, crystalline mass, in which rhomboïdal prisms may be distinguished. It is heavier than sulphuric acid, very volatile, vaporising even at ordinary temperatures, and emitting an odour like that of nitrous acid; melts at 58°, forming a yellow liquid, which boils at about 100°. It dissolves sparingly in water, the solution remaining unaltered in the dark, but decomposing rapidly even in diffused daylight. It dissolves in hydrochloric acid, without losing its characteristic odour, and on adding alcohol to the solution, trichloride of ruthenium is formed. Sulphurous acid colours the solution of ruthenic tetroxide red-purple, changing to violet-blue when heated. Sulphydric acid throws down a black precipitate of oxysulphide. The dry oxide moistened with strong potash, becomes hot, melts, and volatilises in great part, the rest gradually dissolving as rutheniate of potassium. (Claus, J. pr. Chem. lxxix. 28; Jahresb. 1859, p. 260.)

RUTHENIUM, SULPHIDES OF. Sulphydric acid, passed into a solution of either of the chlorides of ruthenium, usually forms a precipitate consisting of sulphide and oxysulphide of ruthenium mixed with free sulphur. The blue solution of the protochloride yields a dark-brown sesquisulphide, Ru^2S^3. When sulphydric acid gas is passed for a long time into a solution of the trichloride, disulphide of ruthenium, RuS^2, is formed, as a brown-yellow precipitate, becoming dark-brown by calcination.

RUTHENIUM-COMPOUNDS, AMMONIACAL. *a. Di-ammoniacal.*—The *oxide*, $RuO.2NH^3$, is obtained by evaporating a solution of the tetrammoniacal oxide, $RuO.4NH^3$, in a dry vacuum, as a yellowish-brown spongy mass, formed of small, very deliquescent, crystalline laminae, containing 5 at. water. When placed on the tongue, it exerts a caustic action, stronger even than that of potash. Its salts resemble those of the following series, excepting that they are of a darker colour:—

β. Tetrammoniacal.—The *chloride*, $RuCl^2.4NH^3.3H^2O$, is obtained by dissolving 1 pt. of chlororutheniate of ammonium, $2NH^4Cl.RuCl^4$, in 16 pts. of water, boiling the solution for an hour with 30 pts. of caustic ammonia and 1 pt. of ammonium-carbonate, evaporating to dryness over the water-bath, digesting the pulverised crystalline mass with 1 pt. of water, and washing it on a filter with weak alcohol, till the free sal-ammoniac is completely dissolved. The salt when dry is dissolved in 4 pts. of hot water containing a little carbonate of ammonium; and the solution, filtered while still hot, deposits the salt on cooling in beautiful golden-yellow, oblique rhombic crystals, which are not very soluble in cold water, and quite insoluble in alcohol. The crystals retain their water till they are heated to a temperature at which they undergo complete decomposition, leaving metallic ruthenium. The solution has a strong tendency to form slightly soluble compounds with other metallic salts. Caustic potash does not eliminate ammonia from it at ordinary temperatures, but liver of sulphur immediately sets ammonia free; with chloride of platinum, it immediately forms a precipitate of the compound $RuCl^2.4NH^3.PtCl^4$.

The chloride, treated with oxide of silver, yields the oxide $RuO.4NH^3$, which, however, has not been obtained in the solid state, as its solution when evaporated gives off half its ammonia, leaving the oxide $RuO.2NH^3$, already described. The solution of the tetrammoniacal oxide resembles that of potash; it absorbs carbonic acid from the air, expels ammonia from its salts, precipitates metallic oxides, and dissolves alumina: it does not, however, exert any action on the salts of copper or silver.

The oxygen-salts of this base, obtained by decomposing the chloride with the corresponding silver-salts, are very soluble in water, but, for the most part, insoluble in alcohol. The *carbonate*, $RuCO^3.2NH^3.5H^2O$, is soluble, strongly alkaline, and crystallises in light-yellow rhombic prisms. The *nitrate*, $Ru(NO^3)^2.2NH^3.2H^2O$, forms small rhomboïdal prisms, having a sulphur-yellow colour and strong lustre, melts when heated, and decomposes with slight detonation. The *sulphate*, $RuSO^4.2NH^3.4H^2O$, crystallises in fine transparent rhombic plates of a golden-yellow colour. When exposed to the air, they give off part of their water, and become opaque, acquiring a metallic aspect. (Claus, J. pr. Chem. lxxix. 28; lxxxv. 129; Jahresb. 1859, p. 263; 1861, p. 320.)

RUTHERFORDITE. A mineral from the gold-mines of Rutherford County, North Carolina, where it occurs in small, brown, monoclinic crystals, which exhibit incandescence when heated. According to Shepard (Sill. Am. J. xii. 209), it contains titanic oxide and ceric oxide; according to T. S. Hunt (*ibid.* [2] xiv. 344), 58 per cent. titanic oxide, 12 lime, &c.

RUTIC ACID. Syn. with CAPRIC ACID (i. 742).

RUTILE. A variety of native titanic oxide. (See TITANIUM.)

RUTILIN. The name applied by Braconnot to a red resinous substance (called *olivin* by Mulder), produced by salicin with strong sulphuric acid: probably impure saliretin.

RUTIN. $C^{25}H^{28}O^{15}$. *Rutinic Acid. Phytomelin. Melin. Vegetable Yellow.* (Weiss, Pharm. Centr. 1842, p. 903.—Borntrӓger, Ann. Ch. Pharm. liii. 385.—Rochleder and Hlasiwetz, *ibid.* lxxxii. 197.—W. Stein, J. pr. Chem. lviii. 399; lxxxviii. 280.—Hlasiwetz, Ann. Ch. Pharm. xcvi. 123; further, Chem. Centr. 1862, p. 449.—Zwenger and Dronke, Ann. Ch. Pharm. cxxiii. 145.—Gm. xvi. 500.)—A glucoside, which appears to be very widely diffused in the vegetable kingdom. It was first obtained from garden rue, by Weiss and by Borntrӓger; afterwards from capers, the flower-buds of *Capparis spinosa*, by Rochleder and Hlasiwetz, also by Zwenger and Dronke; and from the so-called *Waifa*, the undeveloped flower-buds of *Sophora japonica*, by Stein and by W. Martius (N. Jahrb. Pharm. i. 241). According to Stein, safflower yellow is uncrystallisable rutin; the colouring matters of straw and of *Æthalium*, *Hippophaë*, and *Polygonum Fagopyrum* likewise agree in character with rutin.

Preparation: 1. *From Garden rue.*—The dried and comminuted plant is boiled for half-an-hour with common vinegar, and the expressed liquid is set aside for several weeks, or so long as it continues to deposit impure rutin. The deposit is washed with cold water, heated to boiling with 4 pts. of acetic acid and 16 pts. of water, filtered, and left for some days to crystallise. The crystals obtained thus, and by partial evaporation of the mother-liquor, are dissolved in 6 pts. of boiling water; the solution is treated with animal charcoal; and, after addition of $\frac{1}{8}$ of water, the alcohol is distilled off. The rutin crytallises from the residue after some days, the more readily the less strongly the solution has been heated (Borntrӓger, Weiss). A green resin with which the rutin is contaminated is difficult to remove by crystallisation; it is more easily got rid of by acidifying the alcoholic solution with acetic acid, and precipitating with neutral acetate of lead. On removing the lead from the filtrate by sulphydric acid, and evaporating, the rutin crystallises, and may be recrystallised from boiling water. It still contains a substance resembling coumarin, from which it may be freed, though with great difficulty, by repeated boiling with ether. (Zwenger and Dronke.)

2. *From Preserved Capers.*—The capers are macerated in water for a few hours, after which the water is poured off, and the capers are pressed; this process is repeated twice, to remove salt and vinegar. The decoction, obtained by twice boiling the washed capers in not too large a quantity of water, throws down, on standing for 24 hours, a

large quantity of yellowish-white flocks, which are collected, dried, and dissolved in boiling alcohol, whereby a gelatinous substance is left undissolved. The alcoholic solution is mixed with water, and the alcohol is distilled off; the residue then solidifies on cooling, from crystallisation of rutin. The crystals are purified by pressing and recrystallisation from boiling water (Rochleder and Hlasiwetz). Zwenger and Dronke add to the solution in hot water a few drops of solution of neutral acetate of lead (too much would precipitate a compound of rutin and lead-oxide), and free the filtrate from lead by means of sulphydric acid.

3. *From Waifa.*—The coarsely-bruised waifa is repeatedly boiled with alcohol of 80 per cent., and the greater part of the alcohol is distilled off, whereupon the residue thickens to a pulp of impure rutin, amounting to 11 per cent. of the waifa employed. It is crystallised repeatedly from boiling water, and afterwards washed with cold water (Stein). To purify the rutin, hydrate of lead is added to the boiling alcoholic solution, so long as it is coloured brown; the solution is filtered; and the rutin is thrown down from the filtrate by an additional quantity of lead-hydrate. The latter pure yellow precipitate is decomposed by alcoholic sulphydric acid, and the filtrate is free from sulphide of lead, and evaporated to crystallisation. (Stein.)

Properties.—Rutin crystallises from its aqueous solution in pale yellow-delicate needles, probably having the composition $2C^{25}H^{28}O^{15}.5H^2O$. It has a slightly styptic, afterwards saline taste. The crystals, heated to 100°, give off from 1·61 to 2·12 water, and leave a hydrate containing $C^{25}H^{28}O^{15}.2H^2O$ (mean of analyses, 49·51 C, 5·47 H, 45·02 O; calc. 49·66 C, 5·29 H, 45·05 O), which, at 150° to 160°, gives off its 2 at. water (5·63—5·92 per cent.), and leaves anhydrous rutin, $C^{25}H^{28}O^{15}$, containing 52·66 C, 5·02 H, 42·32 O (calc. 52·81 C, 4·93 H, 42·27 O). (Zwenger and Dronke.)

Rutin is nearly insoluble in cold but dissolves easily in boiling water, forming a pale-yellow solution, which is decolorised by acids, and quickly deposits the rutin on cooling. It dissolves slightly in cold absolute alcohol, freely in boiling alcohol of 76 per cent., and crystallises therefrom only on concentration and addition of water. It is insoluble in boiling *ether*. It dissolves freely in hot *acetic acid*, and is partially deposited on cooling. By digestion with moderately dilute mineral acids, it acquires a lemon-yellow colour, and is rendered paler again by water; when heated with acids, it dissolves and suffers decomposition (*infra*). It absorbs *hydrochloric acid gas*. (Stein.)

Rutin dissolves easily in *alkalis* and *alkaline carbonates*—also in *baryta-*, *strontia-*, and *lime-water*, forming yellow solutions, which deposit the rutin unaltered on addition of acids, and turn brown in the air from absorption of oxygen. According to Stein, it decomposes *carbonate of sodium* and *ferrocyanide of potassium*. It is coloured dark-green by *ferric chloride*, brown-red to greenish by *ferrous chloride*. *Acetate of lead*, added to an alcoholic solution of rutin, or in excess to aqueous rutin, forms a yellow precipitate containing $C^{25}H^{28}O^{15}.2Pb''O$. (Borntrӓger; Rochleder and Hlasiwetz.)

Decompositions.—1. Rutin, after dehydration at 160°, cakes together at 190°, and then melts to a yellow viscid liquid, which, on cooling, solidifies to an amorphous mass, and takes up water when immersed in it. When more strongly heated it is carbonised, emitting an odour of caramel, and yielding a distillate containing quercetin (Zwenger and Dronke). Rutin, melted at 180°, forms a yellow viscid liquid on cooling, and partly crystallises; at 220° a yellow sublimate is produced (Borntrӓger). Over a bath of oil of vitriol, rutin becomes coloured at 100°, melts at 120°, giving off gas-bubbles, boils at 200°, and is decomposed at 290°, yielding products of distillation. The water evolved at 200° over the oil-bath contains formic acid; a solution of the melted mass in a little boiling water throws down amorphous quercetin on standing (Stein).—2. *Nitric acid* boiled with rutin produces chiefly oxalic acid (Zwenger and Dronke). According to Stein, it forms picric acid with a trace of oxalic acid. Cold nitric acid colours rutin yellow, then quickly olive, and at last red-brown (Stein).—3. Rutin forms with *oil of vitriol* a brown-yellow (olive-green, according to Rochleder and Hlasiwetz), afterwards brown-red solution, without liberation of sulphurous acid; water throws down from the solution, after an hour, olive-green flocks, after twelve hours a violet precipitate; and the supernatant liquid, when evaporated and freed from sulphuric acid, yields easily soluble crystals (Stein).—4. When boiled with *dilute mineral acids*, rutin splits up into sugar (Stein) and quercetin (Hlasiwetz). The decomposition takes place with peculiar rapidity in an alcoholic solution; it is also effected by formic acid, especially at a temperature of, 110°. When rutin is dissolved in boiling acetic acid of 60 per cent., and again crystallised, the amount of carbon in the crystals (dried at 120°) is increased to 51·8 or 52 per cent.; it now reduces copper solutions, and has, therefore, been partly converted into quercetin (Stein). The decomposition is not effected by emulsin (Zwenger and Dronke). From 100 parts of rutin, dried at 100°, 39·24 to 43·25 parts (mean 41·9) of quercetin were obtained, corresponding with the equation,

$$C^{25}H^{28}O^{15} + 3H^2O = C^{13}H^{10}O^6 + 2C^6H^{12}O^6.$$

Calculation, 43·37 per cent. quercetin (Zwenger and Dronke). Hlasiwetz (Wien. Akad. Ber. 17, 400) obtained 58·03 per cent. quercetin and 44·5 per cent. sugar.

5. Rutin, treated in aqueous or alcoholic solution with *sodium-amalgam*, is converted into paracarthamin. (Stein, iv. 341.)

6. It reduces *nitrate of silver* and *trichloride of gold*, not cuprate of potassium. With water and *silver-oxide*, it forms a dark-red liquid, which leaves, on evaporation, a brown amorphous residue. (Stein.)

RUTINIC ACID. Syn. with Rutin.

RUTIN-SUGAR. This sugar, isomeric with glucose, is produced, together with quercetin, by boiling rutin with dilute sulphuric acid, and, after removing the quercetin and sulphuric acid, may be obtained, by evaporation, solution in alcohol, and precipitation with ether, as a colourless, uncrystallisable syrup. It does not act on polarised light; reduces cuprate of potassium in the cold; yields with boiling nitric acid, oxalic but no picric acid; and is not fermentable.

RUTYL. Syn. with *Capryl*, $C^{10}H^{19}O$, the radicle of rutic or capric acid. It is also applied, but incorrectly, to the alcohol-radicle $C^{10}H^{21}$, properly called *Decyl*. (See Appendix.)

RUTYLENE. $C^{10}H^{18}$. (A. Bauer, Ann. Ch. Pharm. cxxxv. 344; Bull. Soc. Chim. 1865, ii. 265.)—A hydrocarbon polymeric with acetylene, and perhaps identical with menthene, produced by the action of alcoholic potash on tribromide of diamylene, $C^{10}H^{20}Br^3$. It is related to diamylene and rutyl ($C^{10}H^{19}O$), in the same manner as valerylene, C^5H^8, is related to amylene and valeryl, and to campholic acid, $C^{10}H^{18}O^2$, in the same manner as crotonylene, C^4H^6, to crotonic acid, $C^4H^6O^2$.

Rutylene is a colourless liquid, lighter than water, and having an agreeable odour, somewhat like that of turpentine-oil. Boils at about 150°. Vapour-density, obs. = 4·843; calc. 4·778. It is insoluble in water, soluble in alcohol and in ether. Bromine attacks it strongly, with formation of hydrobromic acid and separation of charcoal. If, however, rise of temperature be prevented, dibromide of rutylene, $C^{10}H^{18}Br^2$, is formed. This is a very unstable compound, which decomposes even at ordinary temperatures, and acts strongly on acetate of silver and on alcoholic potash, probably forming, in both cases, the hydrocarbon $C^{10}H^{16}$.

RYACOLITE, or *Rhyacolite* (from ρύαξ, a lava-stream). A mineral from Vesuvius, having the crystallisation of felspar, and resembling the glassy variety. (Dana, ii. 245.)

RYE. See Cereals (i. 823).—Ergot of Rye (*Claviceps purpurea*. T.) contains, according to Neidhardt (N. Jahrb. Pharm. xviii. 193; Jahresb. 1862, p. 516), 31·06 per cent. fat oil, 2·69 resin, 1·3 red colouring matter, 0·8 mannite [mycose, according to Mitscherlich and Berthelot, iii. 1068], and 3·9 osmazome, together with phosphates, a volatile base (trimethylamine), gum, and fungin (cellulose with red colouring matter). The ergotine of Wiggers (ii. 499) is regarded by Neidhardt as resin.

Ergot may be detected in rye-flour by first boiling the flour twice with alcohol, to remove fatty and resinous matters, then treating the expressed residue with alcohol, and adding from 10 to 20 drops of dilute sulphuric acid. If the rye-flour is free from ergot, the liquid remains colourless, or exhibits only a faint yellowish tinge; in the contrary case, it acquires a red colour, more or less deep, according to the quantity of ergot present. (Jacoby, Anal. Zeitschr. iii. 509; Bull. Soc. Chim. 1866, i. 267. See also *Handwörterb. de Chem.* vii. 730.)

S.

SABADILLA SEEDS. The seeds of *Veratrum Sabadilla* (Retz), or *Veratrum officinale* (Schl.), a colchiaceous plant indigenous in Mexico, contain, according to Couerbe (Ann. Ch. Phys. [2] lii. 352), two organic bases, veratrine and sabadilline, and two acids, sabadillic or cevadic acid (i. 843), and veratric acid, together with helonin or veratrum-resin.

Sabadilline, $C^{20}H^{26}N^2O^5$, according to Couerbe, is extracted by exhausting the pulverised seeds with alcohol of specific gravity 0·845, treating the residue left on distilling off the alcohol with dilute sulphuric acid, decolorising the liquid with animal charcoal, and adding caustic potash, which precipitates sabadilline, hydrosabadilline, and veratrine, together with two non-basic substances. This precipitate is dissolved in dilute sulphuric acid, and the solution is mixed with nitric acid as long as a black pitchy precipitate is produced. The liquid filtered therefrom is precipitated by caustic potash; the precipitate is washed, dried, and dissolved in absolute alcohol; and the mass remaining after evaporation of the alcohol is boiled with water, which takes up sabadilline and hydrosabadilline. The former separates on cooling in stellate groups of apparently cubic crystals, which have a faint rose colour, but may be rendered colourless by recrystallisation.

Sabadilline has an extremely acrid taste: it begins to melt at 200°, and decomposes at higher temperatures, emitting fumes, and leaving a bulky cinder. It is moderately soluble in hot water, the solution having a distinct alkaline reaction, freely soluble in alcohol, insoluble in ether. It is decomposed by strong mineral acids, but forms crystallisable salts with dilute sulphuric and nitric acids.

According to Simon (Pogg. Ann. xliii. 493), sabadilline is not a definite substance, but a mixture of resin, alkali, and veratrine, the latter being precipitated by ammonia from the solution of the so-called sabadilline in sulphuric acid. According to Hübschmann, on the other hand (*Mittheilungen des Schweizer Apothekervereins*, Band iii. Heft 1), sabadilline is a definite compound, and is distinguished from veratrine by not exciting sneezing, by its insolubility in ether, and by not being precipitated by ammonia from its solution in sulphuric acid.

Hydrosabadilline or *Sabadilla gum-resin*, $C^{20}H^{28}N^2O^6$, differing from sabadilline by the elements of 1 at. water, is contained, according to Couerbe, in the aqueous mother-liquor of the latter, and separates on evaporation in oily drops, which solidify to a reddish resinous mass. It melts at 165°, is very soluble in alcohol, nearly insoluble in ether, has an alkaline reaction, and unites with acids, but does not form crystallisable salts.

SACCHARAMIDE. $C^6H^{12}O^6 = \left.\begin{matrix}H^4\\(C^6H^4O^2)^{vi}\\H^4\end{matrix}\right\}\begin{matrix}O^4\\N^2\end{matrix}$ (Heintz, Pogg. Ann. cvi. 93; Jahresb. 1859, p. 290.)—This compound separates as a white precipitate when dry ammonia-gas is passed into an ethereal solution of ethylic saccharate (p. 143). It may be crystallised from warm water, but is converted by boiling with water into saccharate of ammonium, and is quickly decomposed by acids into ammonia and saccharic acid.

SACCHARIC ACID. $C^6H^{10}O^8 = \left.\begin{matrix}H^4\\(C^6H^4O^2)^{vi}\\H^2\end{matrix}\right\}O^8$.— An acid, isomeric with mucic acid, produced by the action of nitric acid on cane-sugar, glucose, milk-sugar, and mannite. It was first observed by Scheele (*Opuscula*, ii. 203), who mistook it for malic acid, and it has been studied by Guërin-Varry (Ann. Ch. Phys. [2], xlix. 280; lii. 318; lxv. 332), Erdmann (Ann. Ch. Pharm. xxi. 1), Hess (*ibid.* xxvi. 1; xxx. 402), Thaulow (*ibid.* xxvii. 113), Liebig (*ibid.* xxx. 313; cxiii. 1; Jahresb. 1859, p. 261), and Heintz (Pogg. Ann. lxi. 315; cv. 211; cvi. 93; cxi. 265, 291; Jahresb. 1858, p. 251; 1859, p. 290; 1860, p. 259). See also Gm. xi. 513; Gerh. ii. 145: Kekulé's *Lehrbuch*, ii. 238.

Preparation.—1. One part of cane-sugar is warmed with 3 pts. nitric acid, of specific gravity 1·25 to 1·30, till a reaction is set up; the vessel is then removed from the fire; and after the first brisk action is over, and the liquid has cooled to 50°, it is kept at that temperature over a moderate fire as long as red fumes continue to escape. It is then diluted with half its bulk of water, and divided into two parts, one of which is saturated with carbonate of potassium, and then mixed with the other; or the entire liquid may be neutralised with the alkaline carbonate, and then treated with excess of acetic acid. The liquid, after several days' repose, deposits crystals of acid potassic saccharate, which may be purified by repeated crystallisation from boiling water, with addition of animal charcoal, if necessary (Heintz). Or the acid ammonium-salt may be prepared instead of the potassium-salt. (Liebig.)

2. When 1 pt. of milk-sugar is oxidised with 2½ pts. nitric acid of specific gravity 1·32, diluted with 2½ pts. water, mucic acid (about 33 per cent.) is first formed and separates out; and the liquid filtered therefrom, consisting chiefly of a solution of saccharic acid, may be concentrated at a gentle heat to about one-third, and neutralised with carbonate of potassium.

Free saccharic acid is best prepared from the cadmium-salt. The acid saccharate of potassium or ammonium is dissolved in boiling water; the solution, neutralised with potash or ammonia, is mixed at the boiling heat with the solution of a cadmic salt, and boiled for some time, and the cadmic saccharate thereby precipitated is decomposed by sulphydric acid. (Heintz.)

Properties.—Saccharic acid is not crystallisable, but if rise of temperature has been avoided during its preparation, it may be obtained in the form of a colourless brittle mass. It is deliquescent, easily soluble in *water* and *alcohol*, insoluble in ether. The solution of saccharic acid prepared from cane-sugar is dextrorotatory.

Decompositions.—Saccharic acid turns brown even at the heat of the water-bath. It reduces the metal from solution of *auric chloride*, and when heated, also from ammoniacal *silver-solution*. When oxidised by *nitric acid*, it yields, first, dextrotartaric, then oxalic acid. When heated with *hydrate of potassium* to 250°, it yields acetate and oxalate of potassium:

$$\underset{\text{Saccharate.}}{C^6H^8K^2O^8} + 2KHO = \underset{\text{Acetate.}}{2C^2H^3KO^2} + \underset{\text{Oxalate.}}{C^2K^2O^4} + 2H^2O.$$

Saccharates.—Saccharic acid is mostly dibasic, forming, with the alkali-metals, both neutral and acid salts. With lead, however, it forms a salt containing 3 at. of metal, which replace 6 at. of hydrogen.

The *acid potassium-salt*, $C^6H^9KO^8$, prepared as above, forms trimetric crystals, exhibiting the combination $\infty\bar{P}\infty\ .\ \infty P\ .\ \breve{P}\infty$. Angle $\infty P : \infty P = 103°26°$; $\bar{P}\infty : \breve{P}\infty = 131° 46$. Axes $a : b : c = 1{\cdot}7631 : 2{\cdot}2338 : 1$. Cleavage easy, parallel to oP. It is somewhat difficult of solution in water, 1 pt. of it requiring from 80 to 90 pts. of water. The *neutral potassium-salt*, $C^6H^8K^2O^8$, forms a crystalline crust. The *acid ammonium-salt*, $C^6H^9(NH^4)O^8$, forms quadrilateral prisms, about as soluble as the corresponding potassium-salt. The *neutral ammonium-salt* and the *sodium-salts* have not been obtained in the crystalline form.

Saccharate of barium, $C^6H^8Ba''O^8$, and the corresponding *strontium-* and *calcium-salts*, are precipitates insoluble in water, and when obtained from hot solutions, consist of microscopic crystals. Free saccharic acid does not precipitate the salts of barium, strontium, and calcium, but forms precipitates with baryta-, stontia-, and lime-water. Soluble saccharates, even the acid salts, form precipitates with barium-, strontium-, and calcium-salts.

The *magnesium-salt*, $C^6H^8Mg''O^8.3H^2O$, the *zinc-salt*, $C^6H^8Zn''O^8.H^2O$, and the *cadmium-salt*, $C^6H^8Cd''O^8$, are crystalline, nearly insoluble in cold water, somewhat soluble in boiling water. When neutral saccharate of potassium or ammonium is precipitated by a cold solution of cadmium-salt, a flocculent precipitate is formed, which cakes together into a resinous mass; if the two solutions are mixed at the boiling heat, a white heavy powder is formed, consisting of microscopic needles.

The *bismuth-salt* is obtained, as a flocculent precipitate, on adding neutral saccharate of potassium to a solution of bismuth-nitrate in a large quantity of water. The *copper-salt* is obtained by dissolving cupric hydrate in aqueous saccharic acid. The green solution, if free from excess of acid, deposits a green precipitate, which does not blacken when boiled. The *ferrous salt* is obtained, as a gummy mass, by dissolving metallic iron in saccharic acid and evaporating. *Ferric hydrate* dissolves with yellow colour in saccharic acid and saccharate of potassium.

Saccharates of Lead.—These salts vary greatly in composition, according to the manner in which they are prepared. When saccharate of potassium is boiled with excess of neutral lead-acetate, a resinous salt separates, agreeing approximately in composition with the formula $C^{12}H^{14}Pb''^3O^{16}$; and by boiling the solution decanted therefrom, an amorphous salt is obtained, corresponding with the formula $C^6H^6Pb''^2O^8$ (Heintz). Thaulow, by the same process, obtained a heavy granular precipitate, having nearly the composition $C^{12}H^{10}Pb''^5O^{16}$. If the boiling be prolonged, the precipitate becomes continually richer in lead, and after 9 or 10 hours' boiling, has the composition $C^6H^4Pb''^3O^8$. (Heintz.)

Saccharate of silver, $C^6H^8Ag^2O^8$, is obtained by mixing the neutral potassium-salt with nitrate of silver, as a white precipitate, which, in presence of an excess of the potassium-salt, remains white on boiling and becomes crystalline. It is very soluble in ammonia, the solution depositing metallic silver when boiled.

SACCHARIC ETHERS. *Neutral Ethylic saccharate*, $C^6H^8(C^2H^5)^2O^8$, is obtained by passing hydrochloric acid gas into a solution of saccharic acid in absolute alcohol; or, better, into absolute alcohol containing saccharate of calcium in suspension. In the latter case, a crystalline compound of ethylic saccharate and chloride of calcium, $2C^6H^8(C^2H^5)^2O^8.Ca''Cl^2$, separates, which is easily soluble in water, slightly soluble in alcohol, insoluble in ether. On dissolving this compound in a small quantity of water, adding a little alcohol, and a strong solution of sodic sulphate, evaporating quickly to dryness in a vacuum, exhausting the residue with alcohol, and adding a large quantity of ether, a solution is obtained, which, when left to evaporate, leaves the neutral ethylic saccharate in the form of a syrup, which gradually solidifies to a crystalline mass. It is easily soluble in water and in alcohol, slightly soluble in ether. The ethereal solution, treated with dry ammonia-gas, yields saccharamide (p. 142). (Heintz, Pogg. Ann. cv. 211; Jahresb. 1858, p. 251.)

Ethyl-saccharic acid, $C^6H^9(C^2H^5)O^8$, has not yet been obtained; but by passing hydrochloric acid gas into absolute alcohol in which acid saccharate of potassium was suspended, Heintz obtained a crystallisable compound, $C^6H^7(C^2H^5)O^8$, containing 1 at. water less than ethyl-saccharic acid—probably the ethylic ether of the first anhydride of saccharic acid: thus—

$$\underset{\text{Anhydride.}}{\left.\begin{matrix}(C^6H^4O^2)''\\ H^4\end{matrix}\right\}O^6} \qquad\qquad \underset{\text{Ether.}}{\left.\begin{matrix}(C^6H^4O^2)''\\ H^3(C^2H^5)\end{matrix}\right\}O^6}$$

SACCHARID. $C^6H^{10}O^5$.—A compound produced, according to Gélis (Compt. rend. xlviii. 1062; Jahresb. 1859, p. 547), by heating cane-sugar for some time to 160°. The sugar is then converted into a mixture of saccharid and dextroglucose: $C^{12}H^{22}O^{11} = C^6H^{10}O^5 + C^6H^{12}O^6$; it acquires the appearance of fruit-sugar; only half of it is fermentable; and it reduces only half as much cupric oxide in alkaline solution as an equal quantity of glucose or inverted sugar. By the action of dilute acids, however, it is rendered wholly fermentable, and then behaves towards reducing agents like ordinary glucose.

SACCHARIDES. Berthelot applies this term to compounds formed by heating dextroglucose, and other kinds of sugar, with organic acids. The formation of these compounds is attended with elimination of water, and they are capable of breaking up again, by assimilation of water, into the original acid and carbohydrate: *e.g.*—

$$\begin{array}{ccccccc}
2C^4H^8O^2 & + & C^6H^{12}O^6 & - & 3H^2O & = & C^{14}H^{22}O^7. \\
\text{Butyric acid.} & & \text{Glucose.} & & & & \text{Dibutyro-glucose.} \\
6C^2H^4O^2 & + & C^6H^{12}O^6 & - & 7H^2O & = & C^{18}H^{22}O^{11}. \\
\text{Acetic acid.} & & \text{Glucose.} & & & & \text{Hexaceto-glucose.} \\
4C^4H^6O^6 & + & C^6H^{12}O^6 & - & 5H^2O & = & C^{22}H^{26}O^{25}. \\
\text{Tartaric acid.} & & \text{Glucose.} & & & & \text{Glucoso-tetra-tartaric acid.}
\end{array}$$

The saccharides are subdivided into glucosides, or those produced from dextroglucose; levulosides, from lævo-glucose; galactosides, from lactose or milk-sugar; and inosides, from inosite. The naturally occurring bitter principles, which are resolvable by boiling with dilute acids into an organic acid and glucose, but have not been prepared artificially, are analogous in composition to Berthelot's saccharides. Berthelot likewise includes under *saccharides* the compounds formed by the action of acids on starch, dextrin, cellulose, and other carbohydrates: *e.g.*, xyloïdin from starch and nitric acid, pyroxylin from cellulose and nitric acid.

The formation of the saccharides occurs for the most part by long contact at 100° or 120°; with some kinds of sugar, as with trehalose, the temperature may be raised as high as 180°. Only a part of the sugar thus enters into combination.—They are decomposible into their constituents under the same conditions as the fats, but with greater difficulty. Water scarcely acts upon them at 100°; at higher temperatures the sugar itself would be destroyed. Continuous boiling with dilute acids decomposes them completely into the original acid and fermentable sugar; part of the latter, however, easily undergoes a further decomposition into glucic acid and humus-like bodies. Some saccharides suffer decomposition by contact with ferments.

The saccharides, like the natural fats, are soluble in water when they contain a volatile acid; insoluble when they contain a fixed acid. The soluble saccharides have an intensely bitter taste; they deflect the polarisation in the same direction as the sugar from which they are derived; none of them are volatile, but some of them emit a peculiar smell when warmed.

Respecting the classification of the saccharides, see Berthelot, *Chimie Organique fondée sur la Synthese*, ii. 271; also *Gmelin's Handbook*, xv. 317.

SACCHARIMETERS and **SACCHAROMETERS.** Instruments for determining the amount of sugar contained in solutions. The latter term is, however, applied more especially to hydrometers graduated for the purpose. (See SUGAR.)

SACCHARITE. A granular variety of andesin, having traces of cleavage in one direction, occurring in veins in serpentine at the chrysoprase mines near Frankenstein in Silesia. Specific gravity = 2·668. Contains, according to Schmidt (Pogg. Ann. lxi. 385), 58·93 per cent. silica, 23·50 alumina, 1·27 ferric oxide, 5·67 lime, 0·56 magnesia, 0·05 potash, 7·42 soda, 0·39 oxide of nickel, and 2·21 water.

SACCHAROID. A name given by Kane to a sweetish substance, probably identical with orcin, produced by the decomposition of Heeren's pseudo-erythrin (ethylic orsellinate).

SACCHAROMETER. See SACCHARIMETER.

SACCHARUM. Syn. with SUGAR.

SACCHULMIN, SACCHULMIC ACID. Brown substances obtained in the decomposition of sugar by dilute acids. (See ULMIN.)

SAFETY-LAMP. (See COMBUSTION, i. 1101.)

SAFETY-TUBE. An arrangement adapted to a gas-generating vessel, to prevent the liquid into which the delivery-tube dips, from passing back into the vessel, in consequence of diminished internal pressure. The simplest form consists of a straight tube passing through the cork of the generating vessel and dipping below the surface of the liquid, or of a tube bent twice at right angles, passing just through the cork, so that a portion of liquid may remain in the lower bend, and form a liquid joint, cutting off the communication between the inside of the vessel and the external air. In either case, when the pressure within the vessel becomes less than that of the atmosphere, air will pass in through the safety-tube and restore the equilibrium. The safety-tube likewise diminishes the danger of bursting from sudden increase of tension within the vessel. (For figures of various forms of safety-tube, see *Handwörterbuch der Chemie*, vii. 853.)

SAFFLORITE. Native arsenide of cobalt, containing a considerable quantity of iron. (See COBALT, i. 1042.)

SAFFLOWER. *Carthamus tinctorius* (i. 808).

SAFFRON. A yellow substance, consisting of the dried stigmas, with part of the styles, of the saffron crocus (*Crocus sativus*), a plant indigenous in Greece and Asia Minor, and extensively cultivated in Austria, France, and Spain, formerly also in England. The stigmas are from an inch to 1½ inch long, narrow and roundish where they are attached to the style, but spreading and club-shaped near the extremity, which is truncated. They have an orange or brownish-red colour, yellow in the narrower part, a strongly aromatic, almost intoxicating odour, an aromatic bitter taste, and impart a strong yellow colour to the saliva, as also to water, alcohol, and oils. Strong sulphuric acid colours them first indigo-blue, then red, and finally brown.

Saffron is used as a dye; also in medicine, chiefly for the colouring of tinctures, &c. On account of its high price, it is often adulterated with other substances of similar colour, such as the florets of the safflower or the marigold, slices of the flowers of the pomegranate, &c.; but these substances are easily detected, on close examination, by their different shape and colour. Saffron was formerly met with in two forms, called *hay-saffron* and *cake-saffron*; but the former is now alone in demand, the latter being entirely an artificial compound of the florets of the safflower, gum, and other materials.

According to an analysis by Bouillon-Lagrange and Vogel, saffron contains 7·5 per cent. of volatile oil (including stearoptene), 65·0 saffron-yellow or safranin, 0·5 wax, 6·5 gum, 0·5 albumin, 10·0 vegetable fibre, and 10·0 water.

Quadrat, by evaporating an ethereal extract of saffron, obtained a yellowish fatty body, which was partially soluble in boiling alcohol, and when treated with hot water left a snow-white residue, melting at about 48°. As the alcohol cooled, crystals separated out, while a fatty body (? oleic acid) remained in solution. Similar crystals were likewise obtained by directly boiling the saffron with absolute alcohol, and leaving the liquid to cool. Quadrat also found in saffron, glucose and a perhaps peculiar acid. Saffron when burnt left 8·9 per cent. ash, containing potash, soda, lime, magnesia, chlorine, sulphuric, phosphoric, silicic, and carbonic acids. (*Handw. d. Chem.*, vii. 51; *Penny Cyclopædia*, xx. 309.)

SAFRANIN, or **SAFFRON-YELLOW.** (Bouillon-Lagrange and Vogel, Ann. Chim. lviii. 198.—N. E. Henry, J. Pharm. viii. 399.—Quadrat, J. pr. Chem. lvi. 68.)—A colouring matter obtained, though not in the pure state, from saffron. Quadrat prepares safranin by first exhausting saffron with ether, then boiling it with water, and precipitating the decoction with acetate of lead, decomposing the precipitate with sulphydric acid, then washing it, and boiling it with alcohol of 40 per cent. The alcoholic solution when concentrated first deposits crystals of sulphur, and on evaporating the remaining liquid to dryness, dissolving in water, filtering, and again evaporating, safranin is obtained as a roseate inodorous powder, easily soluble with yellow colour in water and alcohol, very slightly soluble in ether, and slowly altering by exposure to light and air. It is coloured blue by strong sulphuric acid, green by nitric acid, blackish by hydrochloric acid. Rochleder (J. pr. Chem. lxxiv. 1) regards saffron-yellow as identical with the colouring matter of the pods of *Gardenia grandiflora*, and designates both as crocin (ii. 108).

SAGAPENUM. A gum-resin imported from Egypt and Persia, and probably derived from *Ferula persica*. It occurs in commerce, in yellow or reddish agglomerated granules, having an odour of garlic and an acrid bitter taste. It softens in the hand, but does not melt at a higher temperature. Contains, acording to Brandes, volatile oil, two resins, bassorin, gum, malic acid, ash, and impurities.—It yields umbelliferone by dry distillation (Sommer), and when treated with nitric acid, forms styphnic or other acids. (Böttger and Will; Brandes, N. Tr. ii. 2, 97; Pelletier, Bull. Pharm. iii. 481.)

The volatile oil of sagapenum is obtained by distillation with water. It is lighter than water, yellow, limpid, and has a repulsive odour of garlic. When exposed to the sun and air, the oil is converted into a transparent varnish, acquiring at the same time a smell of turpentine. Strong nitric acid, when heated with it, turns it thick and yellowish-red, with formation of oxalic acid. It assumes a dark-red colour with oil of vitriol, and dissolves in alcohol and ether. (Brandes.)

The alcoholic extract of sagapenum is resolved by ether into two resins:—*a*. The *resin insoluble in ether* is brown-yellow, brittle, inodorous and tasteless, and fusible when heated. It dissolves easily in warm caustic potash and in alcohol, but is insoluble in aqueous ammonia, and in volatile and fat oils.—*b*. The *resin soluble in ether* is red-yellow, transparent, tough at first, and has a slight odour of sagapenum, and a mild, afterwards bitter taste. It melts when warmed, and dissolves with dark-red colour in oil of vitriol. It dissolves slightly in aqueous ammonia, partially only in caustic potash, easily in alcohol and ether, and very slightly in hot oil of turpentine and oil of almonds. (Brandes.)

Sagapenum treated with cold alcohol of specific gravity 0·83, yields a pale-yellow solution, a considerable residue soluble in water remaining behind. The pale-yellow resin, which remains on evaporating the alcoholic solution, has a strong smell of garlic, melts at 100°, and gives up to water, when repeatedly boiled therewith, a substance having a bitter and onion-like taste: the residue dried at 110°, dissolved in alcohol, again evaporated, and dried at 66°, is semifluid, and contains 69·06 per cent. C, 8·51 H, and 21·43 O; after being melted for some hours at 100°, it is darker, but still remains sticky, and contains 69·84 per cent. C, 8·63 H, and 21·53 O. (Johnston, Phil. Trans. 1840, p. 361.)

SAGENITE. A variety of Rutile. (See TITANIUM.)

SAGO. A kind of starch, prepared in the islands of the Indian Archipelago, Madagascar, and Guinea, from the pith of the stems of certain palms: e.g., *Sagus Rumphii* W., *S. farinifera* Gärtn., *S. Raffia* Jacq., *S. Raphia* P. B., *S. lævis* Jacq., *S. genuina* Labill. &c.; and in China and Japan from certain Cycads, as *Cycas circinalis* L. and *Cycas revoluta* L. The pith is well stirred up with water on sieves; and the starch deposited from the water is washed, half dried in the air, then rubbed through suitable sieves, to granulate it; and finally dried, either in the open air, or in ovens at a heat of about 60°, whereby the grains become more or less horny and translucent.

Several kinds of sago are distinguished:—*White sago* forms irregular pure white grains; *red sago*, round regular grains, brown-red on one side; *brown sago*, round irregular grains of various sizes, and of a grey-brown colour, lighter in parts; *pearl sago*, yellowish grains of the size of a pin's head. The specific gravity of sago varies from 0·670 to 0·776. The grains, when steeped in cold water, take up more or less of it, and swell up to several times their original bulk, becoming transparent and gelatinous. The water takes up a small quantity of chloride of sodium, and gives a blue colour with iodine, as does also the swelled sago itself. The microscope shows that the external layers of the grains have been most disorganised by the heat employed in drying the sago.

The so-called "German sago" is prepared from ordinary wheat or potato-starch, and is granulated in the same manner as genuine sago. It is pure white, only partly semi-translucent, less hard and more friable than true sago.

SAHLITE. A variety of Augite, from Sahla, in Sweden. It has a dingy green colour, and is coarsely foliated, arising from composition parallel to the base.

SAL. The Latin names formerly used in chemistry to distinguish salts are in some cases still retained in pharmaceutical language. The following are examples of these names:—

Sal acetosellæ. Acid oxalate of potassium.
Sal alkali minerale. Carbonate of sodium.
Sal alkali vegetabile. Carbonate of potassium.
Sal alkali volatile siccum, or simply *Sal volatile*. Carbonate of ammonium.
Sal amarum. Sulphate of magnesium.
Sal aperitivum Fridericianum. Sulphate of sodium.
Sal auri philosophicum. Acid sulphate of potassium.
Sal catharticum. Sulphate of magnesium.
Sal cornu cervi. Carbonate of ammonium.

Sal de duobus. Neutral sulphate of potassium.
Sal digestivum Sylvii. } *Sal febrifugum Sylvii.* } Chloride of potassium.
Sal duplicatum. Neutral sulphate of potassium.
Sal martis. Crystallised ferrous sulphate.
Sal microcosmicum. Ammonio-sodic phosphate.
Sal mirabile perlatum. Disodic orthophosphate.
Sal narcoticum vitrioli. Boric acid.
Sal polychrestum Glaseri, S. Lamerianum, S. Parisiense. Neutral sulphate of potassium.
Sal polychrestum Seignetti. Tartrate of potassium and sodium.
Sal Saturni. Acetate of lead.
Sal secretum Glauberi. Sulphate of ammonium.
Sal sedativum Hombergii. Boric acid.
Sal succini. Amber.
Sal tartari. Carbonate of potassium.
Sal urinæ fixum, S. fusible, S. nativum. Ammonio-sodic phosphate.

SALAMANDER. The common salamander, *Lacerta salamandra* (L.), secretes, in the warts of its skin, a white milky liquid, which has a strong offensive odour and distinct acid reaction, is somewhat viscid when fresh, and quickly coagulates; alcohol causes it to coagulate immediately. This liquid, when introduced under the skin of other animals, exerts a strong poisonous action: in birds it produces violent convulsions, ending in death; in mammals the convulsions are much less violent, and the morbid symptoms ultimately disappear without fatal result. The poisonous principle is said to be of basic nature, and soluble in alcohol. (Gratiolet and Cloez, Compt. rend. xxxii. 592; xxxiv. 729.)

SALANGANA. *Hirundo esculenta.*—This bird is said to construct the edible nests obtained by the Chinese from the coasts of Cochin-China, Java, and other islands of the Indian Archipelago. According to Mulder (J. pr. Chem. xvii. 59), the nests usually have the form of a spoon without the handle; they are white or slightly coloured, have a vitreous fracture, and contain about 90 per cent. of a peculiar nitrogenous substance, which he calls *neossin*; also about 5 per cent. phosphates, and a small quantity of fat. According to Payen (*Précis de Chimie Industrielle*, 4me, éd. ii. 727), the nutritive matter of these nests, to which he gives the name of *cubilose*, exhibits the characters of the neutral albuminoïds.

SALEP. *Saleb, Salab.*—The tuberose roots of certain species of orchis, as *Orchis Morio, O. mascula, O. cariophorus, O. militaris, O. latifolia, O. maculata*, &c. The roots are gathered in summer, when the tuber of the previous year has died away, and the new one is fully developed. They are soaked for a few minutes in boiling water, and then dried. Salep thus prepared forms round or hand-shaped, somewhat flattened, horny, translucent, greyish-yellow lumps, having a sickly taste and faint peculiar odour, and easily reduced to a dirty yellow powder. In cold water this powder swells up slowly, in hot water quickly, to a bulky semi-transparent jelly. One pt. of salep is capable of converting 48 pts. of boiling water into a thick gum, which becomes compact and solid on the addition of magnesia or of borax.

According to some authorities, salep consists chiefly of a gum resembling bassorin (ii. 955), with small quantities of starch and gum; according to Mulder (Ann. Ch. Pharm. xxvii. 283), of pectic acid. According to Schmidt (*ibid.* li. 29), salep, when examined with the microscope, exhibits distinct grains of starch, or at all events of a substance which is turned blue by iodine. Salep-mucilage liquefies when digested with dilute sulphuric acid, the amylaceous substance being converted into gum and sugar, while the cellular membrane forms a precipitate. Salep-bassorin appears to consist merely of this membrane swollen by water. Pulverised salep, dried at 100°, left 1·59 per cent. ash, consisting of calcic carbonate with calcic and magnesic phosphates.

SALHYDRAMIDE. Syn. with HYDROSALICYLAMIDE (iii. 218).

SALICIN. $C^{13}H^{18}O^7$.—(Leroux, Ann. Ch. Phys. [2] xliii. 440.—Braconnot, *ibid.* xliv. 296.—Pelouze and Gay-Lassac, *ibid.* xliv. 220; xlviii. 111.—Piria, *ibid.* lxix. 281; [3] xiv. 257.—Bouchardat, Compt. rend. xviii. 299; xix. 602; xx. 610, 1635.—Gerhardt, Ann. Ch. Phys. [3] vii. 215; *Traité*, iii. 311.—Gm. xv. 430.)—This substance, discovered by Leroux, an apothecary of Vitry-le-Français, exists ready-formed in the barks of several species of willow and poplar, especially, according to Braconnot, in that of *Salix helix, S. amygdalina, Populus tremula*, and *P. græca.* It appears also to be contained in the flower-buds of meadow-sweet (*Spiræa Ulmaria*), and in the green parts of this and other herbaceous spiræas, inasmuch as these plants yield salicylol by distillation with water (Buchner, N. Repert. Pharm. ii. 1); also in castoreum (i. 814), being derived from the willow-barks which constitute the principal food of the beaver. (Wöhler.)

Salicin is produced artificially:—1. By the action of nascent hydrogen on helicin, $C^{13}H^{16}O^7$ (iii. 139). When an aqueous solution of that substance is digested with sodium-amalgam, and evaporated to dryness after supersaturation with carbonic acid, salicin remains in the residue, and may be extracted therefrom by alcohol (**Lisenko.** Zeitschr. Ch. Pharm. 1864. p. 577).—2. Together with benzoic acid, by boiling populin (iv. 690) with lime- or baryta-water:

$$\underset{\text{Populin.}}{C^{20}H^{22}O^{8}} + H^{2}O = \underset{\text{Benzoic acid.}}{C^{7}H^{6}O^{2}} + \underset{\text{Salicin.}}{C^{13}H^{18}O^{7}}.$$

Or, together with ethylic benzoate and benzamide, by heating populin to 100° in a sealed tube with alcoholic ammonia. (**Piria**).

Preparation.—1. Six pounds of dry chopped willow or poplar bark are boiled with water; the liquid is strained, concentrated down to 18 pounds, mixed while still hot with 2 pounds of levigated oxide of lead, digested for 24 hours, and again strained; the residue is thoroughly washed; and the filtrate is evaporated to a syrup, and left to crystallise. An additional quantity of salicin is obtained from the mother-liquors after they have again been treated with oxide of lead, and the entire product is purified by repeated crystallisation (**Duflos**, Schw. J. lxvii. 25).—2. The aqueous decoction of the bark is precipitated with basic acetate of lead; the filtrate is boiled with chalk, till the excess of the basic acetate is decomposed, and the liquid becomes clear and colourless; then evaporated to an extract; and this extract is exhausted with alcohol of 34°, and left to crystallise (**Peschier**, Ann. Ch. Phys. [2] xliv. 418).—3. Sixteen pts. of bark are macerated with 2 pts. lime and with water for 24 hours; the mixture is boiled for half an hour, and strained; the residue is treated in like manner with the same quantity of lime as before; and the whole of the liquids are decanted from the sediment, concentrated, then mixed with 6 to 8 pts. of bone-black, and evaporated to complete dryness. The residue, after being pulverised, is exhausted at a gentle heat with alcohol of 82 per cent., and the alcohol is distilled off from the tinctures; the salicin then crystallises from the residue in pale-yellow granules, which are purified by recrystallisation with help of animal charcoal. (**Erdmann**, Berl. Jahrb. xxxiii. 1, 136.)

Properties.—Salicin crystallises in broad, tabular, or mostly scaly crystals, belonging to the trimetric system, and exhibiting the combination $\infty P . \infty\breve{P}\infty . \breve{P}\infty$. Axes, $a:b:c$, = 0·9274 : 2·4938 : 1. Angle, $\infty P : \infty P = 139° 12'$, $\breve{P}\infty : \breve{P}\infty = 136° 18'$ (**Schabus**). It is white, soluble in water and in alcohol, insoluble in ether and in oil of turpentine. Water at ordinary temperatures dissolves about 5 pts. of salicin; alcohol much less. It melts at 120°, does not give off water till heated to 200°, and decomposes at a higher temperature. Its solutions have a bitter taste, and do not alter vegetable colours. According to some authorities, it possesses febrifugal properties. The solutions turn the plane of polarisation of light to the left; $[\alpha]r = -55·8°$.

Salicin is not precipitated by neutral or basic acetate of lead, by gelatin, or by infusion of galls.

According to **Phipson** (*Chem. News*, vi. 278), an alcoholic solution of 1 at. salicin and 1 at. benzoic acid yields crystals of populin. Salicin also forms crystallisable compounds with tartaric and citric acids. According to **O. Schmidt** (Bull. Soc. Chim. 1866, i. 287) salicin does not yield populin when heated as just mentioned: heated in a sealed tube with benzoic acid and water, it yields a yellow resinous body (saliretin?) and a solution which colours ferric chloride blue (saligenin?).

Decompositions.—1. Salicin heated to 260° gives off water and salicylous acid, together with acid vapours having an odour of caramel, and leaves a yellow residue insoluble in water, which turns brown, and ultimately carbonises. By dry distillation it yields salicylol, together with aromatic products. When distilled with *soda-lime*, it yields a mixture of phenol and salicylol (**Gerhardt**).—2. By the current of a Bunsen's battery of 400 pairs, salicin is resolved into glucose and saligenin, which latter is then converted into salicylol, and ultimately into salicylic acid (**Tichanowitsch**, Petersb. Acad. Bull. iv. 80).—3. It is not altered by *ozone*. (**Gorup-Besanez**, Ann. Ch. Pharm. cx. 106.)

4. When boiled with water and *peroxide of lead*, it yields a solution of lead-formate, and a lead-compound of salicin. Distilled with *peroxide of manganese* and dilute sulphuric acid, it yields large quantities of formic acid and carbonic anhydride; but a mixture of sulphuric acid and *dichromate of potassium* converts it into carbonic anhydride, formic acid, and salicylol.

5. Salicin is coloured red by strong *sulphuric acid*, and the product is decolorised by water; the solution then contains a conjugated acid (**Mulder's** *sulphorufic acid*), together with unaltered salicin. If the mixture be heated, there is also formed a resinous substance, called **olivin** by Mulder, **rutilin** by Braconnot, and probably identical with Piria's **saliretin** (*q. v.*). The red colour imparted to salicin by strong sulphuric acid may serve for the detection of salicin in willow-bark.

6. Salicin heated with *dilute sulphuric* or *hydrochloric acid* is resolved into glucose and saligenin:

$$C^{13}H^{18}O^7 + H^2O = C^6H^{12}O^6 + C^7H^8O^2.$$

The same transformation is effected by contact with water and *emulsin*, at a temperature not above 40° (Piria); or by digestion with *saliva* at 38° or 40°. (Städeler, J. pr. Chem. lxxii. 350.)

7. Salicin treated with very weak *nitric acid*, at ordinary temperatures, is converted into helicin:

$$C^{13}H^{18}O^7 + O = C^{13}H^{16}O^7 + H^2O.$$

Sometimes helicoïdin is formed instead of helicin, especially if the acid has a density of about 12° Bm. (Piria). When salicin is boiled once or twice with nitric acid diluted with ten times its bulk of water, it turns yellow and gives off red vapours, together with the odour of salicylol; and the solution, if then mixed with a ferric salt, acquires the colour of ink. The same solution, when left at rest, deposits salicylous acid, the quantity of which gradually increases on evaporation at a gentle heat, without boiling. But if the liquid be again boiled, it becomes clear, and then on cooling deposits, after a while, needles of nitrosalicylic acid, which are reddened by ferric salts (Gerhardt). By the prolonged action of nitric acid, the salicin is ultimately converted into picric acid, together with oxalic acid. (Braconnot.)

8. Salicin added by small portions to boiling aqueous caustic *soda*, dissolves with effervescence, and the solution when saturated with an acid deposits saliretin. On distilling the neutralised solution, salicylol passes over, and a residue is left containing salicylic acid and a brick-red powder (Bouchardat, Compt. rend. xix. 1179).—9. Fused with excess of *potash*, it gives off a large quantity of hydrogen, and is ultimately converted into salicylate and oxalate of potassium.

10. *Chlorine* converts salicin into chlorosalicin, dichlorosalicin, and perchlorosalicin.—11. A mixture of *hydrochloric acid* and *chlorate of potassium* transforms it into perchloroquinone (p. 29). Salicin distilled with *hypochlorite of calcium* yields chloropicrin, but no perchloroquinone (Stenhouse, Ann. Ch. Pharm. lv. 4; lxvi. 247).—12. An aqueous solution of salicin mixed with *chloride of iodine* solidifies, after a while, to a white magma of crystals containing iodine, which have not been further examined. (Stenhouse, Chem. Soc. J. xvii. 327.)

13. After the ingestion of salicin into the animal body, salicylol and salicylic acid are found in the urine (Laveran and Millon, Ann. Ch. Phys. [3] xiii 145). If the dose is large, the urine contains also unaltered salicin, together with saligenin, and perhaps also phenol. (Ranke, J. pr. Chem. lvi. 1.)

Substitution-derivatives of Salicin.

Benzosalicin. $C^{20}H^{22}O^8 = C^{13}H^{17}(C^7H^5O)O^7$.—This is the composition of *Populin*, a crystallisable substance obtained from the bark, leaves, and root of the aspen (iv. 689).

Chlorosalicin. $C^{13}H^{17}ClO^7$. (Piria, [3] xiv. 275.)—Crystallised salicin exposed to the action of chlorine gas, is converted into a red resinous substance, with copious evolution of hydrochloric acid; but when chlorine is passed into a pulp composed of 1 pt. of finely pulverised salicin and about 4 pts. of water, the whole gradually dissolves, and chlorosalicin separates as a nacreous crystalline precipitate, which must be pressed in a cloth, dried between bibulous paper, shaken up two or three times with ether to remove adhering resinous matter, and crystallised from boiling water.

Chlorosalicin crystallises in long, very light, silky needles containing $C^{13}H^{17}ClO^7.2H^2O$. It is soluble in water and alcohol, insoluble in ether. When heated, it first gives off its water, then melts to a transparent colourless liquid, and finally decomposes, giving off vapours of hydrochloric acid, and leaving a large quantity of charcoal. In contact with emulsin it is quickly resolved into glucose and chlorosaligenin, $C^{14}H^7ClO^2$. Strong sulphuric acid dissolves it with reddish colour. When heated with dilute acids, it is quickly resolved into glucose, and a resin resulting from the metamorphosis of chlorosaligenin. (Piria.)

Dichlorosalicin, $C^{13}H^{16}Cl^2O^7$, is obtained by the action of chlorine on the preceding compound, or by its prolonged action on salicin. It forms long, silky, snow-white needles, containing 2 at. water, which they give off at 100°. It is inodorous, slightly bitter, nearly insoluble in cold water, sparingly soluble in boiling water, moderately soluble in alcohol, and nearly insoluble in ether. By dry distillation it yields chlorosalicylol, together with other products. Its aqueous solution does not precipitate metallic salts. Dilute acids convert it into glucose and a reddish resin. Emulsin acts upon it in the same manner as on monochlorosalicin. (Piria.)

Perchlorosalicin, $C^{13}H^{15}Cl^3O^7$, is formed when chlorine is passed into a heated mixture of water and dichlorosalicin, containing lumps of marble to neutralise the hydrochloric acid as fast as it is formed. It is then precipitated as a yellow crystalline powder, which must be shaken two or three times with ether, and crystallised from weak alcohol. It forms small yellowish needles, containing 2 at. water, which is given off at 100°. It is inodorous, but has a bitter taste, decomposes when heated above 100°, and is resolved by emulsin into glucose and a resinous product. (Piria.)

Plumbosalicin, $C^{13}H^{14}Pb^2O^7$ [?], is obtained by pouring a few drops of ammonia into a hot strong solution of salicin, and gradually adding basic acetate of lead till about half the salicin is precipitated. The lead-compound then separates as a bulky white precipitate, resembling starch when dried, having a bitter and sweetish taste, soluble in acetic acid and in potash. It does not give off any water at 100°. It is decomposed by the weakest acids, salicin being set free. Strong sulphuric acid colours it red.

Lead-compounds of salicin of different composition are obtained under other circumstances, not very well defined. (Piria.)

SALICOSYL. $C^7H^5O^2$. A monatomic radicle which may be supposed to exist in salicylol, or salicylous hydride, $C^7H^5O^2.H$, and its derivatives (p. 161). It was formerly called *salicyl*, but this name belongs properly to the diatomic radicle of salicylic acid.

SALICYL. C^7H^4O. The diatomic radicle of salicylic acid and its derivatives. Not known in the separate state.

SALICYL-ACETIC ACID. $C^9H^8O^4 = \left.\begin{matrix}(C^7H^4O)''\\C^2H^3O\\H\end{matrix}\right\}O^2$.—*Acetosalicylic acid.*

[Formerly regarded as *Acetosalicylic anhydride*, $C^7H^5O^2.C^2H^3O$, in accordance with the monatomic formula of salicylic acid, $C^7H^5O^2.H.O$]. Discovered by Gerhardt, who obtained it by the action of chloride of acetyl on salicylate of sodium (i. 31). It is also produced by heating salicylic acid with chloride of acetyl. As thus obtained, it crystallises in tufts of slender prisms, dissolves completely in water only at the boiling heat, easily in alcohol and ether, and reacts with ferric salts like salicylic acid. It melts easily, and when heated a little above its melting-point, emits the odour of acetic acid. It dissolves in warm nitric acid of specific gravity 1·2, the solution yielding crystals of a nitro-acid. (H. v. Gilm, Ann. Ch. Pharm. cxii. 180.)

SALICYLAMIC ACID. $C^7H^7NO^2 = \left.\begin{matrix}H^2\\(C^7H^4O)''\\H\end{matrix}\right\}\begin{matrix}N\\O\end{matrix}$. (Cahours, Ann. Ch. Phys. [3] x. 349.—Muspratt and Hofmann, Ann. Ch. Pharm. liii. 226.—Limpricht, *ibid.* xcviii. 256; xcix. 249.)—This compound, metameric with oxybenzamic acid, phenyl-carbamic acid, and nitrotoluene, and formerly regarded as *salicylamide*, $N.H^2.C^7H^5O^2$ (that is, as the amide of monobasic salicylic acid, $C^7H^5O^2.H.O$), is produced by the action of ammonia on methylsalicylic or ethylsalicylic acid:

$$\underset{\substack{\text{Methylsalicylic}\\\text{acid.}}}{C^7H^5(CH^3)O^3} + NH^3 = \underset{\substack{\text{Salicylamic}\\\text{acid.}}}{C^7H^7NO^2} + \underset{\substack{\text{Methyl-}\\\text{alcohol.}}}{CH^4O}.$$

To prepare it, 1 vol. of wintergreen-oil (methylsalicylic acid) is mixed and repeatedly agitated with about 6 vols. of strong alcoholic ammonia. The yellowish-brown solution thus obtained, deposits, on evaporation, needles of salicylamic acid, which may be purified by crystallisation from hot water or alcohol.

According to Cahours, it is produced by heating acid salicylate of ammonium, but Limpricht was not able to prepare it in this way.

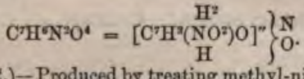
Salicylamic acid crystallises in laminæ having a strong lustre, and a yellowish-white colour not removable by treatment with animal charcoal. It has an acid reaction, is nearly insoluble in cold water, easily soluble in hot water, also in alcohol and in ether. It melts at 132°, and boils at 270°, giving off an aromatic vapour which condenses to shining laminæ of the acid. If it be kept at this temperature till about a fourth part has volatilised, the residue contains salicylimide, which may be extracted by alcohol:

$$C^7H^7NO^2 - H^2O = C^7H^5NO.$$

This reaction affords a decided proof of the diatomicity of salicylic acid, since monatomic acids do not form amic acids and imides (i. 47, 171). Salicylamic acid passed over red-hot lime, is resolved into ammonia, aniline, and phenol. With fuming nitric acid, it forms a nitro-substitute. Strong acids and alkalis convert it, by assumption of water, into acid salicylate of ammonium, $(C^7H^4O)''(NH^4).H.O^2$.

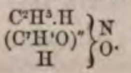
Salicylamates.--Salicylamic acid is so weak an acid, that it is not capable of uniting directly with ammonia, or decomposing alkaline carbonates, but crystallises unaltered from the solution, on evaporation.—The *barium-salt*, $C^{14}H^{12}Ba''N^2O^4$ (at 100°), is soluble in water, and is obtained by treating the acid with baryta-water in a vessel protected from the air.—The *strontium-, calcium-, and magnesium-salts* are similar in properties and composition, and are obtained in like manner; the last, by adding the acid to magnesia suspended in water. All these salts are decomposed by carbonic acid.—The *potassium-* and *sodium-salts* are obtained, as radio-crystalline masses, by decomposing the barium-salt with the corresponding sulphates, and evaporating the filtrate.—*Cupric salicylamate*, $C^{14}H^{12}Cu''N^2O^4$, is precipitated in bright-green microscopic needles, on adding cupric acetate to a solution of either of the preceding salts.—The *silver-salt*, $C^7H^6AgNO^2$ (dried over oil of vitriol) is a greyish-white, not perceptibly crystalline precipitate, which blackens on boiling the liquid. (Limpricht.)

Substitution-derivatives of Salicylamic Acid.



Nitrosalicylamic acid. $C^7H^6N^2O^4 = \left.\begin{matrix} H^2 \\ [C^7H^3(NO^2)O]'' \\ H \end{matrix}\right\} \begin{matrix} N \\ O. \end{matrix}$ *Nitrosalicylamide, Anilamide.* (Cahours, *loc. cit.*)—Produced by treating methyl-nitrosalicylic acid with ammonia in the manner above described: its preparation takes, however, a much longer time (two or three weeks) than that of salicylamic acid, because methyl-nitrosalicylic acid dissolves but slowly in alcoholic ammonia.

Nitrosalicylamic acid is soluble in hot water, alcohol, and ether, and when recrystallised from alcohol, forms yellow needles, which sublime when cautiously heated. It dissolves easily in alkalis, and is precipitated unaltered by acids. The aqueous solution colours ferric salts red. When heated with strong acids or alkalis, it is resolved into ammonia and nitrosalicylic acid. Its salts are not known.

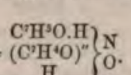


Ethylsalicylamic acid, $C^9H^{11}NO^2 = \left.\begin{matrix} C^2H^5.H \\ (C^7H^4O)'' \\ H \end{matrix}\right\} \begin{matrix} N \\ O. \end{matrix}$ (Limpricht, Ann. Ch. Pharm. xcviii. 262.)—Produced by the action of aqueous ammonia on ethylic methyl-salicylate:

$$C^7H^4(CH^3)(C^2H^5)O^3 + NH^3 = C^7H^6(C^2H^5)NO^2 + CH^4O.$$

If the materials are left to act in the cold, colourless needles of ethylsalicylamic acid are obtained in a few days; if they are heated to 100° in a sealed tube, the action is complete in a few hours.

Ethylsalicylamic acid is soluble in hot water, in alcohol, and in ether, and separates from the ethereal solution in crystals of considerable size. It melts at 110° in the dry state, at 100° when heated with water, and solidifies to a crystalline mass, which sublimes at a stronger heat. From solution in warm potash-ley, hydrochloric acid, or nitric acid, it separates unaltered on cooling; from solution in sulphuric acid on dilution with water. The aqueous solution has a slight acid reaction. It is coloured red by ferric chloride, green by cupric sulphate, and is precipitated by ammoniacal acetate of lead.



Benzoylsalicylamic acid, $C^{14}H^{11}NO^3 = \left.\begin{matrix} C^7H^5O.H \\ (C^7H^4O)'' \\ H \end{matrix}\right\} \begin{matrix} N \\ O. \end{matrix}$ *Benzoylsalicylamide. Salicylbenzamide.* (Gerhardt and Chiozza, Compt. rend. xxxvii. 86.—Limpricht, Ann. Ch. Pharm. xcix. 249.)—Produced by the action of salicylamic acid on chloride of benzoyl. A mixture of the two substances in equivalent quantities is heated to 120°—145° as long as hydrochloric acid continues to escape; and the residue, which remains liquid and viscid for a long time after cooling, but becomes crystalline on the addition of a few drops of alcohol or ether, is washed with a small quantity of ether and dissolved in boiling alcohol, whence it crystallises on cooling in very slender needles united in flocks.

The acid when heated gives off 1 at. water, and is converted into benzoylsalicylamide, $C^{14}H^9NO^2$ (Limpricht). It dissolves very easily in ammonia, but is deposited in its original state when the ammonia evaporates, or when the solution is mixed with an acid; also in the fixed alkalis, forming deep yellow solutions, but is generally resolved at the same time into benzoic and salicylamic acids (Limpricht). It dissolves in warm carbonate of sodium without evolution of carbonic anhydride, and the solution, when treated with acids, deposits very soluble crystals, probably consisting of benzoic and salicylamic acids (Limpricht). Its solution in strontia-water first deposits crystals of benzoate, and afterwards of salicylamate of strontium.

The ammoniacal solution forms a light lemon-yellow precipitate with neutral acetate of lead, and light-blue with sulphate of copper. (Gerhardt and Chiozza.)

Silver-salt.—The ammoniacal solution of the acid forms with nitrate of silver a light lemon-yellow precipitate, which becomes strongly heated with chloride of benzoyl, forming chloride of silver. (Gerhardt and Chiozza.)

Cumylsalicylamic acid, $C^{17}H^{17}NO^2 = \left.\begin{matrix}C^{10}H^{11}O.H\\(C^7H^4O)''\\H\end{matrix}\right\}\begin{matrix}N\\O.\end{matrix}$ —Prepared, like the preceding, with salicylamic acid and chloride of cumyl. Crystallises from alcohol in capillary needles. (Gerhardt and Chiozza.)

SALICYLAMIDE, $C^7H^8N^2O = \left.\begin{matrix}(C^7H^4O)''\\H^4\end{matrix}\right\}N^2$, appears to be produced by the prolonged action of ammonia on ethylic methylsalicylate. (Limpricht, Ann. Ch. Pharm. xcviii. 262.)

SALICYLBENZOIC ACID. $C^{14}H^{10}O^4 = \left.\begin{matrix}(C^7H^4O)''\\C^7H^5O\\H\end{matrix}\right\}O^2$. Syn. with BENZOSALICYLIC ACID (i. 565).

SALICYLIC ACID. $C^7H^6O^3 = \left.\begin{matrix}(C^7H^4O)''\\H^2\end{matrix}\right\}O^2$. *Spinoylic acid. Hyperspiroylic acid.* (Piria, Ann. Ch. Pharm. xxx. 165; xciii. 262.—Löwig and Weidmann, J. pr. Chem. xix. 236; Pogg. Ann. xlvi. 83.—Marchand, J. pr. Chem. xxvi. 395.—Procter, J. Pharm. [3] iii. 275.—Delalande, Ann. Ch. Phys. [3] vi. 346.—Gerhardt, *ibid.* vii. 217.—Cahours, *ibid.* x. 327; xiii. 90, 113.—Ettling, Ann. Ch. Pharm. liii. 77.—Schlieper, *ibid.* lix. 26.—Kolbe and Lautemann, Ann. Ch. Pharm. cxiii. 125; cxv. 157; cxx. 299; Jahresb. 1859, p. 309; 1860, p. 287; 1861, p. 393.—Kekulé, Ann. Ch. Pharm. cxvii. 145; Jahresb. 1860, p. 293.—Gm. xii. 246.—Gerh. iii. 320; iv. 1017.)

This acid, metameric with oxybenzoic acid, exists ready-formed in the flowers of *Spiræa Ulmaria*, and as methylsalicylic acid in oil of wintergreen.

Formation.—1. From salicylol by oxidation wiith aqueous chromic acid (Ettling), or by heating with oxide of copper (Ettling, Piria).—2. By melting salicylol or salicin with hydrate of potassium (Piria):

$$\underset{\text{Salicylol.}}{C^7H^6O^2} + KHO = \underset{\substack{\text{Potassic}\\\text{Salicylate.}}}{C^7H^5KO^3} + H^2.$$

—3. By heating indigo with hydrate of potassium to 300°. The experiment does not always succeed: if the heat be not continued long enough, only phenyl-carbamic acid is produced; if too long, a brown substance is formed. (Ettling.)

5. By passing carbonic anhydride into phenol containing small pieces of sodium. The metal then dissolves with evolution of hydrogen, and salicylate of sodium is formed, together with other products. Salicylic acid has, in fact, the same composition as phenyl-carbonic acid: $C^6H^6O + CO^2 = C^7H^6O^3$ (Kolbe and Lautemann).—6. By the action of nitrous acid on phenyl-carbamic acid (Gerland):

$$C^7H^7NO^2 + HNO^2 = C^7H^6O^3 + H^2O + N^2.$$

Griess (Jahresb. 1861, p. 413), by the action of nitrous acid on phenyl-carbamic acid, obtained an acid, which he calls diazo-salyl-nitric acid, having the composition $C^{14}H^9N^3O^7$; and this, when heated in an aqueous solution, is completely resolved into salicylic acid, nitric acid, and free nitrogen:

$$C^{14}H^9N^3O^7 + 2H^2O = 2C^7H^6O^3 + NHO^3 + N^2.$$

7. Coumaric acid (ii. 93), heated with hydrate of potassium, yields salicylate and acetate of potassium (Delalande, Ann. Ch. Phys. [3] vi. 343):

$$C^9H^8O^3 + 2KHO = C^7H^5KO^3 + C^2H^3KO^2 + H^2.$$

8. Methylsalicylic acid (oil of wintergreen) is resolved by gaseous hydriodic acid into salicylic acid and methylic iodide (Lautemann, Ann. Ch. Pharm. cxxv. 13):

$$C^7H^5(CH^3)O^3 + HI = C^7H^6O^3 + CH^3I.$$

9. Iodosalicylic acid is decomposed by hydriodic acid, even at temperatures below 100°, and more quickly at 100°, into salicylic acid and free iodine (Kekulé, Chem. Soc. J. xvii. 203):

$$C^7H^5IO^3 + HI = C^7H^6O^3 + I^2.$$

Preparation.—*a.* From the flowers of *Spiræa Ulmaria.* The flowers are exhausted with ether, or the water distilled from them, with frequent cohobation, is shaken up with ether; the ethereal solution is distilled; the residue is treated with water, which dissolves salicylic acid and tannin; and the aqueous solution is neutralised with carbonate of potassium, evaporated, and distilled with hydrochloric acid. The watery distillate slowly evaporated yields colourless needles. (Löwig and Weidmann.)

b. From *Oil of Gaultheria* (*Wintergreen*).—The oil is heated with strong potash-ley till no more methylic alcohol is given off from it, and the residue is precipitated with hydrochloric acid. The precipitate is washed with cold water, and crystallised from hot alcohol. (Cahours.)

c. From *Salicylol*, or from *Salicin*.—1. Hydrate of potassium is heated in a silver basin, and as soon as it is melted, salicin is added by small portions, with continual stirring; whereupon the mass turns brown, swells up, and gives off a large quantity of hydrogen. It is then heated as long as hydrogen is given off in presence of excess of potash. If the potash is not in excess, only a small quantity of salicylic acid is obtained, but instead of it, salicylol and a brown resinous substance which it is difficult to convert into salicylic acid, even by repeated fusion with hydrate of potassium. If the process be rightly conducted, the mass becomes nearly colourless, exhibiting only a slight yellowish tint. The mass is dissolved in water; the solution is supersaturated with hydrochloric acid, the vessel being surrounded with cold water; and the resulting crystalline mass is separated from the mother-liquor (which contains oxalic acid), and recrystallised from hot water (Piria, Gerhardt, Marchand).—2. Cupric salicylate is heated in a retort till nothing more escapes at 220°, and the residue has assumed a uniform kermes-brown tint. This residue, consisting of cuprous salicylite, is then introduced into a glass tube, and sulphuretted hydrogen passed over it, whereupon the mass becomes heated and blackened, and salicylic acid sublimes; and in order that the sublimate may not cover up the undecomposed mass, and so protect it from further decomposition, it must be driven forward by the application of a gentle heat. Or the cuprous salicylate is dissolved in warm acetic acid, or in hydrochloric acid diluted with an equal quantity of water; the colourless liquid is precipitated by sulphuretted hydrogen, and the liquid filtered from the sulphide of copper is evaporated to the crystallising point. Or the solution of the copper-salt in acetic acid is supersaturated with ammonia, and precipitated with neutral acetate of lead, the precipitate suspended in hot water, sulphuretted hydrogen passed through the liquid, and the sulphide of lead removed by filtration: the filtrate on cooling yields pure salicylic acid. (Ettling.)

d. From *Indigo* (p. 152).—The heat must be carefully regulated, because, if the required temperature is exceeded, the salicylic acid decomposes, and a brown substance is formed; and if the heating is not continued long enough, nothing but phenyl-carbamic acid is produced.

e. From *Phenol*.—Dry carbonic anhydride is passed into warm phenol, with addition of small pieces of sodium. The metal then dissolves with evolution of hydrogen, and a stiff paste is formed, containing the isomeric salts, salicylate and phenyl-carbonate of sodium, together with unaltered phenol. On acidulating with hydrochloric acid, the phenyl-carbonic acid is decomposed with evolution of carbonic anhydride, and the salicylic acid which is set free may be separated from the phenol by solution in strong aqueous carbonate of ammonium. The solution boiled down till it acquires a slight acid reaction, filtered from separated resin, and mixed with hydrochloric acid, yields salicylic acid, to be purified by recrystallisation with aid of animal charcoal. Salicylic acid is also formed, though in much smaller quantity, by passing carbonic anhydride into a ready-prepared solution of phenylate of sodium in phenol. (Kolbe and Lautemann, Ann. Ch. Pharm. cxv. 177.)

Properties.—Salicylic acid crystallises by spontaneous evaporation of its alcoholic solution in large monoclinic four-sided prisms. From a hot aqueous solution it separates on cooling, in slender needles often an inch long. Particularly large and fine crystals are obtained by slow evaporation of the ethereal solution (Cahours). It melts at 158° (Cahours), at 121° (Procter), at 125° (Ettling). Sublimes at about 200°, without boiling, in slender needles having a strong lustre, and, when pure, may be completely distilled by careful heating (Cahours, Ettling). It has a sweetish-sour taste, and produces irritation in the throat. Reddens litmus rather strongly. It does not act on polarised light.

It is slightly soluble in cold, much more soluble in hot *water*; still more in *alcohol*, moderately soluble in *wood-spirit*, especially when warm. *Ether* dissolves it in somewhat considerable quantity at ordinary temperatures, and still more when heated. Boiling *oil of turpentine* dissolves about $\frac{1}{5}$ of its weight of the acid.

The aqueous solution imparts a deep violet colour to *ferric salts*.

Decompositions.—1. Salicylic acid, when quickly heated, especially if it be impure, gives off phenol (Marchand, Cahours). Heated with pounded glass or quicklime, it is resolved into phenol and carbonic anhydride. (Gerhardt, iv. 389.)

2. Heated with dilute sulphuric acid and *manganic peroxide*, it yields formic acid.

3. *Sulphuric anhydride* converts it into sulphosalicylic acid, $C^7H^6O^3.SO^3$.

4. Fuming *nitric acid* in the cold converts salicylic acid into nitrosalicylic acid; by prolonged action, however, picric acid is produced. The same products are obtained by treating salicylic acid with a mixture of fuming nitric and strong sulphuric acid.

5. With *chlorine* and *bromine*, salicylic acid yields chlorinated or brominated acids, the degree of substitution varying according to the proportions used, and the circumstances of the reaction (p. 156).

6. A mixture of *hydrochloric acid* and *chlorate of potassium* converts it into perchloroquinone (p. 29).

7. Dry salicylic acid (1 at.) distilled with *pentachloride of phosphorus* (2 at. or 3 pts.) yields an oily body, which, after rectifying and collecting the portion which distils between 240° and 270°, consists of salicylic chloride, $(C^7H^4O)''Cl^2$, salicylic chlorohydrate, $C^7H^5O^2.Cl = (C^7H^4O)''\left\{\begin{matrix}Cl\\HO\end{matrix}\right.$ and chlorosalicylic chloride, $C^7H^4Cl^4$, or $(C^7H^4Cl^2)''Cl^2$. The first and third of these bodies are resolved by boiling with water into hydrochloric acid and chlorosalicylic acid, $C^7H^5ClO^2$, isomeric with chlorobenzoic acid; the second yields, in like manner, hydrochloric and salicylic acids.

Such are the results obtained by Kolbe and Lautemann (Jahresb. 1860, p. 288), who however, regard the compound $C^7H^4OCl^2$ as *chloride of chlorosalylic acid*, $C^7H^4ClO.Cl$ (isomeric with chloride of chlorobenzoyl), and the third as *trichloride of chlorosalyl*, $C^7H^4Cl.Cl^3$.

Chiozza (Ann. Ch. Phys. [3] xxxvi. 102; Jahresb. 1852, p. 493), by distilling salicylic acid with pentachloride of phosphorus, had previously obtained an oily distillate, which yielded chlorobenzoic acid (or an isomer) when treated with water. Gerhardt (Ann. Ch. Pharm. lxxxix. 360; Jahresb. 1854, p. 421), by acting in like manner on methylsalicylic acid (oil of wintergreen), obtained salicylic chlorohydrate, $C^7H^5O^2Cl$; and Drion (Jahresb. 1854, p. 423), by the same process, likewise obtained the latter compound, together with salicylic chloride, $C^7H^4OCl^2$. Kekulé (*ibid.* 1860, p. 293), by heating the distillate obtained with wintergreen oil and phosphoric chloride to 180°—200°, to expel oxychloride of phosphorus and the excess of pentachloride (1 at. methylsalicylic acid decomposes only 1 at. PCl^5), obtained a product which, when treated with water, yielded only salicylic acid, no chlorobenzoic or chlorosalylic acid: therefore C^7H^5OCl; but when the chlorinated distillate was further heated to somewhat below 280°, the compound $C^7H^4OCl^2$ was obtained, which yielded with water the chlorinated acid $C^7H^5ClO^2$. Kekulé finds, however, that the composition of the chlorinated distillate is by no means constant, but that the proportion of chlorine increases at each rectification.

Very different results have been obtained by Couper (Ann. Ch. Pharm. cix. 369; Jahresb. 1858, p. 266), who, by gradually dropping 1 at. wintergreen oil into 2 at. pentachloride of phosphorus, and rectifying, obtained a yellowish liquid passing over at about 290°, and a blackish residue which solidified on cooling. This liquid has the composition $C^7H^4Cl^3PO^3$ (*salicyl-trichlorophosphate*), and is resolved by water into hydrochloric, phosphoric, and salicylic acids. Its formation may be represented by the equation:—

$$C^7H^6O^3 \quad + \quad PCl^5 \quad = \quad 2HCl \quad + \quad C^7H^4Cl^3PO^3.$$

8. Dry salicylate of sodium distilled with excess of *phosphoric oxychloride* gives off hydrochloric acid, a viscid liquid which passes over at a high temperature, and on exposure to the air deposits tabular crystals consisting of the phenylic ether of lasylic acid, $C^{13}H^{8}O^2 = \left.\begin{matrix}C^7H^3O\\C^6H^5\end{matrix}\right\}O.$ (Kolbe and Lautemann.)

9. With *chloride of acetyl* salicylic acid forms acetyl-salicylic acid, $C^7H^5(C^2H^3O)O^3$, metameric with terephthalic acid. (H. v. Gilm, Ann. Ch. Pharm. cxii. 180.)

10. Salicylic acid heated with *iodine* yields a mixture of mono-, di-, and tri-iodosalicylic acids (Kolbe and Lautemann), together with tri-iodophenol (Lautemann, Jahresb. 1861, p. 393). The same iodated salicylic acids are produced by dropping tincture of iodine into a cold aqueous solution of salicylate of barium (Kolbe and Lautemann). On adding a solution of iodine in chlorine-water to a warm aqueous solution of salicylic acid, a crystalline precipitate is immediately formed, which after washing with cold water, is found to contain a considerable quantity of an iodine—probably an iodosalicylic acid. (H. Watts.)

SALICYLATES.—Salicylic acid is dibasic, forming acid and neutral salts, represented by the following formulæ:—

$$\text{Acid,} \quad C^7H^5MO^3 = \left.\begin{matrix}(C^7H^4O)''\\HM\end{matrix}\right\}O^2 \text{ and } C^{14}H^{10}M''O^6 = \left.\begin{matrix}(C^7H^4O)^2\\H^2M''\end{matrix}\right\}O^4.$$

$$\text{Neutral,} \quad C^7H^4M^2O^3 = \left.\begin{matrix}(C^7H^4O)''\\M''\end{matrix}\right\}O^2 \text{ and } C^7H^4M''O^3 = \left.\begin{matrix}(C^7H^4O)''\\M''\end{matrix}\right\}O^2.$$

The acid salicylates of diatomic metals may also be regarded as compounds of the neutral salts with the free acid: $C^{14}H^{10}M''O^6 = C^7H^4M''O^3.C^7H^6O^3$. The neutral salicylates of the monatomic metals, potassium, ammonium, and silver, have not been obtained.

Salicylic acid was formerly regarded as monobasic, the salts here considered as acid being then regarded as neutral; indeed, the existence of salicylates containing 2 at. of a monatomic or 1 at. of a diatomic metal was not known till 1855, when several of them were prepared by Piria. The diatomicity of salicylic acid is corroborated by the existence of acid salicylic ethers, oil of wintergreen for example, and by the composition of salicylamic acid and salicylimide (p. 150).

The salicylates of ammonium, potassium, sodium, barium, strontium, magnesium, calcium, and zinc, are soluble and crystallisable. The aqueous solutions of the alkaline salicylates turn brown on exposure to the air. Most salicylates are resolved by dry distillation into phenol and a carbonate.

Salicylate of Ammonium, $C^7H^5(NH^4)O^3$.—Deposited in crystalline scales from a solution of the acid saturated with ammonia, then boiled and evaporated, or in silky needles by spontaneous evaporation of the dilute solution. The crystals are monoclinic (Marignac). It melts at 126° (Procter), and is completely decomposed by distillation into water and salicylamic acid, according to Cahours; according to Limpricht, however, salicylamic acid is not produced in this way.

Salicylates of Barium.—The *acid salt*, $C^{14}H^{10}Ba''O^6.H^2O$, or $C^7H^4Ba''O^3.C^7H^6O^3.H^2O$, is formed by boiling salicylic acid with carbonate of barium, and separates on evaporation in short, concentrically grouped, shining needles, which give off their water at 218° (Cahours). A boiling concentrated solution of this salt mixed with concentrated baryta-water deposits the *neutral salt*, $C^7H^4Ba''O^3.2H^2O$, in small colourless laminæ, which give off their water at 140°. The salt has an alkaline reaction, and is resolved by carbonic acid into the acid salt and carbonate of barium. It dissolves but slightly in water even at the boiling heat. (Piria.)

Salicylates of Calcium.—The *acid salt*, $C^{14}H^{10}Ca''O^6.2H^2O$, prepared like the acid barium-salt, is soluble in cold water, and separates therefrom by spontaneous evaporation in well-developed octahedrons. On mixing a concentrated solution of this salt with a solution of lime in sugar-water containing a large excess of sugar, and warming the liquid in the water-bath, the *neutral calcium-salt*, $C^7H^4Ca''O^3.H^2O$, separates as a sandy insoluble powder, which retains its water at 100°, but gives it off at 180°. It is decomposed by carbonic acid in the same manner as the neutral barium-salt.

Salicylates of Copper.—The *acid salt*, $C^{14}H^{10}Cu''O^6.4H^7O$, remains dissolved when a solution of the acid barium-salt is decomposed by sulphate of copper, and crystallises in long greenish-blue needles, which do not give off their water till heated considerably above 100°. When heated with a quantity of water not sufficient to dissolve it completely, it melts below 100°, and is resolved into salicylic acid and the *neutral copper-salt*, $C^7H^4Cu''O^3.H^2O$, which forms a yellowish-green, light, nearly insoluble powder. The same decomposition of the acid salt is effected by ether. (Piria.)

Potassio-cupric salicylate, $C^{14}H^8Cu''K^2O^6.4H^2O$, is obtained on adding salicylic acid to a solution of cupric tartrate in excess of strong potash-ley, as a light-green crystalline precipitate, which separates from solution in a small quantity of warm water, in emerald-green rhombic plates. It is very soluble in water, insoluble in alcohol and ether, and is resolved by boiling its aqueous solution into cupric oxide and acid salicylate of potassium. It gives off its water below 100°.—*Baryto-cupric salicylate*, $C^{14}H^8Cu''Ba''O^6.4H^2O$, separates on mixing the solution of the preceding salt with chloride of barium, as a siskin-green crystalline precipitate insoluble in water. The water of crystallisation begins to escape at 35°. (Piria.)

Salicylates of Lead.—The *acid salt*, $C^{14}H^{10}Pb''O^6.H^2O$, is obtained by boiling salicylic acid with water and carbonate of lead, in needles having a very brilliant satiny lustre, or by pouring a strong solution of salicylate of ammonium or potassium into a strong solution of acetate of lead, as a white crystalline precipitate, soluble in boiling water (Cahours).—The *neutral salt*, $C^7H^4Pb''O^3$, is obtained as a heavy crystalline powder by adding basic acetate of lead to a boiling saturated solution of the acid salt.—A *basic salt*, $2C^7H^4Pb''O^3.3Pb''O$, separates as a white powder composed of nacreous scales, on boiling the acid salt with a slight excess of ammonia. (Piria.)

Salicylate of Magnesium (acid), obtained by boiling the aqueous acid with magnesia or its carbonate, forms radiating needles often aggregated in a compact mass. It dissolves easily in cold and still more in boiling water. (Cahours.)

Salicylate of Potassium, $2C^7H^5KO^3.H^2O$, is obtained in colourless, shining, silky needles, by saturating the aqueous acid with carbonate of potassium, evaporating to dryness, and treating the residue with strong boiling alcohol. It is converted by chlorine into dichlorosalicylate, and by bromine into **dibromosalicylate of potassium.** Treated with bromine in presence of excess of potash, it yields a red substance resembling sulphide of antimony, insoluble in alcohol, ammonia, and potash, and having the composition of tribromophenol. (Cahours.)

Salicylate of Silver, $C^7H^5AgO^3$, is a white precipitate, which dissolves in a small quantity of boiling water, and separates on cooling in small very brilliant needles. (Cahours.)

Bromosalicylic Acids.

Monobromosalicylic acid, $C^7H^5BrO^3$. (Gerhardt, Ann. Ch. Phys. [3] vii. 217; Cahours, *ibid.* xiii. 99.)—This acid is produced by triturating salicylic acid with a quantity of bromine not sufficient to convert the whole of it. On washing the resulting gummy mass with small quantities of cold alcohol, to extract the unaltered salicylic acid, dissolving the residue in boiling alcohol, and leaving the solution to evaporate, bromosalicylic acid is obtained in colourless prisms having a strong lustre, and somewhat like salicylic acid. It melts when slightly heated; dissolves but sparingly in *water*, even at the boiling heat; pretty readily in *alcohol* and *ether*, especially when warm. It is decomposed by dry distillation. When distilled with fine sand and a small quantity of baryta, it yields thick vapours condensing into a reddish liquid, which by repeated distillation with sand and baryta yields bromophenol: $C^7H^5BrO^3 = C^6H^5BrO + CO^2$.

Bromosalicylic acid forms with ammonia, potash, and soda, crystallisable salts, which are less soluble in water than the salicylates.—It colours ferric salts red, like salicylic acid.

Dibromosalicylic acid, $C^7H^4Br^2O^3$. (Cahours, Ann. Ch. Phys. [3] vii. 102.)—To prepare this acid, pulverised salicylic acid is gradually triturated with excess of bromine as long as any action takes place, and the mixture is left to stand for some hours; the excess of bromine is then washed out with cold water, and the residue dissolved in boiling ammonia. As the solution cools, the ammonium-salt is deposited in slender shining needles. These crystals are dissolved in water; the acid precipitated by hydrochloric acid; the white precipitate washed and dissolved in boiling alcohol, and the solution left to evaporate. Or bromine is dissolved in a concentrated solution of salicylate of potassium, whereupon the liquid becomes heated, and soon deposits crystals of dibromosalicylate of potassium; this salt is decomposed by hydrochloric acid, and the separated acid washed and crystallised from alcohol.

It forms short colourless or slightly reddish needles, which melt at about 150°. It is sparingly soluble in *water*, moderately soluble in *alcohol*, more easily in *ether*. It dissolves in strong *sulphuric acid* at a gentle heat, and is precipitated from the solution by water. Boiling *nitric acid* dissolves it readily, with evolution of bromine and nitrous vapours and formation of picric acid, which crystallises on cooling. When distilled with sand and a small quantity of baryta, it yields dibromophenol.

The dibromosalicylates of ammonium, potassium, and sodium, are even less soluble than the monobromosalicylates. The potassium-salt crystallises from alcohol in shining colourless prisms.

Tribromosalicylic acid, $C^7H^3Br^3O^3$. (Cahours, Ann. Ch. Phys. [3] vii. 104.)—When a mixture of finely pulverised dibromosalicylic acid with excess of bromine is exposed to sunshine for 25 or 30 days, and the resulting crystals are washed with water, and recrystallised from strong alcohol, tribromosalicylic acid is obtained in small yellowish prisms, very hard and friable, insoluble in water, moderately soluble in *alcohol*, very readily in *ether*.

When distilled with sand and a small quantity of baryta, it yields tribromophenol contaminated with a small quantity of oily matter. When boiled with *nitric acid*, it yields bromine-vapours and yellow crystals.

Its compounds with ammonia, potash, and soda are crystallisable, but very sparingly soluble in water. The ammonium-salt forms with silver-salts a precipitate of a deep orange-yellow colour.

Chlorosalicylic Acids.

Only two of these compounds are known, both being produced by the direct action of chlorine on salicylic acid. (Cahours, Ann. Ch. Phys. [3] xiii. 106.)

Monochlorosalicylic acid, $C^7H^5ClO^3$, is produced:—1. By the action of chlorine on excess of salicylic acid, a portion of the acid therefore remaining undecomposed; it is difficult, however, to purify from dichlorosalicylic acid.—2. When chlorine gas is very slowly passed into a concentrated solution of salicylate of potassium, till the liquid, which becomes brown, begins to deposit a dark-green substance; the solution then decomposed by an acid, and the resulting white precipitate washed with water and crystallised from alcohol, slender needles are obtained consisting of chlorosalicylic acid not quite pure.

Dichlorosalicylic acid, $C_7H_4Cl_2O_3$.—This compound is produced by the action of excess of chlorine on salicylic acid. To prepare it, chlorine gas is passed through a concentrated solution of salicylate of potassium as long as the liquid continues to deposit a dark-green body; this substance is washed on a filter with water till the water runs away colourless, then dissolved in boiling water, which is mixed with ⅓ of its volume of alcohol of 36° Bm.; and the needles of the potassium-salt which separate on cooling are repeatedly crystallised from very weak spirit till they become colourless. These crystals are then dissolved in water, the solution mixed with hydrochloric acid, and the resulting white precipitate dissolved in boiling alcohol of 82 per cent.; the solution on cooling yields the acid in needles or in scales, or by spontaneous evaporation in hard, well-formed octahedrons. The acid dissolves sparingly in boiling *water*, and crystallises in slender needles on cooling. It dissolves in gently heated *oil of vitriol*, and separates partially as the liquid cools.

The acid, distilled two or three times with sand and a small quantity of baryta or lime, is completely resolved into carbonic anhydride and dichlorophenol. It dissolves gradually in boiling *nitric acid*, and deposits beautiful yellow laminæ on cooling.

Dichlorosalicylate of ammonium is sparingly soluble in water. The *acid potassium-salt* forms greyish-white needles very much resembling methyl-dichlorosalicylic acid.

Iodosalicylic Acids.

Formation.—1. When tincture of iodine is dropped into a cold aqueous solution of barytic salicylate, $C_7H_4Ba''O_3$, till the yellow colour of the tincture remains permanent, several iodosalicylic acids are formed, which on addition of hydrochloric acid are precipitated together with unaltered salicylic acid. They cannot, however, be separated from one another by water, although their solubility diminishes as the proportion of iodine increases.—2. When 1 at. salicylic acid is fused with 2 at. iodine, and the product is treated with aqueous potash, several iodosalicylic acids are dissolved out, and there remains a red body resembling amorphous phosphorus, which is insoluble in water, alcohol, ether, alkalis, and acids, is not altered by fuming sulphuric acid, but dissolves with red colour in sulphide of carbon; this body appears to be tetriodo-disalicylic acid, $C_{14}H_6I_4O_5$. (Kolbe and Lautemann, Ann. Ch. Pharm. cxv. 157; Jahresb. 1860, p. 291.)

As iodosalicylic acid is reduced by hydriodic acid to salicylic acid even below 100° (p. 152), Kekulé is of opinion that the iodosalicylic acids obtained by fusing salicylic acid with iodine are not directly-formed substitution-products, but are rather formed in the alkaline solution, during the process of separation; perhaps thus:—

$$\underset{\substack{\text{Salicylic}\\\text{acid.}}}{C_7H_6O_3} + I_2 + KHO = \underset{\substack{\text{Mono-iodo-}\\\text{salicylic acid.}}}{C_7H_5IO_3} + KI + H_2O\text{-.}$$

$$\underset{\substack{\text{Salicylic}\\\text{acid.}}}{C_7H_6O_3} + 2I_2 + 2KHO = \underset{\substack{\text{Di-iodosali-}\\\text{cylic acid.}}}{C_7H_4I_2O_3} + 2KI + 2H_2O.$$

$$\underset{\substack{\text{Salicylic}\\\text{acid.}}}{C_7H_6O_3} + 3I_2 + 3KHO = \underset{\substack{\text{Tri-iodo-}\\\text{phenol.}}}{C_6H_3I_3O} + CO_2 + 3KI + 3H_2O.$$

Preparation.—1. Finely pulverised iodine (2 at.) is intimately mixed with salicylic acid (1 at.), and the mixture is heated over a lamp in a wide-bottomed glass vessel, the heat being removed as soon as the fused mass begins to boil. The resulting brown crystalline mass, containing a mixture of mono-, di-, and tri-iodosalicylic acids, with somewhat considerable quantities of tri-iodophenol (iv. 409) and unaltered salicylic acid, is treated with dilute potash, which dissolves everything excepting the red body above mentioned; the filtered alkaline liquid is mixed with hydrochloric acid; and the separated acids are washed with water, which removes nearly all the unaltered salicylic acid. On dissolving the fused residue in excess of sodic carbonate, and neutralising the liquid with hydrochloric acid, the tri-iodophenol, which is soluble only in excess of alkali, separates out; and the filtered liquid yields on evaporation, first, crystals of sodic tri-iodosalicylate, then, on further concentration, satiny needles of sodic di-iodosalicylate, and, lastly, sodic mono-iodosalicylate in small lancet-shaped laminæ. The complete separation and purification of the last two acids is effected by decomposing the sodium-salts with hydrochloric acid, and boiling the separated acids with carbonate of barium, the di-iodosalicylate of barium being very slightly soluble in water, while the mono-iodosalicylate dissolves with moderate facility.—2. A larger product is obtained by dissolving equal weights of salicylic acid and iodine in alcohol of 80 per cent., and boiling the solution for three hours in a flask provided with an upright condensing tube. The brown solution is mixed with water, heated to drive off the alcohol, then supersaturated with carbonate of sodium, and the resulting sodium-salts are further treated as above. (Lautemann, Ann. Ch. Pharm. cxx. 299; Jahresb. 1861, p. 393.)

Mono-iodosalicylic acid, $C^7H^5IO^3$.—This acid, separated from the purified barium-salt by hydrochloric acid, forms a white crystalline mass, slightly soluble in *water*, easily soluble in *alcohol* and *ether*. It crystallises from water acidulated with sulphuric or acetic acid in long silky needles; from alcohol, by slow evaporation, in hard warty groups of needles. It melts at 196°, and, when suddenly heated, is resolved into free iodine, iodophenol, and carbonic anhydride. By boiling with caustic *potash* it is converted into oxysalicylic acid, $C^7H^6O^4$ (iv. 320).

The aqueous and alcoholic solutions of the acid, and likewise the solutions of its salts, colour *ferric chloride* violet.

Iodosalicylate of Ammonium is sparingly soluble in water, and crystallises in needles. —The *barium-salt*, $C^{14}H^8Ba''I^2O^6$, is very soluble in water, and crystallises in rosettes of delicate laminæ, which assume a reddish colour when heated in the moist state.—The *silver-salt* is sparingly soluble, and crystallises in hard grains. (Lautemann.)

Di-iodosalicylic acid, $C^7H^4I^2O^3$, separated from the barium-salt, forms a white amorphous mass, nearly insoluble in *water*, moderately soluble in *alcohol* and *ether*. From water acidulated with sulphuric acid, and from acetic acid, it crystallises like the mono-iodated acid: from alcohol in needle-shaped crystals. It does not melt at 212°, but turns brown from incipient decomposition; when quickly heated, it decomposes with separation of iodine. Boiling *nitric acid* likewise eliminates iodine from it, and probably converts it into dinitrosalicylic acid. By boiling with strong *potash-ley* it is converted into dioxysalicylic or gallic acid, $C^7H^6O^5$, part of which is, however, resolved into carbonic anhydride and dioxyphenic (pyrogallic) acid.—The solutions of di-iodosalicylic acid and its salts colour *ferric chloride* violet.

The di-iodosalicylates are for the most part very sparingly soluble; the most soluble among them is the *sodium-salt*.—The *barium-salt*, $C^{14}H^6I^4Ba''O^6$, crystallises from a moderately concentrated solution, in needles having a satiny lustre. (Lautemann.)

Tri-iodosalicylic acid. $C^7H^3I^3O^3$.—This acid is very difficult to prepare, being very unstable, and apt to split up, during the process of formation by fusing salicylic acid with iodine, into carbonic anhydride and tri-iodophenol. It is insoluble in water, soluble in *alcohol* and *ether*, and crystallises from the former in tufts of needles. It melts at about 157°, with partial decomposition. Alkalis decompose it, abstracting carbonic anhydride and hydriodic acid, and converting it into a red body, $C^6H^2I^2O$.

Tri-iodosalicylate of Sodium is a grey-green mass very slightly soluble in water. (Lautemann.)

Nitrosalicylic Acids.

Two nitro-derivatives of salicylic acid are known,—viz., the mono- and di-nitrated acids.

Mono-nitro-salicylic acid, or simply **Nitrosalicylic acid,** $C^7H^5NO^5 = C^7H^5(NO^2)O^3$. *Indigotic acid. Anilic acid. Nitro-anilic acid. Anilotic acid. Nitrospiroylic acid.* (Chevreul, Ann. Chim. lxxii. 131.—Buff, Ann. Ch. Phys. [2] xxxvii. 160.—Dumas, *ibid.* lxiii. 205; [3] ii. 227. Gerhardt, *ibid.* vii. 325.—Marchand, J. pr. Chem. xxvi. 385.—Piria, Ann. Ch. Pharm. lvi. 35.—Stenhouse, *ibid.* lxx. 253.—H. Major, *Das chem. Laboratorium der Univ. Christiania*, 1854, p. 84.—Gm. xii. 307.—Gerh. iii. 335.)—This acid was first observed by Chevreul among the products of the decomposition of indigo by nitric acid. Gerhardt obtained it by treating salicylic acid with fuming nitric acid. Piria and Major have shown that it is formed, together with helicin, by the action of cold dilute nitric acid upon salicin.

Preparation.—1. From salicylic acid.—Fuming nitric acid acts violently on salicylic acid, converting it into a reddish resinous mass; and on removing the excess of nitric acid by washing with cold water, and dissolving the residue in boiling water, nitrosalicylic acid is deposited in delicate yellowish needles. It may also be prepared by gently heating salicylic acid with very dilute nitric acid. (Gerhardt.)

2. From indigo.—When indigo is gradually added to boiling dilute nitric acid diluted with 10 to 15 times its weight of water, a solution is formed which on cooling deposits nitrosalicylic acid; but the product requires to be purified by several crystallisations, or by transforming it into a lead-salt, and decomposing the latter with sulphydric acid. (Chevreul, Buff, Marchand.)

3. From methyl-nitrosalicylic acid, by boiling with potash, saturating the resulting brown-red liquid with hydrochloric acid, and crystallising the flaky acid which separates. (Cahours.)

Properties.—Nitrosalicylic acid crystallises in colourless needles containing 1 at water, $C^7H^5(NO^2)O^3.H^2O$, which they readily give off on exposure to dry air. It melts at a moderate heat, and solidifies on cooling to a crystalline mass composed of six-sided plates. It reddens litmus, and sublimes at a gentle heat. It is very sparingly soluble in cold *water*, but dissolves easily in boiling water and in *alcohol*. Its solutions are coloured blood-red by ferric salts.

Boiling *nitric acid* converts nitrosalicylic acid into picric acid. A boiling solution of *chloride of lime* converts it into chloropicrin (Stenhouse). By boiling with *hydrochloric acid* and *chlorate of potassium* it is quickly converted into perchloroquinone. The same transformation takes place in a few days when *chlorine gas* is passed into the hot aqueous solution. Nitrosalicylic acid in contact with *nascent hydrogen* dissolves in water, forming a blood-red solution, which gradually deposits purple-red flocks. (Buff.)

Nitrosalicylates, $C^7H^4M(NO^2)O^3$ and $C^{14}H^8M''(NO^2)^2O^6$.—These salts are mostly yellow, take fire when heated, and burn like gunpowder without actual detonation. They redden ferric salts strongly.

The *ammonium-salt*, $C^7H^4(NH^4)(NO^2)O^3$, obtained by saturating the acid with ammonia, crystallises by cooling or spontaneous evaporation in fine needles of a gold or orange-yellow colour.—The *potassium-salt*, $C^7H^4K(NO^2)O^3$, forms yellow silky crystals slightly soluble in cold water, moderately soluble in alcohol.—The *sodium-salt* is yellow, and very soluble in water.

The *barium-salt*, $C^{14}H^8Ba''(NO^2)^2O^6.4H^2O$ (?), obtained by saturating the acid with carbonate of barium, crystallises in shining yellow needles, which are sparingly soluble in cold water, insoluble in alcohol, and give off 12·7 per cent. water of crystallisation at 200°.—A *basic salt*, $C^{14}H^8Ba''(NO^2)^2O^6.Ba''H^2O^2.4H^2O$, is obtained as a yellow powder of the colour of lead-chromate, by precipitating a solution of the preceding salt with ammonia.

The *strontium-*, *calcium-*, and *magnesium-salts* are yellow, and very soluble in water.

The *ferric salt* forms long, dark-red, nearly black needles, which dissolve slowly in water, forming a blood-red solution.

The *neutral lead-salt*, $C^{14}H^8Pb''(NO^2)^2O^6.H^2O$, obtained by saturating the acid with carbonate of lead, or by pouring nitrosalicylate of potassium into a hot solution of a lead-salt, forms a very bulky crystalline precipitate, which increases considerably as the liquid cools.—A *basic lead-salt*, $C^{14}H^8Pb''(NO^2)^2O^6.Pb''O$, is formed when the neutral salt is treated with hot aqueous ammonia; it is a dark-yellow powder, quite insoluble in water, and contains 56 per cent. lead-oxide (Dumas). When a neutral solution of lead-nitrate is poured into a boiling solution of potassic nitrosalicylate, the mixture deposits, after a short time, very slender dark-yellow needles, insoluble in water, and containing 50 per cent. lead-oxide. (Buff.)

The *mercurous salt* is obtained by mixing the solution of potassic nitrosalicylate and barytic nitrate, as a light-yellow precipitate, insoluble in cold, slightly soluble in boiling water.

The *silver-salt*, $C^7H^4Ag(NO^2)O^3$, is obtained by precipitating the ammonium-salt with silver-nitrate, and crystallises easily from boiling water in straw-coloured needles. When heated, it does not detonate, but throws out very bulky vegetations of carbide of silver.

Dinitrosalicylic acid, $C^7H^4N^2O^7 = C^7H^4(NO^2)^2O^3$. *Nitropopulic acid.*—(Cahours, Ann. Ch. Phys. [3] xxv. 11.—Stenhouse, Ann. Ch. Pharm. lxxviii. 1.)—Produced:—1. As an acid methyl-ether, by the action of a mixture of fuming nitric and sulphuric acid on methylsalicylic acid. On boiling the resulting methyl-dinitrosalicylic acid for a few minutes with strong caustic potash, a dipotassic dinitrosalicylate is obtained as a sparingly soluble salt of a splendid red colour; and on treating this salt with strong sulphuric acid, keeping the temperature from rising above 50°, sulphate of potassium is formed, together with dinitrosalicylic acid, which may be dissolved out by cold water. (Cahours.)

2. By digesting the aqueous extract of the branches of certain poplars (*Populus balsamifera, P. nigra*) with dilute nitric acid (Stenhouse). For details of the preparation, see Gmelin's *Handbook*, xii. 314.

Dinitrosalicylic acid crystallises from boiling water in nearly colourless silky needles, or by slow evaporation in small hard prisms. It is very soluble in pure *water*, but only slightly soluble in water containing sulphuric or hydrochloric acid. It dissolves easily in *alcohol* and *ether*. Its taste is very sour at first, then astringent, and finally very bitter. Its solutions impart a persistent yellow colour to the skin. It melts at a moderate temperature, when cautiously heated, and sublimes without alteration.

Dinitrosalicylic acid produces a deep cherry-red colour with *ferric salts*. Strong *nitric acid* at the boiling heat quickly converts it into picric acid (hence, in preparing it from poplar extract, the heat must be kept low). *Oil of vitriol* dissolves it at low temperatures, and water separates it from the solution unaltered; but the mixture carbonises when heated. When heated with *hydrochloric acid* and *chlorate of potassium*, it is converted into perchloroquinone.—*Chloride of lime* does not attack in the cold; but on heating the mixture, a violent action takes place, resulting in the formation of chloropicrin.

Dinitrosalicylates.—Dinitrosalicylic acid forms *neutral salts*, $C^7H^2M^2(NO^2)^2O^3$ and $C^7H^2M''(NO^2)^2O^3$, and *acid salts*, $C^7H^3M(NO^2)^2O^3$ and $C^{14}H^6M''(NO^2)^4O^6$. They are mostly yellow, sparingly soluble, and detonate violently when heated.

The *ammonium-salt*, $C^7H^3(NH^4)(NO^2)^2O^3$, is easily obtained by dissolving the acid in ammonia, and separates on evaporation in small needles of a fine yellow colour.

Potassium-salts.—The *neutral* or *dipotassic salt*, $C^7H^2K^2(NO^2)^2O^3$, is produced when methyl-nitrosalicylic acid is decomposed by boiling with excess of strong potash-ley. It forms beautiful needles having a splendid yellowish-red colour and satiny lustre, and united in stellate groups. It appears to be completely decomposed by continued boiling with potash; detonates violently on glowing coals or on a hot plate (Cahours). The *monopotassic* or *acid salt*, $C^7H^3K(NO^2)^2O^3$, produced by neutralising the aqueous acid with carbonate of potassium (Stenhouse), or by heating the neutral salt with dilute nitric acid (Cahours), crystallises in small lemon-yellow prisms; very sparingly soluble in cold water; insoluble in alcohol or ether. It dissolves very readily in alkaline liquids, and is precipitated therefrom by acids (Stenhouse). It deposits the free acid when boiled with strong hydrochloric acid. It dissolves in slightly heated oil of vitriol, and the solution, on being mixed with water, deposits the acid in crystalline laminæ. It detonates on glowing coals, but not so strongly as the neutral salt.

The *monosodic salt*, $C^7H^3Na(NO^2)^2O^3$, obtained by neutralising the aqueous acid with carbonate of sodium, forms small spicular crystals or yellow shining needles, more soluble in water than the potassium-salt.

Barium-salts. The *neutral salt*, $C^7H^2Ba''(NO^2)^2O^3$, is obtained by adding a boiling solution of caustic baryta to a boiling solution of the acid, as long as the resulting precipitate redissolves on agitation. The filtrate then on cooling deposits small granular crystals.—The *acid-salt*, $C^{14}H^6Ba''(NO^2)^4O^6$, is obtained as a yellow precipitate on adding baryta-water in excess to dinitrosalicylic acid. It is crystalline, and very slightly soluble in boiling water.

The *lead-salt* is very sparingly soluble in water.

The *silver-salt*, $C^7H^3Ag(NO^2)^2O^3$, is obtained, in small granular very slightly soluble crystals, by saturating a hot dilute solution of the acid with carbonate of silver.

Oxysalicylic Acids.

Oxysalicylic acid, $C^7H^6O^4$, and dioxysalicylic acid, $C^7H^6O^5$, are formed by the action of boiling potash-ley on mono- and di-iodosalicylic acid respectively (iv. 320; v. 158).

SALICYLIC ANHYDRIDES. (Gerhardt, Ann. Ch. Phys. [3] xxxvii. 322.)—When dry salicylate of sodium is treated with phosphoric oxychloride, hydrochloric acid is evolved, and two products are formed, both containing the elements of salicylic acid *minus* water, viz.:—

$$\text{Disalicylic acid, } C^{14}H^{10}O^5 = \left.\begin{matrix}(C^7H^4O)'' \\ (C^7H^4O)'' \\ H^2\end{matrix}\right\}O^3 = 2C^7H^6O^3 - H^2O.$$

$$\text{Salicylide} \quad C^7H^4O^2 = (C^7H^4O)''O = C^7H^6O^3 - H^2O.$$

The formation of these compounds may be represented by the equation:—

$$4C^7H^5NaO^3 + PCl^3O = C^{14}H^{10}O^5 + 2C^7H^4O^2 + NaCl + 2HCl + PNa^3O^4.$$

The product of the reaction is a hard mass, which, when heated with water, is converted into a viscous substance soluble in boiling alcohol. The alcoholic solution on cooling deposits disalicylic acid in the form of a thick oil, which very slowly solidifies, and, when treated with boiling water or with alkalis, is converted into salicylic acid. Boiling ether dissolves it, and leaves it on evaporation in the form of a plastic mass.

If salicylic acid be regarded as monobasic, and represented by the formula $C^7H^5O^2.H.O$, disalicylic acid will be its anhydride, $(C^7H^5O^2)^2O$, which is the view of its composition taken by Gerhardt. In like manner, the compounds now denominated salicyl-acetic and salicyl-benzoic acids were formerly regarded as anhydrides (p. 150).

Salicylide, $C^7H^4O^2$, the true anhydride of salicylic acid, is the portion of the above-described product which is insoluble in boiling alcohol. It is white, amorphous, not attacked by boiling water, insoluble in boiling ether. When heated, it melts to a transparent liquid, which solidifies to a translucent mass on cooling. It is not attacked by a boiling solution of sodic carbonate, and but slowly by boiling aqueous ammonia, but potash quickly converts it into salicylate of potassium.

When salicylic anhydride [? disalicylic acid or salicylide] is subjected to dry distillation, the portion which passes over below 300° contains phenol and a body having the composition C^7H^4O [$=$ salicylide, $C^7H^4O^2 - CO$]; and on expelling the phenol by heat, and crystallising the residue from alcohol, with addition of animal charcoal, this body is obtained in silky needles, which melt at 103°, dissolve in 125 pts. alcohol of specific gravity 0·801, and sparingly in water and in ether. The crystals heated with *bromine* to 100° yield a bromine compound, C^6H^3BrO, which melts at 195°, and crystallises from hot alcohol in needles.—A nitro-compound, $C^6H^3(NO^2)O$, crystallising in a similar form, and melting at 150°, is produced by treating the compound C^6H^4O for several days with fuming nitric acid. This nitro-compound is converted by sulphide of ammonium into a base, C^6H^5ON, which crystallises in yellow needles, and forms a crystalline platinum-salt somewhat soluble in water. The compound C^6H^4O yields with strong sulphuric acid a sulpho-acid, which forms a barium-salt crystallising in nodules (H. Marker, Ann. Ch. Pharm. cxxiv. 249). The formation of the compound C^6H^4O was first noticed by Limpricht. (*Lehrb. d. org. Chem.* p. 914.)

SALICYLIC CHLOROHYDRATE. $C^7H^5O^2Cl = (C^7H^4O)''\left\{\begin{matrix}Cl\\HO\end{matrix}\right.$—This body, metameric with chlorosalicylol (p. 171), and commonly called *chloride of salicyl*, is produced, together with chlorobenzoylic chloride, $C^7H^4ClO.Cl$, by the action of pentachloride of phosphorus on methylsalicylic acid (Gerhardt, *Traité*, iii. 343; Drion, Ann. Ch. Pharm. xcii. 423), and on salicylic acid (Kolbe and Lautemann, Jahresb. 1860, p. 288; Kekulé, *ibid.* 293; see also p. 154 of this volume). When separated from phosphoric oxychloride by heating the product to 160°, it forms a slightly-coloured fuming liquid. In contact with water, it becomes heated, and is transformed into hydrochloric and salicylic acids. With methylic and ethylic alcohols, it yields in like manner methyl- and ethyl-salicylic acids. It cannot be distilled without decomposition, hydrochloric acid being then evolved, and a fuming liquid passing over which exhibits all the characters of chlorobenzoylic chloride; a large quantity of carbonaceous matter is also left behind. (Gerhardt.)

SALICYLIC ETHERS. By distilling salicylic acid with an alcohol and strong sulphuric acid, acid ethers are obtained having the composition of salicylic acid in which 1 at. of the typic hydrogen is replaced by an alcohol-radicle, the remaining atom of hydrogen being replaceable by metals, or likewise by alcohol-radicles, yielding neutral salicylic ether.

Methylsalicylic acid, $C^8H^8O^3 = \left.\begin{matrix}(C^7H^4O)''\\CH^3\\H\end{matrix}\right\}O^2$. *Gaultheric acid.* (Cahours, Ann. Ch. Phys. [3] x. 327; xxvii. 5.—Procter, J. Pharm. [3] iii. 27.—Gerhardt, Compt. rend. xxxviii. 32.)—This ether, isomeric with anisic acid, exists ready-formed in the volatile oil of wintergreen (*Gaultheria procumbens*), of which it constitutes about $\frac{9}{10}$, the remainder consisting of a hydrocarbon isomeric with oil of turpentine (ii. 825). On rectifying the commercial oil, the hydrocarbon passes over first at about 200°, and the boiling-point then quickly rises to 222°, at which temperature pure methylsalicylic acid passes over.

Methylsalicylic acid is likewise obtained, unmixed with any hydrocarbon, by distilling with water the bark of the sweet birch (*Betula lenta*); and it may be produced artificially by distilling a mixture of 2 pts. salicylic acid, 2 pts. anhydrous methylic alcohol, and 1 pt. of sulphuric acid specific gravity 1·66; or by treating anhydrous methylic alcohol with salicylic chlorohydrate.

Pure methylsalicylic acid is a colourless oil, having a very penetrating but agreeable odour, and a sweet, cooling, aromatic taste. Specific gravity = 1·18 at 10°. Boiling point 222°. Vapour-density, obs. = 5·42; calc. = 5·719. It is slightly soluble in water, and mixes in all proportions with alcohol and ether. Its aqueous solution is coloured violet by ferric salts. It dissolves *iodine* without decomposing, and forms a brown solution.

Decompositions.—1. When methylsalicylic acid is mixed with strong *nitric acid*, violent spirting takes place, if the mixture is not cooled; but when it is kept cool, methylnitrosalicylic acid is produced (Cahours). By fuming nitric acid, it is converted into methyl-nitrosalicylic acid: by a mixture of fuming nitric acid and oil of vitriol into methyl-dinitrosalicylic acid, or by longer action into methyl-trinitrosalicylic acid (Cahours).—2. *Bromine* added by drops to methylsalicylic acid causes considerable rise of temperature and evolution of hydrobromic acid; the mass, which solidifies on cooling, contains methyl-bromosalicylic and methyl-dibromosalicylic acids, the proportions varying according to the quantity of bromine used. *Chlorine* forms similar products, the quantity of hydrogen replaced never exceeding 2 at., even in sunshine (Procter, Cahours).—3. *Pentachloride of phosphorus* acts violently on the acid, forming salicylic chlorohydrate, methylic chloride, and phosphoric oxychloride:

$$C^7H^5(CH^3)O^3 + PCl^5 = C^7H^5O^2Cl + CH^3Cl + POCl^3.$$

For the results obtained by Couper and by Kekulé, see p. 154.

4. With the *chlorides of benzoyl, cumyl,* and *succinyl,* methylsalicylic acid forms benzoic, cumylic, or succinic methylsalicylate, together with hydrochloric acid, *e.g.*:

$$\underset{\substack{\text{Methylsalicylic}\\ \text{acid.}}}{C^7H^5(CH^3)O^3} + \underset{\substack{\text{Benzoic}\\ \text{chloride.}}}{C^7H^5OCl} = \underset{\substack{\text{Benzoic methyl-}\\ \text{salicylate.}}}{C^7H^4(CH^3)(C^7H^5O)O^3} + HCl.$$

5. By *potash-ley* methylsalicylic acid is resolved, after a few hours at ordinary temperatures, immediately when heated, into salicylic acid and methylic alcohol (Procter, Cahours).—6. Heated with anhydrous *baryta,* it yields carbonate of barium and anisol.—7. With *ammonia,* either gaseous or alcoholic, it forms salicylamic acid and methylic alcohol:

$$\left.\begin{matrix}(C^7H^4O)''\\ CH^3\\ H\end{matrix}\right\}O^2 + NH^3 = \left.\begin{matrix}H^2\\ (C^7H^4O)''\\ H\end{matrix}\right\}\begin{matrix}N\\ O\end{matrix} + \left.\begin{matrix}CH^3\\ H\end{matrix}\right\}O.$$

8. When pieces of *potassium* are dropped into methylsalicylic acid heated to between 30° and 60°, the temperature rises, gas is evolved, and after the addition of a considerable quantity of potassium, the mass solidifies, even if kept at 105°. Soon afterwards it takes fire and leaves a black residue. In one experiment salicylol was produced. (Cahours.)

Methylsalicylates, $C^8H^7MO^3 = \left.\begin{matrix}(C^7H^4O)''\\ CH^3\\ M\end{matrix}\right\}O^2$, the formulæ being doubled for diatomic metals.

The *potassium-salt*, $C^8H^7KO^3$, is obtained, by agitating strong potash-ley with excess of methylsalicylic acid, in pearly scales, which may be purified by washing with the smallest possible quantity of cold water, pressure between bibulous paper, solution in absolute alcohol, and evaporation *in vacuo*. It then forms extremely delicate white needles, having a strong lustre and resembling asbestos (Cahours): six-sided plates (Procter). It is very soluble in water, alcohol, and ether, colours ferric salts purple, and, when heated in the moist state, gives off methyl-alcohol, and leaves salicylate of potassium. The *sodium-salt* resembles the potassium-salt, but is less soluble in water, alcohol, and ether.—The *barium-salt*, $C^{16}H^{14}Ba''O^6.H^2O$, separates in crystalline scales on gradually adding methylsalicylic acid to hot baryta-water, and leaving the liquid to cool. By dry distillation it is resolved into anisol, carbonate of barium, and carbonic anhydride:

$$C^{16}H^{14}Ba''O^6 + H^2O = 2C^7H^8O + Ba''CO^3 + CO^2.$$

The potassium-salt forms precipitates with the salts of lead, copper, silver, and mercury.

Neutral methylsalicylic ethers,—i.e., compounds in which the basic hydrogen of methylsalicylic acid is replaced by methyl, ethyl, amyl, &c.,—are obtained by heating methylsalicylate of potassium with iodide of methyl, ethyl, or amyl, in sealed tubes. The *methyl-compound*, $C^7H^4(CH^3)^2O^3$, boils at 248°, the *ethyl-compound*, $C^7H^4(CH^3)(C^2H^5)O^3$, at 262°, and the amyl-compound above 300° (Cahours, Compt. rend. xxxix. 256). According to Cahours, these ethers are resolved by boiling with potash into salicylic acid and alcohols; but according to Gräbe (Ann. Ch. Pharm. cxxxvi. 124), the methyl-compound thus treated is converted into methoxysalylic acid, $C^7H^5(CH^3)O^3$, and the ethyl-compound into ethoxysalylic acid. (See SALYLIC ACID.)

Benzoic methylsalicylate, $C^{15}H^{12}O^4 = \left.\begin{matrix}(C^7H^4O)''\\ CH^3\\ C^7H^5O\end{matrix}\right\}O^2$, is obtained by heating equal parts of methylsalicylic acid and chloride of benzoyl, as long as hydrochloric acid continues to escape, washing the tenacious gradually crystallising product with potash-ley, and crystallising from alcohol or ether.—It crystallises in oblique rhombic prisms having a splendid lustre. They remain unaltered in warm water. When heated with caustic potash, they are strongly attacked, and give off an aromatic odour; and on treating the aqueous solution of the residue with hydrochloric acid, a precipitate of salicylic acid is obtained. The compound is insoluble in water, but dissolves readily in alcohol and ether. (Gerhardt.)

Cumylic methylsalicylate, $C^{18}H^{18}O^4$ =  $\left.\begin{matrix}(C^7H^4O)'' \\ CH^3 \\ C^{10}H^{11}O\end{matrix}\right\}O^2$, is obtained in like manner with chloride of cumyl, but requires for its production a rather higher temperature. The product is a thick oil, which remains liquid for a long time, but, if mixed with a little ether, solidifies on evaporation to a radiated mass. It is insoluble in water, slightly soluble in cold, more soluble in boiling alcohol, whence it crystallises in highly lustrous rhombic scales; very soluble in ether, and separates therefrom by spontaneous evaporation in oblique rhomboidal prisms, sometimes of considerable size.

Succinic methylsalicylate, $C^{20}H^{18}O^8$ =  $\left.\begin{matrix}(C^7\ddot{H}^4O)^2 \\ (CH^3)^2 \\ (C^4H^4O^2)''\end{matrix}\right\}O^4$.—Prepared by gently heating succinic chloride with about 2 pts. of methylsalicylic acid as long as hydrochloric acid continues to escape, digesting the resulting brown mass with potash-ley, and crystallising it from boiling alcohol. The solution on cooling deposits large rectangular laminæ composed of easily separated fibres. The compound is sparingly soluble in ether. (Gerhardt.)

METHYL-BROMOSALICYLIC ACID, $C^8H^7BrO^3$ =  $\left.\begin{matrix}(C^7H^3BrO)'' \\ CH^3 \\ H\end{matrix}\right\}O^2$. (Cahours, Ann. Ch. Phys. [3] x. 339.)—When bromine is slowly dropped into methylsalicylic acid kept as cold as possible, and the mass which solidifies on cooling is freed from hydrobromic acid by washing with weak alcohol and dissolved in boiling alcohol of 36°, the liquid, as it cools, deposits shining crystalline laminæ of methyl-dibromosalicylic acid, an additional quantity of which may be obtained from the mother-liquor on cooling after evaporation to one-half. The remaining mother-liquor, however, yields by further evaporation crystals of methyl-bromosalicylic acid, which may be purified by three crystallisations from alcohol or by sublimation.

Methyl-bromosalicylic acid forms silky needles, having a peculiar odour, melting at 55°, and subliming without decomposition. It is nearly insoluble in *water*, but dissolves readily in *alcohol* and *ether*. It dissolves in cold concentrated *potash-ley*, apparently forming the salt $C^7H^3KBr(CH^3)O^3$; on heating the liquid, methylic alcohol is given off, and bromosalicylate of potassium remains. A strong solution of *ammonia* gradually converts it into bromosalicylamic acid; distilled with *cyanide of mercury* it forms methyl-cyanosalicylic acid.

METHYL-DIBROMOSALICYLIC ACID, $C^7H^6Br^2O^3$ =  $\left.\begin{matrix}(C^7H^2Br^2O)'' \\ CH^3 \\ H\end{matrix}\right\}O^2$. (Cahours, *loc. cit.*)—This acid is prepared, as above described, by the action of bromine on methylsalicylic acid, or by treating the monobrominated acid with excess of bromine. It crystallises from alcohol in rather large prisms, melting at 145°, and volatilising at a higher temperature. It is insoluble in water, but soluble in *alcohol* and *ether*, especially when warm. With *cyanide of mercury* it behaves like the monobrominated compound. It dissolves in *potash* and in *soda*, forming crystallisable salts, from which it is separated by acids in its original state.

Methyl-dibromosalicylic acid is not attacked by excess of bromine, even in direct sunshine.

METHYL-CHLOROSALICYLIC ACID, $C^8H^7ClO^3$, is formed when methylsalicylic acid is exposed to the action of a small quantity of chlorine; but it is difficult to purify. (Cahours.)

METHYL-DICHLOROSALICYLIC ACID, $C^8H^6Cl^2O^3$. (Procter, J. Pharm. [3] iii. 275.—Cahours, Ann. Ch. Phys. [3] x. 343.)—When chlorine gas is passed into methylsalicylic acid till the action ceases, a yellowish crystalline mass is formed, consisting of methyl-dichlorosalicylic acid mixed with a small quantity of liquid methyl-chlorosalicylic acid. By crystallisation from boiling alcohol, the dichlorinated acid is obtained in colourless rhombic tables (Procter); in needles (Cahours). It melts at 104° (Procter), at about 100° (Cahours), and crystallises on cooling; volatilises without decomposition at a stronger heat (Cahours), and sublimes a little above its melting point in rhombic crystals. It is insoluble in water, soluble in *alcohol* and *ether*; dissolves in cold strong caustic *potash*, and is separated therefrom by acids in its original state. It dissolves slowly in *ammonia*, forming a chlorinated amide. When distilled with *cyanide of mercury*, it yields a compound in which the chlorine is replaced by cyanogen. It is not attacked by chlorine in sunshine.

METHYL-NITROSALICYLIC ACID, $C^8H^7NO^5 = \left.\begin{matrix}[C^7H^3(NO^2)O]''\\ CH^3\\ H\end{matrix}\right\}O^2$. *Indigotate of Methylene.* (Cahours, Ann. Ch. Phys. [3] x. 345.)—Produced by adding fuming nitric acid to methylsalicylic acid, cooled so that no spirting may take place. The liquid then quickly solidifies in a crystalline mass, from which the free nitric acid may be extracted by boiling water; and the product, purified by two or three crystallisations from alcohol, forms very delicate yellowish needles, which melt between 88° and 90°, and may for the most part be volatilised without decomposition. It is very slightly soluble in *water*, easily soluble in boiling *alcohol*. *Potash* and *soda* likewise dissolve it easily, forming methyl-nitrosalicylates; *ammonia* ultimately converts it into nitrosalicylamic acid. Boiling potash decomposes it into methylic alcohol and nitrosalicylic acid.

When fuming *nitric acid* in slight excess is gradually added to methyl-nitrosalicylic acid, a brisk action takes place, and a dark-red solution is formed. If the mixture be not cooled, but gently heated at the last, the liquid becomes turbid, and deposits drops of oil, which, if the heat be discontinued as soon as they cease to increase, form a yellow resinous mass; and this substance, when dissolved in hot alcohol, separates almost completely on cooling, in pale-yellow needles, which melt at 95°, and form on cooling a yellow radiated mass, which, if carefully raised to a higher temperature, sublimes in pale-yellow slender needles. It dissolves sparingly and with slight colour in cold water, and more abundantly in hot water, whence it separates in long, slender, nearly colourless crystals; it dissolves also in alcohol and ether, especially when hot. Neither the aqueous solution nor the acid obtained after decomposition with potash reddens ferric salts. The crystals contain 43·40 per cent. C, 9·57 N, and 3·28 H, and are, therefore, a mixture of methyl-nitrosalicylic and methyl-dinitrosalicylic acids (Cahours). Procter obtained a similar substance by boiling wintergreen-oil with nitric acid of specific gravity 1·14.

METHYL-DINITROSALICYLIC ACID, $C^8H^6N^2O^7 = \left.\begin{matrix}[C^7H^2(NO^2)^2O]''\\ CH^3\\ H\end{matrix}\right\}O^2$. *Acide gaulthérique binitrique. Salicylate de methylène binitrique.* (Cahours, Ann. Ch. Phys. [3] xxv. 6.)—When methylsalicylic acid is dropped into a mixture of fuming nitric acid and fuming oil of vitriol kept cool by cold water, a clear dark-orange-coloured liquid is produced. As soon as the drops of methylsalicylic acid cease to dissolve, a small quantity more of nitrosulphuric acid is added, the mixture shaken till the solution is complete, and the liquid, after some minutes, diluted with eight times the quantity of water, whereupon the methyl-dinitrosalicylic acid separates out, and may be crystallised from solution in boiling alcohol. The aqueous mother-liquor contains methyl-trinitrosalicylic acid.

Methyl-dinitrosalicylic acid forms yellowish-white crystalline scales, which become nearly colourless after two crystallisations. It is heavier than water: melts between 124° and 125°, forming a pale-yellowish liquid, which solidifies in a fibrous mass on cooling, volatilises completely when carefully heated in a retort, and sublimes in very delicate shining laminæ. When suddenly heated, it detonates, and decomposes, giving off a thick black smoke, and leaving a carbonaceous residue.

The acid is insoluble in water, even at the boiling heat, nearly insoluble in cold *alcohol*, but easily soluble in boiling alcohol.

It dissolves in gently-heated *oil of vitriol*, and is precipitated therefrom by water in nearly colourless scales, having a strong lustre. The solution in oil of vitriol gives off carbonic anhydride between 75° and 80°: if it be gradually heated, and too great a rise of temperature prevented by frequent immersion in cold water, a colourless liquid is formed, which is rendered turbid by addition of a large quantity of water, and on cooling yields small shining needles, which dissolve readily in boiling water or alcohol, and crystallise on cooling.—If the solution in oil of vitriol be heated somewhat more quickly, or above 100°, the liquid turns red and ultimately black, giving off carbonic and sulphurous anhydrides, and deposits brown flakes when mixed with water.

Methyl-dinitrosalicylic acid dissolves without decomposition in fuming *nitric acid* at temperatures between 30° and 40°, and is reprecipitated by water in its original state. The solution in gently-heated nitromuriatic acid deposits on cooling needles of the unaltered substance.

By continued boiling, either with fuming or with commercial nitric acid, it is completely decomposed, with formation of picric acid. By the continued action of a mixture of nitric and sulphuric acids, it is converted into methyl-trinitrosalicylic acid. By boiling with strong *potash-ley*, it is resolved into methylic alcohol and dinitrosalicylic acid.

Methyl-dinitrosalicylic acid forms salts containing $C^7H^2M(NO^2)^2(CH^3)O^3$. It dissolves in dilute *potash* and *soda*, forming salts which crystallise by evaporation. The *ammonium-salt*, $C^7H^2(NH^4)(CH^3)(NO^2)^2O^3$, obtained by dissolving the acid in a slight excess of warm caustic ammonia, crystallises in yellow transparent needles, sparingly soluble in cold, very soluble in boiling water; the solution, mixed with an acid, deposits methyl-dinitrosalicylic acid. The *silver-salt*, $C^7H^2Ag(CH^3)(NO^2)^2O^3$, obtained by adding nitrate of silver to a dilute solution of the ammonium-salt, is a yellow powder resembling chromate of lead.

METHYL-TRINITROSALICYLIC ACID, $C^8H^5N^3O^9 = \left.\begin{matrix}[C^7H(NO^2)^3O]''\\ CH^3\\ H\end{matrix}\right\}O^2$. (Cahours, Ann. Ch. Phys. [3] xxv. 20.)—When the product of the action of a mixture of strong sulphuric and fuming nitric acid on methylsalicylic acid is treated with boiling alcohol, and the deposit of methyl-dinitrosalicylic acid is separated, the mother-liquor retains methyl-trinitrosalicylic acid, which crystallises in yellowish transparent plates, but always accompanied by picric acid.

Ethylsalicylic acid, $C^9H^{10}O^3 = \left.\begin{matrix}(C^7H^4O)''\\ C^2H^5\\ H\end{matrix}\right\}O^2$. (Cahours, Ann. Ch. Phys. [3] x. 369.—G. Baly, Chem. Soc. Qu. J. ii. 28.—Gerhardt, *Traité*, iii. 326.)—1. When 4 pts. of alcohol are distilled with 3 pts. of crystallised salicylic acid and 2 pts. of oil of vitriol, alcohol alone passes over first, then a mixture of alcohol and ethylsalicylic acid, and lastly a small quantity of alcohol with a large quantity of ethylsalicylic acid. As soon as sulphurous anhydride begins to escape, the distillation is interrupted, the distillate shaken up with water containing a little ammonia, then washed with water, dried over chloride of calcium, and rectified by two distillations. (Cahours, Baly).—2. When absolute alcohol is added by drops to salicylic chlorohydrate, the mixture becomes heated, and gives off large quantities of hydrochloric acid. As soon as the action ceases, the liquid is distilled, and the portion which goes over towards 225° is collected. (Gerhardt.)

Properties.—Ethylsalicylic acid is a colourless oil, heavier than water. Specific gravity 1·097 (Baly); 1·1843 at 10° (Delffs). Boils at 225° (Cahours); at 221° with the barometer at 28″ 1·3‴ (Delffs); at 229·5° (Baly). It has an agreeable odour, resembling that of methylsalicylic acid. It dissolves sparingly in *water*, easily in *alcohol* and *ether*.

Decompositions.—1. *Chlorine* and *bromine* act strongly on ethylsalicylic acid, producing crystallised substitution-products.—2. With *pentachloride of phosphorus* and with *chloride of benzoyl*, it reacts like the corresponding methyl-compound.—3. *Ammonia* dissolves it slowly, converting it into ethylic alcohol and salicylamic acid.—4. *Fuming nitric acid* converts it into ethylic nitrosalicylate; but when boiled with nitric acid, it yields picric acid.—5. When boiled with *potash* or *soda*, it is resolved into alcohol and salicylic acid.—6. Anhydrous *baryta* attacks it strongly, and the product, when distilled, yields ethylic phenate or phenetol:

$$\underset{\text{Ethylsalicylic acid.}}{C^7H^5(C^2H^5)O^3} = CO^2 + \underset{\text{Phenetol.}}{C^6H^5(C^2H^5)O}.$$

Ethylsalicylates.—The acid dissolves in cold potash- or soda-ley, forming crystallised salts soluble in water. Heated in a sealed tube with *methylic*, *ethylic*, or *amylic iodide*, it yields the ethylsalicylate of methyl, ethyl, or amyl.

Benzoic ethylsalicylate, $C^7H^4(C^7H^5O)(C^2H^5)O^3$, is produced by heating the acid with chloride of benzoyl as long as hydrochloric acid continues to escape. It is a crystalline mass, soluble in alcohol and ether, and separates from its ethereal solution by spontaneous evaporation in the form of an oil, which gradually solidifies in nodular groups of small prisms. (Gerhardt.)

ETHYL-BROMOSALICYLIC ACID, $C^7H^4Br(C^2H^5)O^3$, is produced by the action of bromine on salicylic acid in excess. It dissolves very easily in *alcohol*, and crystallises therefrom in slender needles, very much like methyl-bromosalicylic acid. (Cahours, Ann. Ch. Phys. [3] x. 341.)

ETHYL-DIBROMOSALICYLIC ACID, $C^7H^3Br^2(C^2H^5)O^3$, is produced by treating ethylsalicylic acid with excess of bromine. It crystallises in broad nacreous scales, very slightly soluble in cold, moderately soluble in boiling alcohol. It melts at a rather low temperature, and solidifies on cooling in a mass similar to crystallised bismuth; by fusing about 10 or 15 grammes of it, large well-defined cubes may be obtained. When slowly heated, it volatilises almost without residue. It dissolves in strong caustic *potash*, and is precipitated therefrom unaltered by acids. *Ammonia* ultimately dissolves it, forming dibromosalicylamic acid. (Cahours, Ann. Ch. Phys. [3] x. 364.)

ETHYL-DICHLOROSALICYLIC ACID, $C^7H^3Cl^2(C^2H^5)O^3$, **is produced by passing** chlorine into ethylsalicylic acid heated over a water-bath. The solidified mass obtained at the end of the reaction is purified by pressure between bibulous paper, and one or two crystallisations from alcohol, whence it is deposited on cooling in small, colourless, shining plates. (Cahours, Ann. Ch. Phys [3] xxvii. 461.)

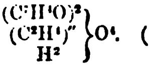
ETHYL-NITROSALICYLIC ACID, $C^9H^9NO^5 = C^7H^4(C^2H^5)(NO^2)O^3$. (Cahours, Ann. Ch. Phys. [3] x. 362.)—When fuming nitric acid is gradually added to ethylsalicylic acid, which is kept cool, a red liquid is formed, from which water throws down a heavy oil, solidifying after a while in a crystalline mass. The oil sometimes remains liquid for several days, but immediately solidifies if a few drops of ammonia are added to saturate the free acid. When the solid mass is repeatedly washed with cold water and dissolved in hot alcohol, the solution yields by evaporation yellow silky crystals, which must be repeatedly recrystallised.

Ethyl-nitrosalicylic acid forms yellowish needles, very much resembling the methyl-compound. It melts in boiling water, and solidifies again on cooling. Heated with *potash* or *soda*, it yields nitrosalicylic acid and alcohol. It is not immediately dissolved by *ammonia*, but when left in contact with it in a closed vessel, it gradually dissolves, forming nitrosalicylamic acid and alcohol.

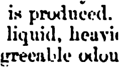
The acid dissolves in cold *potash* or *soda*, forming an ethyl-nitrosalicylate of the alkali-metal.

ETHYL-DINITROSALICYLIC ACID, $C^9H^8N^2O^7 = C^7H^3(C^2H^5)(NO^2)^2O^3$. (Cahours, Ann. Ch. Phys. [3] xxv. 19; xxvii. 462.)—When dinitrosalicylic acid is dissolved in absolute alcohol, and dry hydrochloric acid gas passed into the boiling solution, the liquid evaporated to one-half, and water added, a heavy oil is thrown down which soon solidifies; and if this oil be washed several times with water, and then dissolved in boiling alcohol, the solution on cooling yields crystals of ethyl-dinitrosalicylic acid. The same product is obtained by treating ethylsalicylic acid with nitric and sulphuric acids, in the same manner as methylsalicylic acid is treated for the preparation of methyl-dinitrosalicylic acid (p. 164).

Ethyl-dinitrosalicylic acid forms beautiful yellowish-white scales and plates. It melts at a gentle heat, and solidifies again in the crystalline form on cooling. After being heated for some time, it remains liquid for a considerable time on cooling, and then solidifies in the form of a resin. It forms soluble crystallisable salts with the alkalis. When boiled with *potash*, it is resolved into alcohol and dinitrosalicylic acid.



Ethylene-salicylic acid, $C^{16}H^{14}O^6 = \left.\begin{matrix}(C^7H^4O)^2\\(C^2H^4)''\\H^2\end{matrix}\right\}O^4$. (L. Gilmer, Ann. Ch. Pharm. cxxiii. 277.)—Produced by heating bromide of ethylene with dry salicylate of silver. After purification, it forms white needles, having a fatty lustre, melting at 83°, insoluble in water and in caustic alkalis, soluble in *alcohol*, and precipitated therefrom by ether (Gilmer). According to A. Mayer, on the contrary (Zeitschr. Ch. Pharm. 1864, p. 612), it is more soluble in ether than in alcohol. The laminæ resulting from the first crystallisation are converted by recrystallisation into large colourless or yellowish prisms (Mayer). The compound heated with *pentachloride of phosphorus* gives off hydrochloric acid, phosphoric oxychloride, and chloride of ethylene, and leaves a residue exhibibiting the characters of salicylic anhydride. (Gilmer.)



Amylsalicylic acid, $C^{12}H^{16}O^3 = \left.\begin{matrix}(C^7H^4O)''\\C^5H^{11}\\H\end{matrix}\right\}O^2$. (Drion, Ann. Ch. Pharm. xcii. 513.)—Produced by the action of salicylic chlorohydrate on amylic alcohol. It is necessary to operate on small quantities only: otherwise the action becomes too violent, and a large quantity of phenol is produced.

It is a colourless strongly refracting liquid, heavier than water, and insoluble therein, boiling at 270°, and having an agreeable odour. With cold potash-ley, it forms amylsalicylate of potassium. (Drion.)

When boiled with potash, it yields amylic alcohol and salicylate of potassium.

Heated with *chloride of benzoyl*, it gives off hydrochloric acid, and yields a body which crystallises in needles (benzoic amylsalicylate? Gerhardt); according to Drion, it yields a viscid mass, which does not readily solidify.

SALICYLIDE, $C^7H^4O^2$.—The anhydride of salicylic acid (p. 160).

SALICYLIMIDE, $C^7H^5NO = \left.\begin{matrix}(C^7H^4O)''\\H\end{matrix}\right\}N$. (Limpricht, Ann. Ch. Pharm. xcviii. 261.)—Produced by the action of heat on salicylamic acid (p. 150). The residue, obtained by heating the acid to 270°, is washed with cold alcohol, to remove undecomposed salicylamic acid; it then forms a yellow powder, which under the microscope appears to consist of crystalline needles. Does not melt at 200°. It is coloured purple by ferric chloride.

Salicylimide is insoluble in water and in aqueous ammonia, but is dissolved by *alcoholic ammonia*, forming a yellow solution, which, when evaporated, leaves the compound apparently unaltered. Acids decolorise the solution; acetate of lead forms in it a white, nitrate of silver a yellowish, and sulphate of copper a slight greenish precipitate. It is nearly insoluble in boiling *alcohol* and *ether*.

SALICYLOL, $C^7H^6O^2 = (C^7H^4O)''\left\{\begin{matrix}H\\HO\end{matrix}\right.$ *Salicylous Hydride. Hydric Salicylite. Salicylous acid. Hydride of Salicosyl* (incorrectly *Hydride of Salicyl*). *Volatile Oil of Spiræa.* (Pagenstecher, Ann. Ch. Phys. [2] lxix. 331.—Löwig, Pogg. Ann. xxxv. 383.—Piria, Ann. Ch. Pharm. xxix. 300; xxx. 153; lxxxi. 245.—Dumas, *ibid.* xxix. 306.—Löwig and Weidmann, Pogg. Ann. xlvi. 57.—Ettling, Ann. Ch. Pharm. xxix. 309; xxxv. 241; liii. 77.—Wöhler, *ibid.* xxxix. 121.—Marchand, J. pr. Chem. xxvi. 394.—Bertagnini, Ann. Ch. Pharm. lxxxv. 193.)—This compound, intermediate between salicylic acid, $(C^7H^4O)''\left\{\begin{matrix}HO\\HO\end{matrix}\right.$, and the unknown salicylic aldehyde, $(C^7H^4O)''\left\{\begin{matrix}H\\H\end{matrix}\right.$, was formerly regarded as salicylous hydride, or hydride of salicosyl, $C^7H^5O^2.H$. It was discovered in 1835 by Pagenstecher, who obtained it by distilling the flowers of meadow-sweet (*Spiræa Ulmaria*) with water. It appears, however, not to exist ready-formed in these flowers, as it cannot be extracted therefrom by alcohol (Dumas). It is obtained also from the green parts and the rootstock of *Spiræa Ulmaria*; from the green parts of *Sp. digitata*, *Sp. lobata*, and *Sp. filipendula*, but not from the shrubby spiræas (Wicke, Ann. Ch. Pharm. xci. 374); also from the warty secretion of the larvæ of *Chrysomela populi* (Liebig, Schweizer), and, according to Enz (Jahresb. 1859, p. 312), from the beetles themselves by distillation with water.

Artificial formation.—1. By the dry distillation of quinic acid (Wöhler).—2. By the oxidation of saligenin, either in the free state or as contained in salicin or populin; therefore by the action of potassic chromate and sulphuric acid (Piria), or of aqueous osmic acid (Buttlerow, J. pr. Chem. lvi. 278) on saligenin, salicin, or populin, or by the action of bromine or iodine on salicin in water containing potash (Lefort). From saligenin, $C^7H^8O^2$, it is formed by direct oxidation; and as salicin is a glucoside of saligenin (p. 147), and populin has the composition of benzoylsalicin, its formation from these bodies is likewise easily intelligible.—3. By the fermentation of salicin (Ranke, J. pr. Chem. lvi. 1).—4. In the decomposition of helicin (iii. 139), by fermentation, by acids, or by heating with alkalis.

Preparation.—1. From the flowers of *Spiræa Ulmaria*. These flowers distilled with water yield an essential oil, consisting of salicylol mixed with a hydrocarbon having the composition of turpentine-oil, and a camphor-like substance which solidifies at ordinary temperatures. On neutralising this distilled liquid with potash, evaporating nearly to dryness to expel the hydrocarbon (this part of the operation being performed in a retort to keep out the air), then slightly supersaturating the residue with phosphoric acid, and distilling, salicylol passes over, partly as aqueous solution, partly in oil-drops. It may be further purified by repeatedly agitating the last distillate with ether, shaking up the decanted ethereal solution with potash, supersaturating the potash solution with phosphoric acid, and distilling. (Löwig, *Lehrbuch*, ii. 747.)

2. From *salicin*, by oxidation with chromic acid. The best proportions, according to Ettling, are 3 pts. salicin, 3 pts. acid chromate of potassium, 4½ pts. strong sulphuric acid, and 36 pts. water. The potassic chromate is intimately mixed with the salicin; about ⅔ of the water is poured upon the mixture, which is then well agitated in the retort; the whole of the sulphuric acid, diluted with the remainder of the water, is then poured in at once, and the agitation is repeated. A slight evolution of gas then takes place, lasting for half or three-quarters of an hour, the liquid at the same time becoming heated to between 60° and 70°, and assuming an emerald-green colour. As soon as this reaction has ceased, the liquid must be moderately heated. Salicylol then passes over, and condenses in the receiver in the form of a heavy oil, its formation being accompanied by the evolution of carbonic anhydride and formic acid. The distillation is continued till the condensed water is no longer milky. The salicylol dissolved in the water may be extracted by agitating with ether, and evaporating the ethereal solution. The residue in the retort is a solution of chrome-alum, on the surface of which there usually floats a resinous matter, resulting from the decomposition of part of the salicylol. 250 grms. of salicin thus treated yield about 60 grms. of salicylol.

The aqueous extract of willow-bark may also be used instead of pure salicin for the preparation of salicylol. The salicylol thus obtained is purified by combining it with an alkali, concentrating the solution, and distilling it with dilute sulphuric acid.

Properties. Salicylol is a colourless or reddish oil, having a pleasant aromatic odour, like that of bitter-almond oil, and an acrid burning taste. It turns red on exposure to the air, but may be rendered colourless again by a single distillation. Specific gravity = 1·173 at 13·3°. Boiling point, 196·5° (Piria), 182° (Ettling). Vapour-density, obs. = 4·276; calc. = 4·225. It solidifies at − 20°, is inflammable, and burns with a bright but smoky flame.

Salicylol dissolves with moderate facility in *water*; its solution has no action upon litmus; it is coloured deep violet by *ferric salts*. *Alcohol* and *ether* dissolve it in all proportions. The solutions have no action in polarised light.

Salicylol decomposes *alkaline carbonates*, even in the cold. Caustic alkalis dissolve it, with formation of salicylites. When heated with *hydrate of potassium*, it is converted into salicylate of potassium, with evolution of hydrogen:

$$C^7H^6O^2 + KHO = H^2 + C^7H^5KO^3.$$

Ammonia converts it into hydrosalicylamide (iii. 218):

$$3C^7H^6O^2 + 2NH^3 = C^{21}H^{18}N^2O^3 + 3H^2O.$$

By *chlorine* it is converted into chlorosalicylol; by *bromine* into bromosalicylol. *Iodine* dissolves in salicylol without alteration: *nitric acid* converts it into nitrosalicylol; by prolonged boiling with nitric acid, it yields picric acid and carbonic anhydride. Boiled with *hydrochloric acid* and *chlorate of potassium*, it yields perchloroquinone and carbonic anhydride (Hofmann):

$$C^7H^6O^2 + 5Cl^2 + O^2 = C^6Cl^4O^2 + 6HCl + CO^2.$$

By boiling with *acid chromate of potassium* and *dilute sulphuric acid*, it is partly converted into salicylic acid (Ettling). It is likewise oxidised to salicylic acid by boiling with *cupric oxide* in alkaline solution, a precipitate of cupric oxide being formed at the same time. It also reduces *oxide of silver*. When exposed to the vapour of *sulphuric anhydride*, it is converted into a neutral insoluble body, isomeric with salicylol, and related to it in the same manner as benzoin to bitter-almond oil.

COMPOUNDS AND DERIVATIVES OF SALICYLOL.

Salicylol, as already observed, is intermediate in composition between salicylic acid and salicylic aldehyde; and accordingly it forms, on the one hand, salts called salicylites, by exchange of its typic hydrogen for metals, *e.g.* $(C^7H^4O)''\left\{\begin{matrix}K\\HO\end{matrix}\right.$, and, on the other hand, crystalline compounds with acid sulphites of alkali-metals.

These latter compounds are obtained either by direct combination, or by the action of sulphurous anhydride on the salicylites of the alkali-metals:—*Ammonium-salt.*—An aqueous solution of acid sulphite of ammonium easily dissolves salicylol, forming a yellow oily liquid, which after some hours solidifies to a crystalline mass. The product dissolves in hot water, and separates on cooling in shining slightly yellow needles. When exposed to the air for some days, it changes to a brown viscous mass, having a very bitter taste.

Potassium-salt, $C^7H^6O^2.KHSO^3$.—Salicylol shaken up with an aqueous solution of acid potassic sulphite of 28° Bm., dissolves without colour; and the saturated solution solidifies in a few seconds, forming a white inodorous crystalline mass, which may be recrystallised from alcohol. When dry sulphurous anhydride is passed into a cold saturated alcoholic solution of potassic salicylite at a temperature between 40° and 50°, till the yellow colour disappears, and the liquid is then left at rest, it soon becomes filled with slender needles arranged in spherical groups. The compound is white, with a pearly lustre, and a faint odour of salicylol. It dissolves abundantly in cold water, easily in warm alcohol, less easily in cold alcohol. When heated, it gives off sulphurous anhydride and salicylol, leaving a residue of potassic sulphite, which afterwards changes to sulphate. The aqueous solution, when heated, soon becomes turbid, and deposits salicylol; heated with acids, or mixed (even in the cold) with alkalis or alkaline carbonates, it turns yellow, and yields a salicylite. The solution takes up iodine, at first without coloration; when it begins to show colour, the whole of the sulphurous acid is converted into sulphuric acid, and the salicylol is set free. With bromine the solution forms sulphuric acid and bromosalicylol. (Bertagnini.)

Sodium-salt.—A solution of acid sodic sulphite, agitated with a large quantity of salicylol, solidifies to a white crystalline mass, the solution of which in hot water deposits, on cooling, shining crystals, having a sulphurous taste and odour, soluble in pure water; also, with partial decomposition, in boiling alcohol. (Bertagnini.)

Metallicderivatives of Salicylol. Salicylites, $C^7H^5MO^2 = (C^7H^4O)''\left\{\begin{matrix}HO\\M\end{matrix}\right.$ and $C^{14}H^{10}M''O^4 = (C^7H^4O)^2\left\{\begin{matrix}(HO)^2\\M''\end{matrix}\right.$.—These compounds are obtained by the action of salicylol on metallic oxides and hydrates. The salicylites of the alkali-metals are moderately soluble in water; most of the others are insoluble. They are yellow, and contain water of crystallisation. The solutions colour ferric salts violet. In the moist state they quickly decompose, emitting the odour of roses, and turning brown, and ultimately black.

Salicylites of Ammonium.—The *neutral salt*, $C^7H^5(NH^4)O^2$, is obtained by agitating salicylol with strong aqueous ammonia at a gentle heat, and crystallises on cooling in yellow needles. It is slightly soluble in cold water, still less in alcohol; melts at 115°, and volatilises without alteration at a higher temperature. When kept in the moist state in a closed vessel, it gradually decomposes; blackens, becomes semifluid, gives off ammonia, and acquires a very penetrating odour of roses. The alcoholic solution, evaporated with excess of ammonia, yields golden-yellow needles of hydrosalicylamide (Ettling, iii. 219). When macerated with potash or soda, it gives off ammonia only after some time, or when heated. Acids decompose it immediately, separating salicylol. It decomposes the metallic salts of the stronger acids, yielding the ammonium-salt of the acid, and a salicylite of the metal (Löwig and Weidmann). An *acid salicylite of ammonium* is obtained by dissolving the neutral salt in warm water, and adding salicylol; it crystallises, on cooling, in groups of slender, transparent, yellow needles. (Berzelius, *Lehrb.* iv. 350.)

Salicylites of Potassium: α. Neutral, $C^7H^5KO^2$.—1. Potassium dissolves in aqueous salicylol with evolution of hydrogen, forming salicylite of potassium (Löwig).—2. When salicylol is mixed with potash-ley of about 45° Bm., the whole solidifies to a yellow crystalline mass, which separates from the excess of potash-ley; it must be quickly pressed between bibulous paper, and dissolved in a small quantity of hot absolute alcohol, whence the salt crystallises on cooling (Piria).—3. Salicylol is dissolved in three times its bulk of 50 per cent. alcohol, and caustic potash-solution is added till the mass becomes solid; 1 vol. more of the same alcohol is then added, and the whole gently warmed till the solid mass is dissolved. The crystals, which separate on cooling, are washed with a small quantity of cold strong alcohol, whereby they are rendered lighter, then pressed between bibulous paper, and immediately dried *in vacuo* over oil of vitriol (Ettling).—The salt crystallises in small straw-coloured prisms (Löwig); golden-yellow square tables, with a pearly lustre, and unctuous to the touch (Piria, Ettling). It is slightly soluble in water, and has an alkaline reaction. According to Piria, it contains water of crystallisation, which cannot be completely expelled. At 100° it assumes a dark straw-yellow colour, and gives off 10·72 per cent. water (calc. 10·17); and no more at 120°.

It is permanent at ordinary temperatures when dry, but decomposes quickly in the moist state, yielding acetic and melanic acids (iii. 867). When heated, it decomposes with appearance of fire, but without separation of charcoal. (Löwig.)

β. Acid salt, $C^7H^5KO^2.C^7H^6O^2$.—Salicylol is added to the solution of *α* in hot alcohol, till a sample of the liquid on cooling no longer yields tables, but specular crystals; it is then left to cool slowly, and the resulting crystals are washed till the yellow colour disappears. White needles united in tufts, somewhat less alterable than the neutral salt in moist air; decomposes with water into the neutral salt and salicylol. (Ettling.)

Salicylites of Sodium.—The *neutral salt* resembles neutral salicylite of potassium.—The *acid salt*, $2(C^7H^5NaO^2.C^7H^6O^2).H^2O$, prepared like the corresponding potassium-salt, crystallises more readily in slender white needles, which are permanent in the air. At 100° it gives off only 0·007 per cent. water; at 135°, *in vacuo*, 4·036 per cent., and at 140° 4·35 per cent. It bears a temperature of 150° without decomposition, but decomposes at higher temperatures, giving off salicylol. (Ettling.)

Salicylite of Barium, $C^{14}H^{10}Ba''O^4.2H^2O$, separates as a yellow crystalline powder, when chloride of barium is poured into a concentrated solution of potassic salicylite. A hot solution of baryta saturated with salicylol, and left to cool, deposits the same salt in yellow needles. It contains 8·6 per cent. water, which it gives up at 160° in a current of dry air.—The *strontium-* and *calcium-salts* are sparingly soluble.—The *magnesium-salt* is obtained by agitating aqueous salicylol with hydrate of magnesium, as a light-yellow, nearly insoluble powder.

Cupric Salicylite, $C^{14}H^{10}Cu''O^4$, is easily obtained by agitating a cold solution of salicylol in 50 or 60 times its volume of alcohol, with aqueous cupric acetate. The liquid then assumes a fine green colour, and becomes filled, after some time, with iridescent needles of the same colour. These crystals are very slightly soluble in water and in alcohol. An additional quantity of them may be obtained by saturating the acetic acid set free in the reaction with an alkali. An aqueous solution of salicylol shaken up with recently precipitated cupric hydrate, yields a cupric salicylite in the form of a very light powder of a green colour. Cupric salicylite heated to 220° gives off salicylol, benzosalicylol, and carbonic anhydride, leaving a residue of cupric salicylate.

Salicylites of Iron.—The *ferrous salt* is obtained, as a dark-violet precipitate, on adding ammonia to a solution of ferrous chloride mixed with salicylol.—*Ferric salt.* A solution of ferric chloride, mixed with salicylol, immediately assumes a dark-violet colour. The mixture loses its colour on exposure to the air, but recovers it on a fresh addition of salicylol.

Salicylites of Lead.—*a. Neutral.* Recently precipitated hydrate of lead in contact with aqueous salicylol is converted into a light-yellow powder made up of small shining scales.—*β.* A *basic salt*, $C^{14}H^8Pb''O^4.Pb''O$, is precipitated in light-yellow grains, on mixing an alcoholic or aqueous solution of salicylol with basic acetate of lead, or with the neutral acetate and ammonia. With an alcoholic solution of salicylol, the precipitation does not take place immediately. The salt precipitated in the cold is flocculent at first, but gradually becomes crystalline. It is anhydrous.

Mercury-salt.—Mercuric oxide is not attacked by salicylol. A strong solution of mercuric chloride poured upon salicylite of ammonium forms light bulky flocks.

Silver-salt. Obtained by double decomposition, as a yellow precipitate, which soon blackens and decomposes. With very dilute solutions no precipitate is formed; but the sides of the vessel become covered, after about 24 hours, with a pellicle of reduced silver: in a hot solution this reduction takes place immediately. Aqueous salicylol reduces oxide of silver.

Zinc-salt. -Aqueous salicylol shaken up with oxide of zinc, forms a yellow solution, which, when evaporated in a vacuum, leaves a yellow pulverulent residue.

Organic derivatives of Salicylol.—These compounds are formed by the action of salicylol on the chlorides of acid organic radicles.

Acetosalicylol, $C^9H^8O^3 = C^7H^5(C^2H^3O)O^2$. *Acetosalicyl.* (Cahours, Ann. Ch. Pharm. civ. 109; cviii. 312.)—When equal volumes of salicylol and acetic chloride are heated together, the mixture becomes viscous, and evolves large quantities of hydrochloric acid; and if, when this action is over, the liquid be heated for some hours to 100° in a sealed tube, it yields, on slow cooling, brownish prismatic crystals of acetosalicylol, which may be purified by pressure between bibulous paper, and repeated crystallisation from alcohol.

Acetosalicylol is metameric with coumaric acid, $C^9H^7O^2.H.O$, and acetobenzoic anhydride, $C^2H^3O.C^7H^5O.O$. It is insoluble in water, slightly soluble in ether and in cold alcohol, more freely in boiling alcohol, from which it separates almost completely in slender needles.

Anisosalicylol, $C^{15}H^{12}O^4 = C^7H^5.(C^8H^7O^2)O^2$, is produced by treating salicylol with chloride of anisyl. (Cahours.)

Benzosalicylol, $C^{14}H^{10}O^3 = C^7H^5O^2.C^7H^5O$. *Benzosalicyl. Parasalicyl.* (Ettling, Ann. Ch. Pharm. liii. 77.—Cahours, *ibid.* lxxviii. 228; cviii. 312.)—This compound, metameric with benzoic anhydride, $(C^7H^5O)^2O$, and oreoselone, is produced: 1. By the dry distillation of cupric salicylite. On treating the oily distillate, from which crystals have already separated, with potash-ley, the benzosalicylol remains undissolved, and may be crystallised from warm alcohol or ether (Ettling).—2. By the action of benzoic chloride on salicylol. (Cahours.)

Benzosalicylol crystallises in obliquely bevelled triclinic prisms melting at 127°, and forming a pale-yellow liquid, which solidifies to a radiate mass at 98°. At 180° it sublimes in long needles, undecomposed, and without previous ebullition. It is insoluble in water, but dissolves easily in alcohol and ether; also, without decomposition, in gently-warmed sulphuric acid. Hot strong nitric acid dissolves it with evolution of nitrous vapours, and formation of picric acid. With chlorine or bromine in sunshine it forms crystalline products.

Cumosalicylol, $C^{17}H^{16}O^3 = C^7H^5.(C^{10}H^{11}O)O^2$. *Cumosalicyl.*—Produced by treating salicylol with chloride of cumyl. Crystallises in colourless prisms, resembling toluosalicylol. (Cahours.)

Succinosalicylol.—Salicylol treated with chloride of succinyl yields a compound which crystallises in colourless needles.

Toluosalicylol, $C^{15}H^{12}O^3 = C^7H^5(C^8H^7O)O^2$. *Toluosalicyl.*—Prepared by heating together equal volumes of salicylol and toluylic chloride, pressing the resulting brownish mass between bibulous paper, treating it with hot potash-ley and then with water, and crystallising from strong alcohol. It forms shining, colourless, friable, easily fusible prisms, insoluble in cold water, slightly soluble in boiling water and in cold alcohol, more easily in hot alcohol and in ether. It is not decomposed by distillation with hydrate of potassium. Forms crystallisable substitution-products with chlorine, bromine, and fuming nitric acid. (Cahours, Ann. Ch. Pharm. cviii. 312.)

Bromosalicylols. *Monobromosalicylol*, $C^7H^5BrO^2$. *Bromosalicylous Acid.* (Löwig, Pogg. Ann. xxxvi. 383.—Piria, Ann. Ch. Phys. [3] lxix. 281.—Heerlein, J. pr. Chem. xxxii. 65.)—Produced by adding bromine-water, not in excess, to an alcoholic solution of salicylol, and separates, on addition of water to the liquid, in small colourless needles. It is less fusible than the corresponding chlorine-compound, sublimable, and distils over with vapour of water. It dissolves in *alkalis*, yielding metallic bromosalicylites.

Bromosalicylol forms, with the *acid sulphites of the alkali-metals*, crystalline compounds, which are decomposed by prolonged boiling, or by heating with acids. The *potassium-salt* crystallises in small, colourless, shining needles; the *sodium-salt* in interlaced needles.

Dibromosalicylol, $C^7H^4Br^2O^2$.—Obtained by treating salicylol with excess of bromine-water. It forms long yellowish needles, insoluble in water, soluble in alcohol and in ether. With potash it yields potassic dibromosalicylite; sulphydric acid converts it into the sulphydrate of sulphodibromosalicylol. (Heerlein.)

Chlorosalicylols. *Monochlorosalicylol*, $C^7H^5ClO^2$. *Chlorosalicylous Acid.* (Löwig, Piria, *loc. cit.*)—Salicylol is strongly attacked by chlorine; and if, after the evolution of hydrochloric acid has ceased, a current of dry air be passed through the liquid, chlorosalicylol remains as a yellow crystalline body, which dissolves in boiling alcohol, and crystallises on cooling in colourless, nacreous, rectangular plates. It has an unpleasant odour and burning peppery taste; melts when heated, and sublimes in long snow-white needles; it is inflammable, and burns with a green flame. It is insoluble in *water*, but soluble in *alcohol* and *ether*. It dissolves in strong *sulphuric acid* with yellow colour, and is precipitated from the solution by water. With *ammonia* it forms hydrochlorosalicylamide, $C^{21}H^{15}Cl^3N^2O^3 = 3C^7H^5ClO^2 + 2NH^3 - 3H^2O$ (iii. 219).

Chlorosalicylol dissolves easily in *alkalis*, forming metallic chlorosalicylites. The *potassium-salt* crystallises in radiate groups of red scales. Its solution treated with chloride of barium, yields *barytic chlorosalicylite*, $C^{14}H^8Ba''Cl^2O^4.H^2O$, in the form of a yellow crystalline powder.

Chlorosalicylol dissolves easily also in the *acid sulphites of the alkali-metals*, forming crystalline compounds.

Dichlorosalicylol, $C^7H^4Cl^2O^2$? is produced, according to Löwig, by the prolonged action of chlorine on salicylol. On removing the excess of chlorine by exact saturation with ammonia, agitating the liquid with ether, and evaporating the ethereal solution, a soft red body remains, having a pungent odour, melting at 25°, and forming red salts with the alkalis and alkaline earths. It gave by analysis 39·8 per cent. carbon, 2·4 hydrogen, and 37·1 chlorine, whence Löwig supposes it to be dichlorosalicylol, the formula of which requires 44·0 per cent. carbon, 2·1 hydrogen, 37·1 chlorine, and 20·7 oxygen; but it evidently requires further examination.

Cyanosalicylol, $C^8H^5NO^2 = C^7H^5(CN)O^2$.—This compound, metameric with isatin, is produced by the action of bromide of cyanogen, dissolved in absolute alcohol, on salicylite of potassium. Bromide of potassium then separates, and the alcoholic solution yields by evaporation yellowish crystalline scales of cyanosalicylol, which is a weak base capable of uniting with acids. (Cahours, Ann. Ch. Pharm. cviii. 322.)

Iodosalicylol, $C^7H^5IO^2$?—Iodine dissolves in salicylol without alteration; but by distilling a mixture of potassic iodide and chlorosalicylol, chloride of potassium is obtained, together with a brown sublimate analogous in properties to chlorosalicylol. (Löwig.)

Nitrosalicylol, $C^7H^5NO^4 = C^7H^4(NO^2)O^2$. *Nitrosalicylous Acid. Spiroylic Acid.* (Löwig, *loc. cit.*)—Prepared by treating salicylol, at a gentle heat, with moderately strong nitric acid. It crystallises in transparent yellow prisms, slightly soluble in water, very soluble in alcohol and in ether; its solution imparts a persistent yellow stain to the skin. It melts when heated, and solidifies to a crystalline mass on cooling; sublimes partially at a higher temperature.

Nitrosalicylol dissolves easily in alkalis, forming crystallisable salts. When saturated with *ammonia*, it forms a blood-red liquid, leaving, on evaporation, a yellow residue, from which potash eliminates ammonia, even in the cold. The solution of the sodium-salt forms a yellow precipitate with *lead-salts*, a green precipitate with *cupric salts*, and imparts to *ferric chloride* a deep cherry colour. These salts explode when heated.

Nitrosalicylol unites with acid sulphites of alkali-metals. The *ammonium-salt* does not appear to crystallise. The *potassium-salt* is more soluble than the sodium-salt.—The *sodium-salt*, obtained by dissolving nitrosalicylol in a warm solution of acid sulphite of sodium, crystallises on cooling in golden-yellow interlaced needles, soluble in water, insoluble in alcohol.

Sulphosalicylol, C^7H^6OS. *Thiosalicol.* (Cahours, Compt. rend. xxv. 458.)—This body, which has the composition of salicylol in which half the oxygen is replaced by sulphur, is produced by the action of sulphydric acid on hydrosalicylamide in alcoholic solution. It is a pulverulent substance, which forms salts with the alkalis, and colours ferric salts violet-red.

Bromosulphosalicylol, C^7H^5BrOS, is obtained by the action of sulphydrate of ammonium on bromosalicylol, as a brown resinous substance, soluble in potash.—When sulphydric acid gas is passed into an alcoholic solution of dibromosalicylol and water is thus added, a resinous body is precipitated, consisting of sulphydrate of dibromosulphosalicylol, $C^7H^4Br^2SO.H^2S$.

SALICYL-SULPHURIC ACID. $C^7H^6SO^6$. Syn. with SULPHOSALICYLIC ACID.

SALICYLURIC ACID. $C^9H^9NO^4 = \left.\begin{matrix}H^2\\(C^7H^4O)''\\(C^2H^2O)''\\H\end{matrix}\right\}\begin{matrix}N\\O^2\end{matrix}$. (Bertagnini, *Il Nuovo Cimento*, i. 363.)—This acid, related to salicylic acid in the same manner as hippuric to benzoic acid (iii. 156), is found in the urine after salicylic acid has been swallowed. To prepare it, the acid urine voided after taking salicylic acid is evaporated down to 12° Bm., acidulated with hydrochloric acid, shaken up with ether, and the ether is distilled from the ethereal solution. The residue yields, by spontaneous evaporation, large crystalline nodules, which, when freed from the mother-liquor by pressure, dissolved in boiling water, and treated with animal charcoal, yield a crystalline mass, consisting for the most part of slender needles, mixed with larger needles of salicylic acid. On heating this mixture in a current of air to between 140° and 150°, the salicylic acid volatilises; and the residue, crystallised from hot water containing animal charcoal, yields pure salicyluric acid.

This body crystallises in slender, shining, crystalline needles, which when obtained from the aqueous solution are grouped concentrically. It has a somewhat bitter taste, and a strong acid reaction: melts at about 160°, and solidifies in the crystalline form. It dissolves easily in boiling water and in alcohol, less easily in cold water and in ether. The solutions colour ferric salts violet, like salicylic acid.

Decompositions.—1. Between 160° and 170°, the acid turns brown, and begins to decompose, yielding a sublimate of salicylic acid. At a stronger heat, it swells up and gives off ammonia, leaving a residue of charcoal.—2. When boiled with excess of baryta-water, it does not form any salicylate of barium; a small quantity of ammonia is, however, given off.—3. Heated for a short time with fuming hydrochloric acid, it dissolves, and crystallises out again unaltered; but if the boiling be continued for two or three hours, the acid is resolved into salicylic acid and glycocine:

$$\left.\begin{matrix}H^2\\(C^7H^4O)''\\(C^2H^2O)''\\H\end{matrix}\right\}\begin{matrix}N\\O^2\end{matrix} + H^2O = \left.\begin{matrix}(C^7H^4O)''\\H^2\end{matrix}\right\}O^2 + \left.\begin{matrix}H^2\\(C^2H^2O)''\\H\end{matrix}\right\}\begin{matrix}N\\O.\end{matrix}$$

4. When it is boiled with water and peroxide of lead, the latter is decolorised; and on boiling the solution, small shining needles separate out.

Salicylurates.—The acid decomposes carbonates. Its salts crystallise easily.

The *barium-salt* is obtained by dissolving carbonate of barium in the warm acid. As the solution cools, the salt crystallises in large hard prisms, which become opaque and give off water when heated, then melt and decompose, giving off ammonia and an oil which smells like phenol, and leaving a residue of barytic carbonate. The salt is sparingly soluble in cold water.

Calcium-salt.—*a.* When carbonate of calcium is dissolved in the aqueous acid, the solution on cooling yields aggregated needles, which are sparingly soluble in cold water, and insoluble in alcohol.—*b.* When milk of lime is added by successive small portions to the warm aqueous acid, a solution is at first obtained, which suddenly solidifies to a crystalline mass, insoluble in boiling water.

SALIGENIN, $C^7H^8O^2$, probably $= \left.\begin{matrix}(C^7H^6)''\\H^2\end{matrix}\right\}O^2$.—(Piria, Ann. Ch. Pharm. lvi. 53; lxxxi. 245.—Beilstein and Seelheim, *ibid.* cxvii. 83.—Gm. xii. 233.)—A compound produced from salicin by the action of acids and of emulsin (Piria):

$$\underset{\text{Salicin.}}{C^{13}H^{18}O^{7}} + H^{2}O = \underset{\text{Saligenin.}}{C^{7}H^{8}O^{2}} + \underset{\text{Glucose.}}{C^{6}H^{12}O^{6}}.$$

Also from salicylol, $C^{7}H^{6}O^{2}$, by the action of sodium-amalgam in presence of water. (Reinecke and Beilstein, Ann. Ch. Pharm. cxxviii. 179.)

Preparation.—1. An aqueous solution of salicin, acidulated with sulphuric or hydrochloric acid, is heated till it just boils up; the liquid is then saturated with chalk, and the filtrate shaken with ether, which takes up the saligenin. A considerable quantity of saliretin is always formed at the same time.—2. When 50 pts. of finely pulverised salicin suspended in 500 pts. of water are shaken up with 3 pts. of emulsin (ii. 486), and heated in lukewarm water to a temperature not exceeding 40°, the salicin dissolves, being decomposed in the course of 24 hours into glucose and saligenin. When no more than the prescribed quantity of water is employed, part of the saligenin crystallises out; and if the liquid be then twice shaken up with an equal bulk of ether, and the ethereal liquid evaporated over the water-bath, the residue solidifies in a white mass composed of pearly laminæ, which may be pressed between paper, and repeatedly crystallised from boiling water (Piria). Beilstein and Seelheim purify it by recrystallisation from benzene.

Properties.—Saligenin crystallises in white rhombic tables having a pearly lustre, or in small colourless rhombohedrons. By spontaneous evaporation of the aqueous solution, there is formed a white opaque mass, composed of microscopic, shining, iridescent laminæ (Piria). Specific gravity = 1·1613 at 25° (Beilstein and Seelheim). Saligenin is unctuous to the touch. In vacuo over oil of vitriol, it does not give off water, but partly volatilises, in consequence of which the oil of vitriol becomes covered with a crimson crust.—It melts when heated, forming a colourless transparent liquid, which solidifies to a crystalline crust at 82°. When heated for some time to 100°, it yields a sublimate of delicate, white, shining, iridescent luminæ.—The aqueous solution imparts a bright indigo colour to ferric salts. (Piria.)

Saligenin dissolves in 15 pts. of *water* at 22°, and in all proportions of boiling water; easily also in *alcohol* and *ether* (Piria). One part of saligenin dissolves in 52·5 pts. of *benzene* at 18°, and in a much smaller quantity at the boiling heat (Beilstein and Seelheim). The solutions do not act on polarised light. It dissolves in *ammonia*, and appears to combine with potash. The aqueous solution does not precipitate the salts of barium, calcium, copper, neutral lead-acetate, mercuric chloride, nitrate of silver, or tartar-emetic. With basic acetate of lead, it forms a scanty precipitate, of variable composition. It imparts to ferric salts a bright indigo colour, which is quickly destroyed by heat, or by the action of chlorine or acids. The alcoholic and ethereal solutions do not exhibit this colouring.

Decompositions.—1. Saligenin heated above 100° gives off aqueous vapour and salicylol. Between 140° and 150°, it becomes very viscid, and solidifies on cooling to a mass, which is less crystalline the more strongly it has been heated; and at length there is formed an amber-coloured translucent resin having the properties of saliretin.—2. Exposed to the air in contact with *platinum-black*, it is quickly converted into salicylol; at higher temperatures the same conversion is produced by mere contact with the air, or by *chromic acid*, *oxide of silver*, &c., without the formation of any other organic substance or of carbonic anhydride:

$$C^{7}H^{8}O^{2} + O = C^{7}H^{6}O^{2} + H^{2}O.$$

Mercuric oxide does not act upon saligenin.—When saligenin is heated with *sulphuric acid* and *peroxide of manganese*, carbonic anhydride and formic acid are produced, without a trace of salicylol.—3. *Chlorine gas* acts violently on dry saligenin, giving off hydrochloric acid and forming a yellow resin, which gradually turns red, and ultimately solidifies to a mass composed of small crystals, which melt and turn red when exposed to the further action of chlorine. *Bromine* acts in a similar manner.—The chief product formed by the action of chlorine gas on a concentrated aqueous solution of saligenin, is trichlorophenic acid (iv. 392).—4. With *iodine* and *phosphorus* saligenin forms a brown liquid, which appears to contain $C^{7}H^{6}O.IH$, but is very unstable (Limpricht).—5. Saligenin heated with *dilute acids*, is resolved into saliretin and water: $C^{7}H^{8}O^{2} = C^{7}H^{6}O + H^{2}O$.—6. Strong *sulphuric acid* colours saligenin deep red, like salicin.—7. Strong *nitric acid* dissolves it, with evolution of nitrous vapours and carbonic anhydride, and formation of picric acid. Dilute nitric acid converts it into salicylol, partly also into yellow crystals of nitrosalicylol (p. 172).—8. Saligenin is not perceptibly altered by *potash-ley* at ordinary temperatures, but appears to unite with it. When heated with solid *potassic hydrate*, it gives off hydrogen, and forms salicylate of potassium:

$$C^{7}H^{8}O^{2} + KHO = C^{7}H^{5}KO^{3} + 2H^{2}.$$

9. *Sodium* acts upon saligenin dissolved in pure ether, with evolution of hydrogen, and

formation of a precipitate, consisting of the sodium-compound $C^{14}H^{15}NaO^4$. A solution of saligenin in benzene reacts with sodium in a similar manner, excepting that the precipitate formed is not of constant composition (**Beilstein and Seelheim**).—10. *Pentachloride of phosphorus* converts saligenin into saliretin, with evolution of hydrochloric acid and phosphoric oxychloride (**Beilstein and Seelheim**):

$$C^7H^8O^2 + PCl^5 = 2HCl + POCl^3 + C^7H^6O.$$

—11. Saligenin is also converted into saliretin by heating to 100° with acetic anhydride and ether; also when hydrochloric acid gas is passed into a solution of saligenin in glacial acetic acid (**Beilstein and Seelheim**).—12. Saligenin is attacked by *chloride of benzoyl*, with evolution of hydrochloric acid, and formation of a compound containing $C^7H^7(C^7H^5O)O^2$, apparently analogous to the compound ethers. (**Limpricht.**)

Chlorosaligenins. These compounds are produced by the action of emulsin on the corresponding chlorosalicins (p. 149). They are all, like saligenin itself, converted into resinous matters by contact with acids.

Monochlorosaligenin, $C^7H^7ClO^2$, crystallises from hot water in pure colourless rhomboidal plates, exactly like saligenin. It dissolves in water, alcohol, and ether, turns ferric salts blue, and is changed into a resin (? *chlorosaliretin*), under the influence of acids. (**Piria.**)

Dichlorosaligenin, $C^7H^6Cl^2O^2$, and *Perchlorosaligenin*, $C^7H^5Cl^3O^2$, are produced in like manner from di- and per-chlorosalicin, but only in very small quantities. (**Piria.**)

SALIGLYCIC ACID. Syn. with SALICYLURIC ACID.

SALIRETIN. C^7H^6O. (**Piria**, Ann. Ch. Pharm. xxx. 178, 189; lvi. 45.—**Gerhardt**, Ann. Ch. Phys. [3] vii. 215.)—This body, which differs from saligenin by the elements of 1 at. water, is produced by the action of dilute acids on saligenin, or on salicin, glucose being also formed in the latter case. The transformation is effected by the greater number of acids, even in very dilute solution, provided the liquid be heated to the boiling-point. The saliretin then rises to the surface in the form of a resinous body, generally yellowish, sometimes quite white. In general, the more dilute the acid (sulphuric or hydrochloric) employed, the purer is the product obtained. It may be further purified by solution in alcohol and precipitation with water. According to Piria, 100 pts. saligenin treated with dilute hydrochloric acid, and heated to between 120° and 130°, lose 15·39 per cent. water (calc. 14·52 per cent.).

Saliretin is insoluble in water and ammonia, but soluble in alcohol, ether, and strong acetic acid, and is precipitated from these solutions by water. Potash and soda likewise dissolve it, and the solutions are not precipitated by water; but acids (even carbonic acid) separate the saliretin in the form of a white gelatinous pulp. Sulphuric acid colours saliretin blood-red. Strong nitric acid converts it at the boiling heat into picric acid, without formation of oxalic acid. By dry distillation it yields phenol, water, and a copious residue of charcoal.

SALISBURIA. The fruit of *Salisburia adiantifolia* (or *Gingko biloba*) contains, besides gum, sugar, pectin, citric acid, butyric acid, &c., 9 per cent. of a fatty oil which is extracted from it by ether. This oil is yellow, has an acid reaction, solidifies in the crystalline state at 0°, contains a fatty acid, $C^{24}H^{48}O^2$, melting at 35°, and called by **Schwarzenbach** (Jahresb. 1857, p. 529), **gingkoic acid**.—The fleshy part of the fruit contains 74·6 per cent. water, 24·3 dry organic matter, and 1·1 ash.

SALITE. Syn. with SAHLITE.

SALITHOL. Syn. with ETHYLIC PHENATE or PHENETOL (iv. 391).

SALIVA. (**Lehmann**, Lehrb. ii. 9.—**Gorup-Besanez**, *Lehrb.* 433.—**Bidder u. Schmidt**, *Verdauungssäfte*, p. 1.—**Bernard**, *Leçons Phys. Exp.* 1856, vol. ii.—**B. Eckhard**, *Beiträge*, ii. 205.—**Ordenstein**, *ibid.* p. 101.—**Oehl**, *Saliva umana*, 1864.—**Kühne**, *Lehrb. Phys. Chem.* p. 1.)

Several organs—viz., the parotid, submaxillary, sublingual, and buccal glands—pour into the mouth their respective secretions, which, mixed together, form what is called mixed saliva, or briefly saliva.

Parotid Saliva, or the secretion of the parotid gland, may readily be obtained by canalization of the Stensonian duct. The quantity secreted by one gland, in man, has been estimated, for the 24 hours, at 1·4 grm. per kilo of body-weight (**Oehl**). The first drops, obtained after introducing the tube, are turbid and acid, probably from decomposing epithelium; the secretion afterwards flows clear and alkaline. On standing, it becomes turbid, with deposition of carbonate of calcium, probably owing to escape of carbonic acid. **Oehl** states that the fluid, as it escapes from the tube, is often acid, especially when the subject is fasting; he also maintains, that transparency belongs to the acid secretion only, an alkaline or a neutral saliva being always turbid, even as it flows from the tube. There are no special morphotic constituents. Specific gravity (man) 1·0031—1·0043; solid residue, ·571—·616 per cent. Bidder and Schmidt found, in the dog, in 1000 pts. water, 995·3, solids 4·7, of which organic matters 1·4, salts 3·3 (potassic and sodic chlorides 2·1, calcic carbonate 1·2). Parotid saliva is free from mucin, contains a very small quantity of globulin, and a larger but still small amount of albumin. In the horse, Bernard found a material separable by saturation with magnesian sulphate (? globulin). In man, sulphocyanate of potassium is invariably (?) found (to the extent of ·03 per cent.) (Oehl). Bromides and iodides pass readily from the blood into saliva, apparently being substituted for the chlorides, which are proportionately lessened.

Submaxillary Saliva, which flows into the mouth through the Whartonian duct, is a generally transparent, but sometimes turbid, and always more or less viscid fluid, of distinct alkaline reaction, and of very variable specific gravity. Bidder and Schmidt found in the dog, in 1000 pts.—water, 991·45; solids, 8·55: of which organic matters 2·89, salts 5·66 (potassic and sodic chlorides 4·50, calcic and magnesian carbonates and phosphates 1·16). When obtained by canalization, it is limpid as it flows from the tube, but almost immediately becomes viscid. Besides mucin, to which constituent the viscidity is due, it contains a small quantity of globulin and of albumin. In man, according to Oehl, it gives faintly the reactions of sulphocyanate of potassium.

The submaxillary gland is subject to the influence of different systems of nerves, and the quality of the secretion depends on the kind and degree of nervous action set going. Excitation of the *chorda tympani*, and excitation of the *sympathetic* nerve belonging to the gland, produce two distinct kinds of saliva. The chorda-saliva is transparent, distinctly alkaline, free from morphotic constituents, moderately viscid, of specific gravity 1·0039—1·0056, and yields 1·2—1·4 per cent. solid residue. The sympathetic saliva is always turbid or opaque, extremely viscid, and contains peculiar gelatinous microscopical masses, of variable size. There are also other varieties of submaxillary saliva, which have not as yet been closely studied.

Sublingual Saliva is alkaline, exceedingly viscid, with a solid residue of 9·98 per cent., and contains sulphocyanate of potassium.

Buccal Saliva, or *Oral Mucus*, obtained by ligaturing the ducts of all the other salivary glands, is very viscid, and abounds in morphotic constituents—viz. epithelium, with mucus, and the so-called salivary corpuscles. In 1000 pts. Bidder and Schmidt found 9·98 solid residue, of which organic matters 3·84, inorganic matters 6·13.

Mixed Saliva varies in its qualities, according as one or other of its component secretions preponderates. It is generally alkaline, but sometimes acid, probably from acid fermentation of saccharine aliment retained in the cavities and folds of the mouth. The total quantity secreted in the 24 hours varies exceedingly; Bidder and Schmidt calculate it, for man, at 1400 grms.; Lehmann at 473 grms.

Uses of Saliva.—By virtue of its fluidity and viscidity, saliva is of great assistance in mastication and deglutition. Animals, when the ducts of the salivary glands are ligatured, chew and swallow with great difficulty.

When raw starch is exposed at 35° to human saliva, frequently renewed, the starch-granulose is after a while dissolved, and finally converted into dextrin and sugar. Boiled starch treated in the same way is almost instantaneously converted into dextrin and sugar.

In man, parotid and submaxillary saliva, or infusions of the respective glands, possess equally with mixed saliva this power over starch. In the dog, the sympathetic submaxillary saliva alone acts on starch, and that very feebly (Kühne). In the pig, rabbit, and guinea-pig, infusions of the salivary glands, and probably also their secretions, are as energetic as in man. In the horse, the ox, the sheep, and the cat, the secretions and glandular infusions are entirely or almost entirely inactive. In man the change effected by saliva on boiled starch is sufficiently rapid to allow of a considerable production of sugar during the act of mastication. But it is evident that in many animals the saliva can have no such function.

Ptyalin.—This action of saliva on starch is not due to the morphotic elements, to mucus, to the globulin, or to the other albuminoid constituents, but seems to belong to a special "active principle" or "ferment," for which the name ptyalin may be profitably reserved. If saliva be treated, first with dilute phosphoric acid, and then with lime-water, the bulky precipitate of phosphate of calcium carries down with it the greater part of the ferment, together with albumin. If the separated deposit be agitated with distilled water, it gives up the ferment but not the albumin: hence by filtration a clear liquid is obtained, acting powerfully on starch, but free from albumin. From this the ferment may be precipitated by alcohol, forming, when carefully dried, an amorphous powder (mixed with phosphates), containing nitrogen, but not exhibiting the xanthoproteic reaction. (Cohnheim.)

Ptyalin is most active in a neutral or faintly alkaline solution; the addition of an acid, or an alkali, first delays, then arrests, and finally destroys its action. It is most active at a temperature of about 35°; its properties are wholly destroyed when its solution is boiled. The presence of an excess of glucose hinders its action.

M.F.

SALLOW-THORN, or **SEA-BUCKTHORN.** *Hippophaë rhamnoides* (ii. 155).

SALMIAC. Syn. with SAL-AMMONIAC, or CHLORIDE OF AMMONIUM.

SALMONIC ACID. *Salmsäure. Lachssäure.*—A reddish fatty acid, existing, according to Frémy and Valenciennes (J. Pharm. [3] xxviii. 401), in the reddish muscles of various species of salmon, most abundantly in *Salmo salmo* and *S. hamatus*.

SALSAPARILLIN, or **SALSEPARIN.** Syn. with SARSAPARILLIN.

SALSOLA. A genus of chenopodiaceous plants, growing on the seashore, and generally on soils rich in common salt. They yield a large quantity of ash, chiefly consisting of sodic carbonate, on which account several species (*Salsola Kali, S. Soda*, &c.) are cultivated for the preparation of natural soda, or barilla. *Salsola Soda* is cultivated for this purpose chiefly in Spain, near Alicante.

The ashes of several species of salsola from the Kirghis Steppe, have been analysed by Göbel (*Reise in die Steppen des südlichen Russlands*, Dorp. 1837 and 1838; *Handw. d. Chem.* vii. 204). The young plants of *Salsola brachiata*, air-dried, yielded 30 per cent. ash, of which 66·5 per cent. was soluble in water; older plants gave only 18 per cent. ash, containing 63·5 per cent. of soluble salts. Young plants of *S. clavata* gave 42 per cent. ash, of which 74 per cent. was soluble; young plants of *S. lanata* gave 19·0 per cent., of which 38 per cent. was soluble in water. Old plants of *S. laricina* gave 7·0 per cent. ash, containing 44·5 per cent. of soluble salts; old plants of *S. tamariscina* 9·3 per cent. ash, containing 45 per cent. soluble salts.

SALT. Sodic chloride, *sea-salt*, or *common salt*, the substance which is always denoted when the word "salt" (Gr. ἅλς, Lat. *sal*, Fr. *sel*, Germ. *Salz*) is used without qualification in ordinary language, was doubtless the first body to which this name was given. The word salt itself, in its Greek form, sufficiently establishes this fact,—ἅλς in the feminine being used for the sea, and ἅλς in the masculine for the solid product left when sea-water evaporates. In endeavouring to trace some of the most important of the steps by which this word, from having been the specific name of a particular substance, has come to be used as a generic term of wider application than any other in the whole vocabulary of chemistry, we find that the first extension of its meaning was in connection with the leading idea which the etymology of the word shows to have been attached to it from the beginning. This idea evidently was very nearly what would have been expressed, in the language of a later time, by saying that sea-salt was the essence, or essential principle, of sea-water. Accordingly, when it was observed that other watery liquids yielded, under the same conditions as sea-water, a solid substance, not very unlike sea-salt in appearance, the name salt was applied to these substances also. Thus, according to Kopp (*Geschichte der Chemie*, iii. 2), Aristotle calls the residue deposited on cooling by the evaporated lixivium of wood-ashes, salt, and Dioscorides and Pliny enumerate as one of the kinds of salt, mild fixed alkali; some other allied substances also bore the same name. But, as Kopp very judiciously points out, this extension of the name salt to other bodies than that to which it was first applied, indicated ignorance of the real differences of these bodies, rather than any clear perception of analogies among substances recognised as distinct. The use of the term was, however, such as to show, clearly enough, that the notion which it originally conveyed was that of a soluble solid substance produced from a watery liquid by evaporation.

This original idea of solubility, as the most characteristic property of saline or salt-like substances, retained its ground down to the times of the alchemists; but, as the different bodies to which the common name of salt was applied came to be more accurately distinguished from each other, it became necessary to adopt for them distinctive appellations; and thus in the writings of Albertus Magnus, Raymund Lully, and their contemporaries of the thirteenth century, occur such specific names as *sal marinum*, *sal petræ* or *sal nitri*, *sal ammoniacum*, *sal vegetabile* (potashes), &c. All the substances denoted by these names have been ever since classed as salts: but that the ideas attached to the word salt, at the period referred to, were very vague and indefinite, is shown by the fact that all the then known metallic salts, a class of compounds which possess, in as marked a degree as any, the characters now recognised as saline, were denied the name of salts by Basil Valentine (in the latter part of the fifteenth century), and classed together as vitriols. There can be no doubt, however, that this arbitrary distinction, as it seems to us, between metallic salts and other salts, was in harmony with the chemical ideas generally prevailing at the time. For the alchemists, the main problem presented by chemistry was the study of the metals, just as for Lavoisier and his school it was combustion, and for Berzelius it was the quantitative composition of mineral salts as illustrating the doctrine of definite proportions. Hence it is not surprising that substances either produced from metals, or from which metals could be obtained, should have been regarded by the alchemists as of an essentially different nature, and, so to speak, as possessing a higher rank than the substances known to them as *salts*. Accordingly, this separation was generally maintained as long as alchemy held its ground, but was abandoned as wider views grew up in the science; and even during the alchemical period it was not recognised by those chemists who were not alchemists. Thus Bernard Palissy, in a tract, "*Des Sels divers et du Sel commun*" published in 1580, classed together as salts, common salt, saltpetre, the vitriols, alum, borax, sugar, corrosive sublimate, tartar, and sal-ammoniac. (See *Life of Bernard Palissy of Saintes*, by Henry Morley, London, 1855, pp. 96, 97.)

The most important modification which the original idea of a salt underwent, before the beginning of the eighteenth century, was that it implied a substance not only possessed of solubility, but capable of affecting the sense of taste. It is not clear at what period the latter property began to be generally recognised as an essential character of salts, but it was commonly received as such in the sixteenth century. In making the possession of taste an essential quality of salts, chemists were evidently led by the analogy of chloride of sodium, the original salt, whose remarkable flavouring power has been a chief cause of its common employment from the earliest ages. ("Can that which is unsavoury be eaten without salt?"—Job vi. 6.) During all this period, therefore, all that seems to have been implied, when this or that particular substance was called a salt, was that some undefined degree of resemblance in external qualities, especially in the two just mentioned, was perceived between it and common salt; and it is probable that the notion which underlay the application of the same name to these various compounds, was rather that of their being modifications of a single fundamental substance than radically distinct though analogous bodies.

But during the latter part of the fifteenth, the whole of the sixteenth, and a great part of the seventeenth centuries, the term salt was used not only in the sense that has been explained, as a generic name for certain definite preparable substances, but also in a much more abstract sense, as the name of one of the supposed ultimate elements of all material things.

Thus, according to Basil Valentine, all inorganic substances were made up of salt, sulphur, and mercury; and Paracelsus (in the early part of the sixteenth century) declared that the same three substances were the elements of all bodies, organic as well as inorganic—a doctrine which was adopted by a great many succeeding chemists. And until the rise of analytical chemistry, and the foundation of the modern views of the nature of the chemical elements by Boyle in the latter part of the seventeenth century, salt was almost always enumerated as one of the elements, although opinions varied considerably as to the others.

In order to understand this use of the word salt, it is needful to remember that the idea of an "element," at the period we are referring to, was very different from that which is expressed by the same word now. It had much less reference to *composition*, as now understood, than to what were supposed to be the intrinsic and fundamental *properties* of material bodies. The principles recognised as elementary by the chemists of that age, differed both in name and in attributes from the elements admitted by the Greeks; nevertheless, the notion of an element was still essentially of the same quality as that acted upon by Aristotle, when he selected as elements Fire, Water, Air, and Earth, on the ground that they appeared to him the most distinct embodiments of Heat and Cold, Dryness and Moisture, which he regarded as the fundamental qualities of matter. Accordingly, when we find salt spoken of as one of the elements, and as a constituent of all manner of substances—as it is, for instance, by Palissy in the treatise already referred to: "I tell you further, that there is nothing in this world which has no salt in it, whether it be in man, the beast, the trees, plants, or other vegetative things, or even in the very metals, &c."—we are not to understand the statement as we should if it were made by a modern chemist, but should rather take it as implying that saline properties (solubility and taste) were supposed to belong in some degree to all substances. In particular, the notion that salt was a constituent of the metals was clearly nothing more than the theoretical conception, in accordance with the general modes of thought prevailing at the time, which corresponded to the known fact that by various processes the metals could be actually transformed into salts; for the conversion, say, of iron into green vitriol, was not then regarded as a process of combination of iron with other substances, but simply as a process in which iron was modified in such a manner as to allow its previously latent saline qualities to be manifested.

The name salt being applied to all substances which were soluble and possessed of taste, included some which differed greatly in other properties. Thus, in addition to neutral salts, it included the acids and alkalis. As the properties of these two classes of bodies became known, it was gradually recognised that they were in many respects antagonistic, and especially that, by their action upon each other, their distinguishing characters were more or less completely obliterated, new and comparatively indifferent substances being generated. These observations led to the subdivision of salts into three classes, variously distinguished by different chemists. From about the year 1700, the names by which the three classes of salts were generally indicated were *salia acida*, *salia alcalina*, and *salia salsa*, *salia media*, or *salia neutra*.

The relation which had thus been already partially perceived between acids, alkalis, and neutral salts, was made by G. F. Rouelle, in 1744, the basis of a general theory of salts, which closely approximated to that very generally adopted in quite recent times. The importance of the step made by Rouelle was such as to make it desirable to state his views in his own words. In the introduction to a paper on Salts in the Memoirs of the Academy of Sciences of Paris, for the above-mentioned year (*Mém. Acad. Roy. Sciences*, 1744, p. 353), he says: "La plûpart des chymistes ne donnent le nom de sel neutre, moyen ou salé, qu'à un très-petit nombre de sels; il y en a même eu qui n'ont donné ce nom qu'au seul tartre vitriolé, demandant pour caractère de ces sels que l'acide et l'alcali qui les forment soient tellement unis qu'ils résistent à toute décomposition; d'autres ont admis avec le tartre vitriolé les deux sels neutres formés par l'union des acides du sel marin et du nitre à des bases alcali fixes, tels sont le sel marin et le nitre; d'autres y joignent trois autres sels formés par l'union des trois acides à un alcali volatil, qui sont le sel ammoniacal secret de Glauber ou le sel ammoniacal vitriolique, le sel ammoniacal ordinaire, et le sel ammoniacal nitreux; il y a eu d'autres chymistes qui ont joint au nombre de ces sels neutres plusieurs autres substances salines. Je donne à la famille des sels neutres toute l'extension qu'elle peut avoir; j'appelle sel neutre, moyen ou salé, tout sel formé par l'union de quelque acide que ce soit, ou minéral ou végétal, avec un alcali fixe, un alcali volatil, une terre absorbante, une substance métallique, ou une huile." And again, in another paper in 1754, he says, referring to the one already quoted: "J'ai étendu le nombre de ces sels autant qu'il était possible, en définissant génériquement le sel neutre un sel formé par l'union d'un acide avec une substance quelconque, qui lui sert de base et lui donne une forme concrète ou solide." (*Mém. Acad. Roy. Sciences*, 1754, pp. 573, 574: see also Kopp, *Geschichte der Chemie*, iii. 68, 69.) Rouelle was not the first to recognise that the combination of acids with alkalis gave rise to neutral salts; but, according to Kopp, he was the first to declare formation by the union of acid and base to be the characteristic mark of neutral salts, and thus rested the idea of a neutral salt upon chemical composition, instead of upon external properties.

As a consequence of the alteration which Rouelle introduced in the definition of salts, some substances which had previously been considered as belonging to it (for instance sugar) were excluded from it, and others—namely insoluble salts, such as horn-silver and calomel—which had previously been excluded, were now included in it; and, moreover, an essential distinction was made between acids and alkalis on the one hand, and neutral salts on the other. These views did not, however, immediately meet with universal acceptance. Solubility was still regarded by most chemists as an essential quality of salts. The idea which commonly prevailed as to the nature of salts, ninety or a hundred years ago, may be gathered from the following extracts. In the fourteenth volume, published in 1765, of Diderot and D'Alembert's "Encyclopédie," is an article on Salts, commencing thus: "SEL ET SELS.—On comprend sous le nom de *sel* trois espèces de substances; les acides, les alkalis, et les *sels* neutres; en réunissant les propriétés communes à ces trois classes, on trouve que les sels sont des corps solubles dans l'eau, incombustibles par eux-mêmes, et savoureux; il faut bien se défendre d'appeler *sel* tout ce qui se crystallise, sans quoi nous confondrions plusieurs corps très-différens entre eux." In a *Dictionnaire de Chymie* (Macquer's), published at Paris in 1766, salts are defined as follows:—"Les propriétés essentielles de toute matière qu'on doit regarder comme saline, sont d'affecter le sens du goût, ou d'avoir de la saveur, d'être dissoluble dans l'eau, et d'avoir toutes les autres qualités principales, comme la pesanteur, la fixité, moyennes entre celles de l'eau, et celles de la terre pure." (*Op. cit.* ii. 412). A few years later, Bergman, in his *Sciagraphia regni mineralis* (§ xx.), thus states the distinguishing marks of salts:—"Sales audiunt, qui in linguâ plus minus saporis excitant, et probe pulverati aquâ ebulliente, saltem millies ponderosiore, solvi possunt. Igne liquescunt et plerique mutantur vel destruuntur." In his *Thoughts on a Natural System of Fossils*, after characterising salts almost in the same words (§ xlvii.), he points out (§§ xlviii.—l.), that taste, depending on the varying perceptions of individuals, is necessarily a very uncertain criterion; while solubility, being a property which admits of an infinite number of degrees, is hardly less so, unless defined by arbitrarily-chosen conditions. Bergman seems, however, to have perceived that the saline character was fundamentally a matter of composition, even to the extent of inferring solubility in the case of substances which had not been proved experimentally to be soluble: thus, in § li. of the work last quoted, he says:—"Vitriolated ponderous earth, commonly called *spatum ponderosum*, aërated lime, fluorated lime, impregnated with the acid of the *lapis ponderosum*, are all saline earths by the force of composition, and are even without doubt soluble, though to what extent experience has not yet determined."

Such then were the prevalent opinions as to the nature of salts, when Lavoisier, by his discovery of the important functions of oxygen, changed the whole aspect of chemical science. Lavoisier's own ideas on the subject of salts are thus expressed by him:—"Les substances acidifiables, en se combinant avec l'oxygène, et en se convertissant en acides, acquièrent une grande tendance à la combinaison; elles deviennent susceptibles de s'unir avec des substances terreuses et métalliques, et c'est de cette réunion que résultent les sels neutres. Les acides peuvent donc être regardés comme de véritables principes salifians, et les substances auxquelles ils s'unissent pour former des sels neutres, comme des bases salifiables. . . .

"Cette manière d'envisager les acides ne me permet pas de les regarder comme des sels, quoiqu'ils aient quelques-unes de leurs propriétés principales, telle que la solubilité dans l'eau, etc. Les acides, comme je l'ai déjà fait observer, résultent d'un premier ordre de combinaisons; ils sont formés de la réunion de deux principes simples, ou au moins qui se comportent à la manière des principes simples, et ils sont par conséquent, pour me servir de l'expression de Stahl, dans l'ordre des mixtes. Les sels neutres, au contraire, sont d'un autre ordre de combinaisons, ils sont formés de la réunion de deux mixtes, et ils rentrent dans la classe des composés. Je ne rangerai pas non plus, par la même cause, les alkalis ni les substances terreuses, telles que la chaux la magnésie, etc., dans la classe des sels, et je ne désignerai par ce nom que des composés formés de la réunion d'une substance simple oxygénée avec une base quelconque." (*Traité élémentaire de Chimie*, ed. 1789, vol. i. pp. 162–164). Although these views were in the main, with the exception of what related to the constitution of the acids, only a reiteration of those expressed forty years previously by Rouelle, they were felt by Lavoisier to be so little in harmony with contemporary opinion, that he thought it needful to add to the passage we have quoted the following apologetic foot-note:—"On regardera peut-être comme un défaut de la méthode que j'ai adoptée, de m'avoir contraint à rejeter les alkalis de la classe des sels, et je conviens que c'est un reproche qu'on peut lui faire; mais cet inconvénient se trouve compensé par de si grands avantages, que je n'ai pas cru qu'il dut m'arrêter."

In accordance with these views, the history of whose spread and adoption makes part of that of the antiphlogistic system in general, a salt was a combination of a highly-oxidised substance (an acid) with a base. The bases of the metallic salts were already known to be oxides, and the same was soon demonstrated, by Davy, to be true of the earths, alkaline earths, and fixed alkalis. Hence salts soon came to be defined as compounds of electronegative oxides (acids), with electropositive oxides (bases), and all salts were consequently regarded as containing oxygen. Salts were, however, known in which the presence of oxygen could not be directly proved, and amongst them was common salt itself. As a natural consequence, the constitution of such bodies gave rise to much discussion. The application of Lavoisier's doctrine to the chlorides, for instance, caused them to be regarded as compounds of metallic oxides with muriatic acid, supposed to contain oxygen. This was the view adopted by Gay-Lussac and Thénard (*Mémoires d'Arcueil*, ii. 357, 358 [1809]; and *Recherches physico-chimiques*, ii. 155—176 [1811]) as the most probable conclusion that could be drawn from their investigations into the nature of these compounds, and maintained by Berzelius until about the year 1820. (See his *Lehrbuch der Chemie*, [first German edition, 1820, translated from the second Swedish edition], vol. i. especially, pp. 707—714; also *Jahresbericht*, i. 46, [1821]; ii. 60—62, 70 [1822]; iii. 98 [1823].) Davy, on the other hand, who never adopted very fully Lavoisier's views, regarded the chlorides as compounds of the metals with a simple body, chlorine, comparing them to the simple metallic oxides, and represented the salts known to contain oxygen as double oxides. Speaking of these substances, he says: "They are, in fact, all compounds of oxygen with double bases; and when one fixed alkali, or earth, or oxide, separates another, it may be supposed that the basis only is changed. Thus, where hydrat of potassa separates lime from its nitric solution, it may be conceived that the potassium only takes the place of the calcium, and that the oxygen and water of the hydrat of potassa unite to this metal, and that the potassium unites to the oxygene, nitrous acid and water of the solution." (*Elements of Chemical Philosophy* [1812], p. 495.)

The adoption of Davy's views of the constitution of the chlorides was greatly promoted by the discovery of iodine in 1811, and the investigation of it by himself and by Gay-Lussac in 1813—14, one of the first consequences of which was that Gay-Lussac himself became convinced of the elementary nature of both iodine and chlorine. And important additional evidence, that oxygen was not essential to the constitution of salts or acids, was afforded by Gay-Lussac's discovery of cyanogen, and analysis of anhydrous prussic acid, in 1815. In consequence of these discoveries, a large number of chemists, if they did not adopt Davy's views of the constitution of salts in general (for which see also the article ACIDS, i. 41, 42), at least admitted that, in addition to ordinary salts, which they regarded as formed by the union of (anhydrous) acids with metallic oxides, there was another class of salts—comprising the chlorides, iodides, sulphides, cyanides, and perhaps the fluorides—into whose composition oxygen did not enter. Berzelius, however, held fast to Lavoisier's definition of salts ("Unter Salz verstehen wir eine Verbindung einer Säure mit einem Alkali einer Erdart, oder einem Metalloxide:" *Lehrbuch*, ed. 1820, i. 817), and consistently declared in consequence that, if the chlorides, &c. were constituted as represented by the adherents of the new theory, they could not be salts at all. ("Daher ist das salzsaure Natron oder Kochsalz [welches durch seine Geschlechtsähnlichkeit mit anderen Salzen Anlass gegeben hat, das Wort Salz als allgemeine Benennung des ganzen Salzgeschlechts zu gebrauchen], der neuen Theorie gemäss, kein Salz mehr. . . . ."—*Op. cit.*—"Die salzsauren Salze sind in dieser Theorie keine Salze, z. B. Kochsalz ist nicht eine Verbindung von Natron mit einer Säure, sondern eine Verbindung von Natrium mit Chlor."—*Ibid.*) Berzelius perceived, what most chemists of that time do not seem to have done, that the chemical history of iodine afforded in reality no new argument in favour of Davy's theory, all the combinations of iodine admitting of precisely the same kind of interpretation as the corresponding compounds of chlorine, on the supposition that both were oxidised compounds of unknown elements. (For his views of the chlorine-compounds, see i. 902.) The sulphides he did not admit into the category of salts at all; the cyanides, however, especially cyanide of mercury and prussiate of potash, could not be denied the possession of distinctly saline properties. But even these substances were not regarded by him as affording conclusive evidence that true salts could exist without containing oxygen; for, although it was certain that they contained, in addition to metal, nothing but carbon and nitrogen, the latter element was at this time regarded by Berzelius as itself a compound of oxygen with an unknown radicle, nitricum. Representing one combining proportion of this supposed radicle by R (= 6), and one combining proportion of oxygen by O (= 8), his view of the constitution of nitrogen and its oxides may be represented by the following formulæ:—

Nitrogen	=	RO	Nitrous acid (anhydrous)	=	RO^4
Nitrous oxide	=	RO^2	Nitric peroxide	=	RO^5
Nitric oxide	=	RO^3	Nitric acid (anhydrous)	=	RO^6

(For the reasons urged by Berzelius in support of these views, which were mainly founded on the phenomena attending the formation of ammonium-amalgam, see his *Lehrbuch der Chemie*, ed. 1820, i. 225, 226; 491, 492; 613—619; 806; 810.)

The circumstance which chiefly contributed to make Berzelius at last receive the so-called "chloristic theory" was Faraday's discovery, in 1821, of the sesquichloride, protochloride, and bichloride of carbon. It had been, from the first, one of Davy's strongest arguments against the existence of oxygen in chlorine, and consequently in the chlorides, that chlorine was not decomposed by carbon even at the highest temperatures. The opponents of his views declared that this experiment was inconclusive, for chlorine could not be decomposed, under these circumstances, without the formation of carbonic acid or oxide, and (hypothetically) anhydrous muriatic acid, to the formation of which there would be no tendency unless these compounds were themselves capable of combining together, and they maintained that there was no evidence of the possibility of such a combination. The chlorides of carbon discovered by Faraday were, however, precisely such compounds; and, upon the old view of the constitution of chlorine, could not be otherwise represented than as combinations of (hypothetically) anhydrous muriatic acid, with anhydrous oxalic acid, carbonic oxide, and carbonic acid respectively. Such an interpretation of the nature of these substances seemed to Berzelius so little in harmony with their properties, as to be even less probable than the views as to the elementary character of chlorine and iodine, which he had hitherto opposed. He afterwards saw a confirmation of these views in the colour of red prussiate of potash, discovered in 1822 by Leopold Gmelin: in his account of this salt, in his Third Annual Report (p. 98), he says that he had hitherto regarded the reddish colour of the sesquichloride and other sesquisalts of iron as favouring the idea that they contained as a proximate constituent the red sesquioxide; but, as a red salt was now known which demonstrably contained no oxygen, he considered this view no longer tenable.

In 1825, Berzelius himself discovered the sulphur-salts, and thus afforded a fresh proof that substances perfectly devoid of oxygen could possess all the characters of salts. In consequence, he seems to have entirely changed his opinions as to what were the essential marks of a salt. He now says distinctly that it is not a question of composition but of properties: "When, for example, sodium combines with chlorine, the product is common salt, the most characteristic of all salts; but when sodium combines with oxygen, it does not produce a salt, but a substance which acquires properties analogous to those of common salt only by combination with an acid. The idea which is to be connected with the word salt cannot, therefore, be deduced from composition, for, in the first place, the salt is composed of two simple bodies, and in the second of two oxides. The idea of what a salt is must, consequently, be derived from that kind of electrochemical indifference, which chemists have from antiquity very fitly called *neutrality*, and which results from the combination of substances without respect to the elements of which the neutral compound is formed." (*Jahresb.* vi. 185 [1826].) Berzelius's views of the nature of salts are further illustrated by the manner in which he classified the simple bodies in relation to them. At the place last quoted he divides the elements as follows:—

A. Electronegative:

1. Those which produce *salts* by direct union with electropositive elements.—Halogens: namely, chlorine, iodine, and probably fluorine.
2. Those which produce *bases* by union with electropositive elements, and *acids* by union with electronegative elements of the third class.—Amphigens; namely, oxygen, sulphur, selenium, and tellurium.
3. The remaining non-metallic elements, and the electronegative metals: by union with the second class of electronegative elements they form *acids* (and sometimes also very weak bases). This class contains nitrogen, carbon, arsenic, &c.

B. Electropositive:

The electropositive elements do not admit of subdivision: by combination with electronegative elements of the first class, they form *salts*; with those of the second class, *bases*; with those of the third class, *alloys*.

Salts themselves were divided into two classes: the first class, called haloid salts, included those formed (like chloride of sodium) by the union of an electropositive metal with a halogen; the second class, amphid salts, was composed of those formed (like potassic sulphate) by the union of an acid and a base, and was subdivided into four genera—namely oxysalts, sulphosalts, seleniosalts, and tellurisalts—according to the nature of the amphigen contained in them. (See further Berzelius, *Jahresb.* viii. 137—143 [1828], where the same views are again insisted on.)

These views were accepted, almost without question, by the great majority of chemists; and they will be recognised by every reader as having been reproduced, with very little variation, in nearly every textbook of chemistry published from the year 1830 till within the last ten years, and even in many that are still more recent. It is hardly needful to say, that it is for this reason that we have discussed Berzelius's opinions at so great a length. There were, however, always a few chemists to whom the division into haloid salts and amphid salts appeared arbitrary and inadmissible. The most important of the earlier attempts to reduce all salts into a single class gave rise to the so-called "binary" theory, already alluded in the article ACIDS (i. 42 and 45, foot-note). This theory, however, never exerted a very important influence on the progress of chemistry, and it is therefore not needful to discuss the arguments by which it was supported and opposed.

If we try now to state what is the idea which is attached to the word salt, as at present used in chemical science, we find it impossible to do so in very precise terms. Probably we may most correctly define this idea by saying that it implies the capability of readily undergoing *double decomposition*. ("Nous appelerons *sels*, ou *corps binomes*, tous les composés chimiques formés par deux parties, l'une métallique et l'autre non-métallique, pouvant ainsi s'échanger par double décomposition."—Gerhardt, *Introduction à l'étude de la Chimie par le Système Unitaire*, 1848, p. 91.) In its most restricted signification, the word salt suggests a substance which, if soluble in water, can produce *rapid* double decompositions with other soluble substances, or, if insoluble, can be produced as a precipitate, as the result of a rapid double decomposition taking place between soluble substances. This is certainly the idea suggested by the application of the word salt to chloride of sodium, nitrate of potassium, sulphate of barium, nitrate of silver, hydrochlorate of aniline, &c. By an inevitable extension of meaning, the name salt is also sometimes given to substances which, like chloride of ethyl, give rise to *slow* processes of double decomposition with aqueous solutions of the salts specially so called. By a still further extension, it is sometimes applied to such bodies as acetate of ethyl, or stearin, and even these compounds do not mark the limit of its occasional application. The fact is, that as there is no class of bodies known—not even excepting the elements themselves—which do not, under certain conditions, give rise to reactions which must (or may) be represented as double decompositions, so there is no class of bodies to which the name salt, as implying capability of double decomposition, is completely inapplicable. The name is, however, most commonly and most appropriately applied to those bodies of which reaction by double decomposition is the most characteristic property, and which exhibit such reactions under the most familiar conditions. G. C. F.

SALT GARDENS. *Marais salins.* Shallow ponds or ditches, excavated on the seashore and puddled with clay, for concentrating sea-water by spontaneous evaporation, and obtaining common salt. (See SODIUM, CHLORIDE OF.)

SALT LAKES. *Salzseen.* Inland seas containing considerable quantities of chloride of sodium, and other constituents of sea-water and salt-springs, carried down by the various streams which flow into them. As the water evaporates during the hotter season of the year, chloride of sodium, more or less pure, separates out, and the remaining water approaches in composition to the mother-liquor of ordinary salt-springs, containing considerable quantities of the chlorides of magnesium and calcium, and comparatively little chloride of sodium; also bromides, potassium-salts, &c. The proportions of these several constituents vary with the season of the year, according to the temperature, and the quantity of fresh water brought down by rivers.

Salt-lakes are especially numerous in the great basin of Northern Asia, the lowest part of which is occupied by the Caspian Sea and Lake Aral. In the government of Astrachan there are 129 of these lakes, of which 32 are worked for the production of salt. Near Kistiar, in the government of the Caucasus, there are 21, from 18 of which salt is likewise obtained. One of the most considerable of these salt-lakes is the Elton Lake, in the Steppe of Kirghis, between the Rivers Volga and Ural. As the water of this lake evaporates in summer, the chloride of sodium separates out in loose masses, which afterwards become denser. It is very impure, containing large quantities of magnesium-chloride, which gives it a sharp and bitter taste. If, however, this deposited salt remains in the lake, and is exposed to the solvent action of fresh water in the following spring, the chloride of magnesium and other foreign salts, being more soluble than the chloride of sodium, are first dissolved, and the chloride of sodium remains as a compact, stony, bluish mass, having a pure saline taste. A black mud is at the same time deposited upon it, and forms a sharp demarcation between the deposits of successive years. This lake, in 1832, yielded, 40,000 tons of salt.

The following tables exhibit the percentage composition of the water of several salt-lakes :—

Water of the Dead Sea.

	C. G. Gmelin.	Marchand.	Booth and Muckle.	Moldenhauer.	Boussingault.
		Sp. gr. 1·185	Sp. gr. 1·227	Sp. gr. 1·160 (summer of 1854).	Sp. gr. 1·194 (spring of 1865).

The following analyses of the water of the Dead Sea, in different parts and at different depths, have lately been published by A. Terreil (Compt. rend. lxii. 1329; Zeitschr. f. Chem. [2] ii. 415):—

Dead Sea.

	In the sea near Ras Dale.	Lagune north of Sodom.	North side near the island.	Five miles east of Wady Mrabba.	Near Ras Mersed.	Five miles east of Ras Feschkah.	The same.	Five miles east of Wady Mrabba.
Depth in metres . . .	Surface	Surface	Surface	20	42	120	200	300
Specific gravity at 15° . .	1·0216	1·0375	1·1647	1·1877	1·2151	1·226	1·2300	1·2563

Calcium	0·2150	0·4481	0·9094	1·1472	0·3693	0·3704	0·4218	1·7269
Sodium	0·0885	0·7845	2·2400	1·3113	2·4786	2·5071	2·5107	1·4300
Potassium	0·0474	0·0779	0·3547	0·3520	0·2421	0·3990	0·4503	0·4386
	2·5703	4·7912	19·2153	20·7131	24·2628	24·5732	25·1101	25·9984

Traces of carbonic acid, ammonia, ferric oxide, alumina, and organic matter were likewise found; no iodine, phosphoric acid, lithium, cæsium, or rubidium.

The table shows:—1. That the density and concentration of the water increases with the depth.—2. That the composition varies throughout the entire breadth. The water to the north of Sodom contains a larger proportion of sodium- than of magnesium-chloride; and, as a consequence of this, small fish are able to live in it.—3. That the proportions of the different constituents are the same at all depths, the bromine alone appearing to increase in a greater ratio at a depth of 300 metres.

The quantities of potassium-salt and of bromine in the water are remarkably great. The water of the springs and rivers in the neighbourhood contains chlorine, sulphuric acid, carbonic acid, lime, magnesia, potash, and soda, but no appreciable quantity of bromine.

Salt Lakes of the Northern Asiatic Basin.—*a.* Oroomiah Lake, in the north-west of Persia; specific gravity 1·555 (Hitchcock).—*b.* Elton Lake, in spring (Göbel).—*c.* The same in summer (Erdmann).—*d.* The same in autumn (G. Rose). In the clay soil of the shore of this lake, Rose found small crystals of gypsum; small groups of crystals of magnesium-sulphate were also found floating on the water.—*e.* Bitter-salt Lake of Kigatsch, one of the arms by which the Volga flows into the Caspian Sea. At the bottom of this lake there is a deposit of sodio-magnesic sulphate, a foot thick.—*f.* Salt-lake of Tasly, near the highroad from Sympheropol to Eupatoria.—*g.* Lake of Bogdo, north-east of the Bogdoberg in the Caspian Steppe.—*h.* Salt-lake of Tschakrakskoi, not far from Kertsch, separated only by a narrow strip of land from the Sea of Azof.—*i.* Stepanow Lake.—*k.* Indertsch Lake.—*l.* Putrid lake on the east coast of the Crimea, separated only by a narrow tongue of land from the Sea of Azof. The water contains a small quantity of calcic sulphate, and smells of sulphydric and hydrochloric acids.—*m.* Salt-lake of Arsargar, the largest next to the Bogdo Lake, between the Rivers Volga and Ural.

100 pts. of the Lake-water contain:—

	a.	*b.*	*c.*	*d.*	*e.*	*f.*	*g.*	*h.*	*i.*	*k.*	*l.*	*m.*
Chloride of sodium .	19·0	13·1	7·4	3·8	10·5	18·1	21·6	28·9	22·4	23·9	14·2	17·8

The analyses *e* to *m* are by Göbel (*Reise in die Steppen des südlichen Russlands*): these waters were examined for bromides and potassium-salts only in a few cases; but it is probable that these salts exist in all salt-lakes. (*Handw. d. Chem.* vii. 218.)

SALTPETRE. Nitrate of potassium (see Nitrates, iv. 98). Nitrate of sodium is often called Chili Saltpetre.

SALT-RADICLE. The chlorous or electronegative constituent of a salt, according to the binary theory: *e.g.*, Cl in KCl, SO^4 in K^2SO^4, &c.

SALTS, NOMENCLATURE OF. See Nomenclature (iv. 125).—The following salts were denoted in the older language of chemistry by particular names, some of which are still occasionally used:—

Salt (Ammoniacal, Fixed). Chloride of calcium.

Salt (Ammoniacal, Secret) of Glauber. Sulphate of ammonium.

Salt (Arsenical, Neutral) of Macquer. Acid arsenate of potassium.

Salt (Bitter, Cathartic). Sulphate of magnesium.

Salt (Common). Chloride of sodium.

Salt (Digestive) of Sylvius. Acetate of potassium.

Salt (Diuretic). Acetate of potassium.

Salt (Epsom). Sulphate of magnesium.

Salt (Febrifuge) of Sylvius. Chloride of potassium.

Salt (Fusible). Phosphate of ammonium.

Salt (Fusible) of Urine. Phosphate of sodium and ammonium.

Salt (Glauber's). Sulphate of sodium.

Salt (Green). In the mines of Wieliczka the workmen give this name to the upper stratum of native salt, which is rendered impure by a mixture of clay.

Salt (Marine). Chloride of sodium.

Salt (Marine, Argillaceous). Chloride of aluminium.

Salt (Microcosmic). Phosphate of sodium and ammonium.

Salt (Nitrous Ammoniacal). Nitrate of ammonium.

Salt of Amber. Succinic acid.

Salt of Benzoin. Benzoic acid.

Salt of Canal. Sulphate of magnesium.

Salt of Colcothar. Sulphate of iron.

Salt of Egra. Sulphate of magnesium.

Salt of Lemons (Essential). Acid oxalate of potassium.

Salt of Saturn. Acetate of lead.

Salt of Sedlitz. Sulphate of magnesium.

Salt of Seignette. Tartrate of potassium and sodium.

Salt of Soda. Carbonate of sodium.

Salt of Sorrel. Acid oxalate of potassium.

Salt of Tartar. Carbonate of potassium.

Salt of Vitriol. Purified sulphate of zinc.

Salt of Wisdom. Ammonio-mercuric chloride, $2NH^4Cl.Hg''Cl^2.H^2O$.

Salt (Perlate). Disodic orthophosphate.

Salt (Polychrest) of Glaser. Sulphate of potassium.

Salt (Sedative). Boracic acid.

Salt (Spirit of). Hydrochloric acid was formerly called by this name, which it still retains in commerce.

Salt (Sulphureous) of Stahl. Sulphite of potassium.

Salt (Wonderful). Sulphate of sodium.

Salt (Wonderful, Perlate). Disodic orthophosphate.

SALT SPRINGS. This name is applied to waters which contain large quantities of chloride of sodium in proportion to their other constituents, and are therefore used for the extraction of that salt. In many saltworks, artificial salt-springs are formed by dissolving rock-salt or bay-salt in sea-water, or in a weak solution of sodium-chloride. (See Sodium, Chloride of.)

SALVIA. The garden sage, *Salvia officinalis*, yields, by distillation with water, an essential oil, which is light-yellow or nearly colourless when fresh, but after a time becomes darker and deposits a camphor. It has an aromatic taste, and a penetrating camphoraceous odour, like that of the plant. It floats on water, its specific gravity varying from 0·86 to 0·92 (Zeller). It boils between 130° and 160°, but not at a constant temperature. According to Rochleder (Ann. Ch. Pharm. xliv. 4), the composition and boiling-point of the oil vary greatly with its age, and when rectified over solid potash, it yields oils differing in composition and boiling-point. These oils may be regarded as compounds of the hydrocarbon C^6H^{10}, with varying quantities of oxygen (from 3 to 11 per cent.). Sage-oil treated with cold concentrated nitric acid becomes hot, and is converted, with evolution of gas, into a red resinous mass, which when distilled with water gives off common camphor, $C^{10}H^{16}O$, mixed with an oil. When sage-oil is dropped into fuming nitric acid at the boiling heat, it dissolves, giving off a mixture of carbonic anhydride and nitric oxide. If the liquid be then distilled with water, pure camphor collects in the condensing tube. In the formation of camphor from sage-oil, 2 atoms of the hydrocarbon, C^6H^{10}, give up 2 at. C and 4 at. H, which escape as carbonic anhydride and water:

$$2C^6H^{10} + O^7 = C^{10}H^{16}O + 2CO^2 + 2H^2O.$$

Another camphor, or stearoptene, is deposited from sage-oil when kept for a long time in a badly-closed vessel. (Herberger, Repert. Pharm. xxxiv. 138.—Gm. xiv. 399.)

Hlasiwetz (J. pr. Chem. li. 355), by boiling volatile oil of mustard with soda-lime, once obtained an oil which had the odour of sage-oil, and contained 80·0 per cent. carbon, 11·1 hydrogen, and 8·9 oxygen, agreeing nearly with the formula $C^{12}H^{20}O$ (80·25 C, 10·91 H, and 8·84 O). Its formation may perhaps be represented by the equation:

$$\underset{\text{Allylic sulphocyanate.}}{5(C^3H^5.CyS)} + 3Na^2O = \underset{\text{Sage-oil.}}{C^{12}H^{20}O} + \underset{\text{Sodic propionate.}}{C^3H^5NaO^2} + \underset{\text{Sodic sulphocyanate.}}{5NaCyS.}$$

Respecting the ferment-oil of *Salvia pratensis*, see ii. 636.

SALYLIC ACID. This name was given by Kolbe and Lautemann to a supposed isomer of benzoic acid. Chiozza, as already observed (p. 154), by treating the product of the action of phosphoric chloride on salicylic acid with water, obtained an acid having the composition of chlorobenzoic acid, $C^7H^5ClO^2$. This acid was afterwards examined by Limpricht and v. Uslar, who found that it differed in crystalline form and melting-point from ordinary chlorobenzoic acid (i. 555), and therefore regarded it as isomeric with the the latter. This conclusion was corroborated by the experiments of Kolbe and Lautemann (p. 154), who designated the chlorinated acid obtained from salicylic acid, as chlorosalylic acid; also by those of Kekulé (Ann. Ch. Pharm. cxvii. 145; Jahresb. 1860, p. 395). Kolbe and Lautemann also found that chlorosalylic acid differed from chlorobenzoic acid in its behaviour with sodium-amalgam, the latter being scarcely acted upon thereby, whereas the former is easily deprived of the whole of chlorine, and is converted into salylic acid, $C^7H^6O^2$, isomeric with benzoic acid.

Salylic acid precipitated from the alkaline solution by hydrochloric acid, and purified by recrystallisation from water, is said to form very small needles, which under the microscope never exhibit the indented form of benzoic acid. It is more volatile than the latter, melts at nearly the same temperature, viz. at 119° (benzoic acid melting at 121°), is much more soluble than benzoic acid, 1 pt. of it dissolving at 0° in 237 pts. water, whereas benzoic acid requires 607 pts. Some of the salts of salylic acid differ also in form and solubility from the corresponding benzoates. (Kolbe and Lautemann.)

Griess, by acting on diazobenzo-oxybenzamic acid (iv. 293) with nitrous acid, has also obtained an acid isomeric with benzoic acid, which he regards as identical with Kolbe and Lautemann's salylic acid.

On the other hand, according to E. Reichenbach and Beilstein (Ann. Ch. Pharm. cxxxii. 309; Bull. Soc. Chim. 1865, ii. 53), the so-called salylic acid, whether prepared from salicylic or from diazobenzo-oxybenzamic acid, is nothing but ordinary benzoic acid, more or less contaminated with foreign substances. After being distilled with water, converted into a sodium-salt, precipitated by hydrochloric acid, and once recrystallised, it exhibits all the characters of pure benzoic acid; likewise in its salts, and in the nitro-acid prepared from it.

Gräbe (Ann. Ch. Pharm. cxxxvi. 124; Bull. Soc. Chim. 1866, i. 432), by treating methylic methylsalicylate, $C^7H^4(C^2H^3)^2O^3$ (p. 162), with potash, has obtained an acid containing $C^8H^8O^3$, which he regards as methoxysalylic acid, $C^7H^5(CH^3)O^3$, perhaps methoxybenzoic acid. [Cahours obtained salicylic acid by the same reaction].

This acid crystallises in large tables, slightly soluble in cold water, easily soluble in boiling water and in ether. Its solution is strongly acid, and does not give with ferric salts the reaction characteristic of salicylic acid. It melts at 99°, and is partly resolved by distillation into carbonic anhydride and anisol.

Ethylic methylsalicylate treated with potash yields, in like manner, an acid containing $C^9H^{10}O^3 = C^7H^5(C^2H^5)O^3$. (Gräbe.)

SAMADERA INDICA (Gärtn.), *Vithmannia elliptica* (Vahl). A tree of the simarubaceous order (class *Terebinthaceæ*), growing in Java, and called by the Malays *Galip Pahit*. The almond-shaped fruits (which are enclosed in leathery capsules) and the bark are distinguished by a peculiar intensely bitter taste. According to C. L. Blume (Arch. Pharm. cxlvi. 265; Handw. vii. 222), the fruit and bark contain, in 100 pts.:—

	Fruit.	Bark.
Matters soluble in ether . . .	34·2	1·4
" " alcohol . . .	8·4	5·1
" " water . . .	10·6	1·2
" " potash . . .	0·1	trace
Cellulose	39·0	70·6
Water . . . , . . .	4·6	11·8
Ash-constituents	2·7	7·9

Ether extracts from the fruit, a colourless oil, having a peculiar odour, and saponifiable by alkalis. The alcoholic extract of the fruit consists chiefly of a brown, very bitter substance (perhaps a resin), which is somewhat soluble in water, absorbs moisture from the air, and deliquesces.—The aqueous infusion of the fruit yields a deliquescent, very bitter extract, containing tannic acid and a peculiar bitter principle called samaderin. The ash of the fruit contains carbonate of calcium and the chlorides of calcium and potassium.

From the bark, ether extracts a light-yellow fat of soft resinous consistence, which is only partially saponified by alkalis, and appears to be a mixture of resin and fat. The alcoholic and aqueous extracts of the bark have the same constituents and properties as those of the fruit.

Samaderin, the chief bitter constituent of the bark and fruit, is most easily prepared from the aqueous infusion by evaporating it to an extract, and treating the extract repeatedly with small quantities of alcohol; it may be purified by solution in water, and treatment with animal charcoal. It is dazzling white, with a foliated and somewhat feathery crystalline structure; has a persistent and intensely bitter taste, stronger perhaps than that of any other known substance; dissolves in water more easily than in alcohol, and to a slight extent also in common ether. Its solutions are perfectly neutral. When heated, it melts and gives off vapours having a sharp bitter taste. Hydrochloric and nitric acids colour it yellow. Strong sulphuric acid immediately produces with it a splendid red-violet colour, which disappears after a while; a considerable quantity of feathery, strongly iridescent crystals is formed at the same time. Samaderin produces no particular reaction with metallic salts, or with tincture of iodine, chromate of potassium, or ferrocyanide of potassium.

SAMARSKITE. Uranoniobate of yttrium and iron, occurring near Minsk, in the Ilmen Mountains (iv. 55).*

SAMBUCUS. A genus of plants belonging to the order *Caprifoliaceæ*. The berries of the dwarf elder or danewort (*Sambucus Ebulus*) contain malic acid (Braconnot), and a very gelatinous soft resin which may be used as birdlime.

The root-bark of the common elder (*Sambucus nigra*) contains, according to Simon, an emetic and purgative soft resin, which may be obtained by treating the alcoholic extract with ether, and evaporating.—The flowers contain a volatile oil, which is very soluble in water, and is therefore not easily obtained by distillation with water. The best way of preparing it, according to Winckler, is to concentrate the water in which fresh elder-flowers have been macerated, saturate it with common salt, shake up with ether, and evaporate the ether. It is colourless, lighter than water, and has the penetrating odour of the flowers, which, like musk, is capable of filling a very large space. At 0° it solidifies to a crystalline mass, like oil of roses. It has a very high boiling-point. When exposed to the air, it turns brown, thickens, and acquires the odour of decayed elder-flowers. It is said to contain sulphur. Elder-berries contain, according to Scheele, malic but no citric acid; also sugar, gum, a peculiar sudorific substance (which likewise exists in the flowers), and a red colouring matter, which is turned blue by a small quantity of alkali, green by a larger quantity.

---

* It is there called "uranoniobite" of yttrium, &c.; but the acid formerly called niobine, or hyponiobic acid, is now known to be the only oxygen-acid of niobium, and is therefore called *niobic acid* (iv. 785).

SAMECH PARACELSI. An obsolete name of neutral potassic tartrate.

SAMOÏTE. An aluminous silicate allied to allophane, occurring in stalactitic forms in the lava of Upolu, an island of the Navigator group. It has a lamellar structure, whitish colour, and slightly nacreous lustre; hardness = 4·0 to 4·5; specific gravity = 1·7 to 1·9. Contains, according to B. Silliman, jun., 31·26 per cent. silica, 37·21 alumina, and 30·45 water, together with 4·06 magnesia, 0·01 calcic carbonate, 0·06 soda; according to another analysis, however, 35·19 silica, 31·95 alumina, and 30·80 water; the formula is therefore doubtful.

SAMPHAN. Syn. with Sapan.

SAND. This name is mostly applied to quartz occurring in a granular or pulverulent form, as on the seashore, in the beds of rivers, and covering extensive tracts on many parts of the earth's surface; but it is also extended to other minerals occurring in a similar condition: hence the terms dolomitic sand, iron sand, titaniferous sand, &c.

SANDAL-WOOD. *Sandal-wood, Santal-wood, Red Saunders-wood.*—A dye-wood furnished by the *Pterocarpus Santalinus*, a papilionaceous tree indigenous in the tropical parts of Asia. It occurs in commerce, sometimes in large heavy billets of a fine red colour (caliatur-wood)—sometimes as a red, loose, dusty powder. It has a somewhat harsh taste, and when warmed or rubbed gives off a faint agreeable odour. It is used in India, together with one-tenth of sapan-wood, chiefly for dyeing silk and cotton, to which, and also to wool, it imparts reds of various shades, according to the kind of mordant used. (See *Ure's Dictionary of Arts*, &c., iii. 631.)

Sandal-wood contains a peculiar red resinous colouring-matter, called **santalin**, and, according to **Meier** (Ann. Ch. Pharm. lxxii. 320), five other amorphous resinous bodies which he designates as **santalic oxide**, **santalide**, **santaloïde**, **santalidide**, and **santaloïdide**; the last four being extracted from the wood by water—the first, together with santalin, by alcohol. These five bodies have not, however, been obtained pure, and their separate existence is very doubtful.

Santalin, or **santalic acid**, $C^{15}H^{14}O^{5}$ (?), is prepared by treating the wood with ether, and evaporating the resulting solution; dissolving the highly-coloured crystals thus obtained in alcohol, after having exhausted them with water; precipitating the alcoholic solution with acetate of lead; boiling the violet precipitate several times with alcohol, then suspending it in that liquid, and decomposing it with dilute sulphuric acid. (**Meier**.)

Santalin forms small crystals of a fine red colour, and without taste or smell. It is insoluble in water, but very soluble in alcohol, forming a blood-red solution which reddens litmus. It melts at 104°, and at a higher temperature becomes resinous and puffs up. It contains, according to **Westermann** and **Häffely** (Ann. Ch. Pharm. lxxiv. 226), 65·85 per cent. C and 5·2 H, the formula $C^{15}H^{14}O^{5}$ requiring 65·7 C, 5·1 H, and 29·2 O.

The alcoholic solution of santalin precipitates lead-salts, but not the salts of barium, silver, or copper. Santalin dissolves easily in ammonia and in potash, forming violet solutions, which precipitate the alkaline earths.

The *barium-salt* is a violet crystalline precipitate, which, when dried at 100°, gives by analysis 53·2 to 53·7 per cent. C, 4·6 to 3·5 H, and 22·9 BaO, the formula $C^{30}H^{26}Ba''O^{10}$ requiring 52·7 C, 3·8 H, and 22·4 BaO.

The *lead-salt*, $C^{30}H^{26}Pb''O^{10}.Pb''H^{2}O^{2}$, gave by analysis 35·3 to 37 per cent. C, 2.8 H, and 44·6 to 44·9 lead-oxide, the formula requiring 36·2 C, 2·8 H, and 44·5 PbO.

SANDARACA. Syn. with Realgar (i. 386).

SANDARACH. A gum-resin which exudes from *Thuja articulata*, a small coniferous tree growing in Barbary. It occurs in pale-yellow elongated plates, covered with a very fine dust, and having a vitreous lustre on the fractured surface. It has a faint odour, and crumbles between the teeth without softening. According to **Johnston** (J. pr. Chem. xvii. 157), sandarach is a mixture of three acid resins. The α-resin forms a white or yellow powder, slightly soluble in alcohol, and not easily fusible. It forms but a small part of the entire resin, and contains 78·04 to 78·46 per cent C, and 9·80 to 9·91 H, whence Johnston deduces the formula $C^{20}H^{30}O^{2}$ (calc. 79·47 C, 9·93 H, and 10·60 O). The β-resin, which forms three-fourths of the whole, has a light-yellow colour, softens at 100°, and dissolves easily in cold alcohol. Contains 75·08 to 76·60 C, and 9·71 to 10·04 H, whence $C^{20}H^{30}O^{3}$ (calc. 75·47 C, 9·41 H, and 15·12 O). The γ-resin is a light-yellow powder, soluble in boiling alcohol, melting with difficulty, and decomposing at the same time. Contains 75·53 to 75·59 C, and 9·35 to 9·47 H, whence the formula $C^{20}H^{30}O^{3}$.

SANDEL-WOOD. Syn. with Sandal-wood.

SANGUINARIA CANADENSIS. The root of this plant, belonging to the papaveraceous order, contains sanguinarine or chelerythrine, and, according to Gibb (Pharm. J. Trans. [2] i. 454), two other alkaloids, called porphyroxine and puccine; but the two latter have been but imperfectly examined. (Gm. xvii. 162.)

SANGUINARINE. *Chelerythrine, Pyrrhopine.* $C^{19}H^{17}NO^4$. (Dana, Annals of the Lyceum of New York, ii. 245.—Probst, Ann. Ch. Pharm. xxix. 120; xxxi. 350.—Polex, N. Br. Arch. xvi. 77.—J. Schiel, Ann. Ch. Pharm. xliii. 233; Sill. Am. J. [2] x. 220.—Gm. xvii. 156.)—An alkaloïd discovered, as sanguinarine, by Dana, in the roots of *Sanguinaria canadensis*; as chelerythrine, by Probst, and as porphyroxine by Polex, in the common celandine (*Chelidonium majus*): the identity of the alkaloïds from these two sources was demonstrated by Probst and Schiel. In celandine it is found chiefly in the roots and unripe fruit; in *Sanguinaria* it exists also in the leaves, and most probably in the seed. It is also found in the roots of the yellow-horned poppy (*Glaucium luteum*), together with glaucopicrine, but not in the green parts of the plant, which contain glaucine (ii. 845, 846).

Preparation: 1. From the roots of *Sanguinaria canadensis.*—The dried and powdered root is exhausted with ether, hydrochloric acid gas is passed into the filtrate, and the impure hydrochlorate o fsanguinarine thereby thrown down, is collected and dried. In the ether there remains a brown greasy resin, together with a little sanguinarine, which is recovered by evaporating, exhausting the residue with water containing sulphuric acid, and precipitating by ammonia. The precipitated hydrochlorate is dissolved in water; the solution is precipitated by ammonia; the precipitate is washed, dried, and dissolved in ether; and the solution is shaken with animal charcoal till the supernatant liquid appears colourless. The precipitate, again thrown down from the filtrate by hydrochloric acid gas, is decomposed by aqueous ammonia, and afterwards washed and dried (Probst; Schiel). Schiel purifies sanguinarine extracted by other methods, by precipitating its ethereal solution with hydrochloric acid gas or sulphuric acid.

2. From the roots of *Chelidonium majus.*—The fresh or dried root is exhausted with water containing sulphuric acid: the liquid is precipitated by ammonia; and the precipitate is washed, freed from water as far as possible by pressing, and dissolved, while still moist, in alcohol containing sulphuric acid. The alcoholic solution, diluted with water, is submitted to distillation, and after the alcohol is driven off, precipitated by ammonia. The precipitate is dried between bibulous paper as quickly as possible, at a very gentle heat, powdered, and treated with ether, which dissolves chiefly sanguinarine. On expelling the ether, there remains a viscid turpentine-like mass, to be treated with as small a quantity as possible of water containing hydrochloric acid, which leaves resin undissolved. The solution is evaporated to dryness, and the residue washed with ether, hydrochlorate of sanguinarine then remaining. This is dissolved in a little cold water, which leaves most of the hydrochlorate of chelidonine undissolved; the solution is evaporated, and the residue again treated with water so long as hydrochlorate of chelidonine continues to separate. From the last aqueous solution the sanguinarine is thrown down by ammonia, and is purified by washing and drying, and subsequently dissolving in ether and evaporating. (Probst.)

3. From *Glaucium luteum.*—The dried and powdered roots of plants of one to two years' growth are exhausted with water containing acetic acid; the extract is precipitated by excess of ammonia; and the precipitate is washed, dried, and exhausted with ether, which leaves nearly pure sanguinarine on evaporation. The product is dissolved in the smallest possible quantity of water acidulated with hydrochloric acid; the water and excess of acid are evaporated; and the remaining hydrochlorate of sanguinarine is freed from chlorophyll by washing with ether, after which it is dissolved in a little water, and mixed with an equal volume of strong hydrochloric acid, which precipitates it almost completely, the supernatant liquid retaining only a small quantity, precipitable by ammonia. The precipitated salt may be obtained in the crystalline form, by dissolving it in water and evaporating the solution. By decomposition with ammonia it yields sanguinarine, which is crystallised from ether, with addition of water. (Probst.)

Properties.—Sanguinarine is obtained from absolute alcohol, by spontaneous evaporation, in groups of crystalline nodules (Probst); in white, pearly, fine grains (Dana); in star-shaped groups of transparent needles, and white nodules (Polex). It is insoluble in water, but soluble in *alcohol* and *ether*. The ethereal solution leaves, on evaporation, a turpentine-like body, which gradually hardens to a shining friable mass (Probst). The crystals become opaque and brown on drying (Polex). It is tasteless (Schiel); in the mouth it slowly creates a very faint taste (Dana); in alcoholic solution it has a burning sharp taste (Probst); very bitter (Schiel). It acts as a powerful narcotic poison. The dust excites violent sneezing (Probst). According to Dana and Schiel, it has an alkaline reaction; but according to Probst and Polex, it is neutral. On exposure to the air it gradually assumes a yellowish-white colour (Dana), and in presence of small quantities of acid vapours becomes immediately red (Polex; Schiel). It softens at 65° like a resin (Probst), melts at a somewhat high temperature, and burns completely, giving off ammoniacal vapours (Polex). It is decomposed by nitric acid. Its composition (at 100°—105°) is shown in the following table:—

	Calculation.		Schiel. *a.*	Schiel. *b.*
C^{19}	228	70·59	69·66	70·34
H^{17}	17	5·26	5·16	5.21
N	14	4·33	5·23	5·07
O^4	64	19·82	19·95	19·38
$C^{19}H^{17}NO^4$	323	100·00	100·00	100·00

a was prepared from *Sanguinaria*, *b* from *Chelidonium*.

Sanguinarine unites with *acids*, which it colours a fine orange-red, forming neutral salts, partly crystallisable, having a burning sharp taste, a narcotic action, and dissolving, for the most part, in water. From the solutions, sanguinarine is separated by ammonia, the fixed alkalis, or magnesia, in the form of a grey-white curdy precipitate (Probst). Concentrated acids have but little action on sanguinarine in the cold (Polex). Acetate of sanguinarine forms yellowish-white precipitates with tartar-emetic, ferric chloride, mercurous nitrate, mercuric chloride, and silver nitrate: iodine precipitates the solution of a crimson, chromate of potassium of a yellow, and chloride of gold of a dark-red-yellow colour. Basic acetate of lead and tincture of galls do not produce precipitates. (Polex.)

SANGUISORBA PRÆCOX. A rosaceous plant, formerly used as a styptic. 100 pts. of the fresh plant contain 71·0 water, 10·3 matter soluble in water, 9·2 soluble in dilute potash, 8·9 cellulose, and 1·9 ash free from carbonic acid. The ash contains, in 100 pts., after deduction of carbonic acid, 13·7 potash, 7·7 soda, 27·0 lime, 3·9 magnesia, 0·9 alumina and ferric oxide, 33·9 silica, 4·1 sulphuric anhydride, 7·6 phosphoric anhydride, and 1·2 chlorine.

SANIDIN. Glassy felspar (ii. 620).

SANIDOPHYR. A name given to trachytic porphyry, on account of the crystals of sanidin which are embedded in it.

SANTALIC ACID, SANTALIDE, SANTALIN, &c. (See SANDAL-WOOD, p. 187.)

SANTONIN. *Santonic acid*, $C^{15}H^{18}O^3$.—This substance was discovered in 1830 by Kahler (Brandes. Archiv. xxxiv. 318, xxxv. 216), and about the same time by Alms (*ibid.* xxxiv. 319, xxix. 190), in wormseed, *Semen contra*, *Semen cinæ*, or *Semen Santonici*, the undeveloped flower-heads of *Artemisia Vahliana*, and other species of the same genus. It has been investigated chiefly by H. Trommsdorff (Ann. Ch. Pharm. xi. 90) and W. Heldt (*ibid.* lxiii. 10 and 40). See also Gm. xvi. 250.

To prepare it, a mixture of wormseed, with a small quantity of dry slaked lime is exhausted with hot alcohol, the alcohol expelled by distillation, and the remaining liquid supersaturated with acetic acid. The precipitate thereby formed is purified by solution in alcohol, and treatment with animal charcoal.

Santonin crystallises in flattened hexagonal prisms, or interlaced tufts of crystals, which are colourless at first, but turn yellow on exposure to light. From an ethereal solution it is deposited in rhombic plates: sp. gr. = 1·247. Santonin has very strong lævorotatory power; for the transition-tint $[\alpha] = -230°$ at 20° in alcoholic solution, weaker after addition of alkalis, but not diminished by acids (Buignet, J. Pharm. [3] xl. 252). It is neutral according to Kahler, acid according to Ettling; inodorous; tastes slightly bitter after being kept for some time in the mouth, very bitter in alcoholic solution. It exerts an anthelmintic action, but is sometimes fatal to children when given in quickly-repeated doses of 1 to 2 grains or more (Lavater, Pharm. Viertelj. ii. 110). Larger doses of santonin given to adults produce colour-blindness, lasting for several hours. (Wells, J. Pharm. [3] xv. 111.—Martini, Compt. rend. xlvii. 259; l. 545.)

Santonin gives by analysis 72·40 to 72·6 per cent. carbon, and 7·47 to 7·67 hydrogen, the formula $C^{15}H^{18}O^3$ requiring 73·17 C, 7·32 H, and 29·51 O.

Santonin is nearly insoluble in cold, rather more soluble in hot *water*; very soluble in boiling *alcohol*, less in *ether*. According to Trommsdorff, 1 pt. of santonin requires for solution 43 pts. alcohol at 22·5°, 12 pts. at 50°, and 2·7 pts. at 80°; of ether, 5·75 pts. at 17°, 42 pts. at 40°; of water, 5000 pts. at 17·5°, and 250 at 100°. Santonin dissolves in 4·3 pts. of *chloroform*.(Schlimpert, N. Br. Arch. c. 151); also in *acetic acid* and *volatile oils*.

Santonin melts at 136° to a colourless liquid, which solidifies to a crystalline mass on cooling, but by prolonged fusion, it undergoes a molecular change, and becomes amorphous: the same character is exhibited by many other crystalline resinous bodies—helenin for example. Santonin sublimes without decomposition when heated in small quantities; but when larger quantities are heated, a considerable portion decomposes, yielding an oil, which solidifies on cooling to a brown resinous substance. By prolonged exposure to light, most quickly in alcoholic solution, it is converted into photosantonin, $C^{11}H^{14}O^3$. (Sestini, iv. 627.)

Santonin, suspended in water, and submitted to the action of *chlorine gas*, is converted into mono-, di-, or tri-chlorosantonin, according to the circumstances of the experiment (Sestini). It also yields a crystallisable substitution-product with *bromine*. (Heldt.)

Santonin dissolves without decomposition in strong *sulphuric acid*, and is precipitated from the solution by water; the solution turns red after a while, and yields a resinous substance. According to Kossmann (J. Pharm. [3] xxxviii. 81), santonin boiled with dilute sulphuric acid is resolved into glucose, and a resinous body which he calls santiretin. According to O. Schmidt, however (Zeitschr. f. Chem. [2] i. 212), no such decomposition takes place, even when the ebullition is kept up for a considerable time. If the water be not renewed as it evaporates, the acid, as it becomes concentrated, turns the santonin brown, and converts it into a resinous product—probably dehydrated santonin—which when treated with water and crystallised from alcohol, yields the santonin in its original state. (Schmidt.)

Fuming nitric acid also dissolves santonin; dilute nitric acid converts it, by prolonged ebullition, into a bitter non-crystallisable body, very soluble in water and in alcohol, and finally into a crystallisable acid, also very soluble in water and alcohol, probably succinic acid. Hydrocyanic acid is also formed, together with other volatile products.

Santonin dissolves in *caustic fixed alkalis*, forming definite compounds. It does not appear to combine with ammonia. When it is digested with alcohol and metallic oxides, the liquid assumes a fine crimson colour, which disappears after some time.

The santonates are decomposed by prolonged ebullition, santonin being set free. The *potassium-salt*, obtained like the sodium-salt, forms a gummy mass. The *sodium-salt*, $2C^{15}H^{17}NaO^3.9H^2O$, or $2(C^{15}H^8O^3.NaHO).7H^2O$, is obtained by digesting an alcoholic solution of santonin with sodic carbonate, till the mixture is decolorised; then evaporating to dryness at 30°, exhausting the residue with absolute alcohol to separate the excess of sodic carbonate, and leaving the filtrate to evaporate. It is then deposited in slender interlaced needles, which by crystallisation from a very small quantity of water, are converted into large rhombic prisms, with the dominant faces ∞P, ∞P̆∞, P̄∞. Angle ∞P : P = about 141°; P̆∞ : P̆∞ (brach.) = about 102°. The crystals lose about 7 per. cent. water at 100°. (Heldt.)

The *barium-salt*, $2C^{15}H^8O^3.Ba''H^2O^2.H^2O$ (at 100°), is obtained, by digesting hydrate of barium with alcoholic santonin till the red colour disappears, then filtering, evaporating to dryness at 37·5°, exhausting with water, and again evaporating, as a white crust, slightly gelatinous, and drying up to a light powder.

The *calcium salt*, $2C^{15}H^{18}O^3.Ca''H^2O^2$ (at 100°), obtained in like manner, crystallises in silky needles.

The *lead-salt*, $2C^{15}H^{18}O^3.Pb''O$ (at 120°), is obtained by mixing a boiling alcoholic solution of santonin with neutral acetate of lead, filtering, and exposing the mixture for some time to a temperature of 30° to 40°, avoiding the access of atmospheric carbonic acid. The compound is then deposited in mammellated groups of small nacreous needles.

Santonate of potassium forms a pale-blue precipitate with *cupric salts*, chamois-coloured with *ferric salts*, white with *mercurous*, *silver*, and *zinc salts*; it does not precipitate mercuric salts.

Bromosantonin. When bromine is dropped gradually into a cooled alcoholic solution of santonin, and the liquid is left to evaporate, a brown resin is gradually deposited, together with white, tasteless, inodorous crystals of a brominated santonin, which is very unstable, dissolves with difficulty in water, more easily in boiling alcohol and in ether; also in alcoholic potash, forming a cherry-red liquid. (Heldt.)

Chlorosantonins. (Heldt, Ann. Ch. Pharm. lxiii. 34.—Sestini, Bull. Soc. Chim. 1866, i. 202.)—These compounds are formed by the action of chlorine or of hypochlorous acid on santonin. They are less altered by light in proportion as they contain more chlorine.

Monochlorosantonin, $C^{15}H^{17}ClO^3$, appears to be produced by the action of chlorine-water on excess of santonin. Sestini, by adding half a litre of recently prepared chlorine-water to an equal volume of water holding 10 grms. of santonin in suspension, then shaking the liquid strongly in a closed vessel till the odour of the chlorine was no longer perceptible, and crystallising the product from alcohol, obtained first crystals of santonin, then a confusedly crystalline mass, which turned yellow on exposure to light, but less quickly than santonin, and contained 11·3 per cent. chlorine; -mula of monochlorosantonin requires 12·7 per cent.

Dichlorosantonin, $C^{15}H^{16}Cl^2O^3$.—When santonin suspended in water is exposed to the action of a slow current of chlorine for 10 or 11 hours, a product is obtained which crystallises from alcohol in groups of small laminæ, containing 22·4 per cent. chlorine (Sestini). Heldt, by dissolving santonin in warm hydrochloric acid containing a little alcohol, and adding small crystals of potassic chlorate, stirring all the while, and keeping the liquid warm, obtained a white amorphous mass, which when dissolved in hot alcohol, and crystallised by spontaneous evaporation, yielded delicate white shining needles, which gave by analysis 21·9 per cent. chlorine (it probably contained a small portion of monochlorosantonin).

Dichlorosantonin is insoluble in water, but dissolves easily in *alcohol* and *ether* (Heldt); less easily in alcohol than trichlorosantonin, easily in *chloroform* (Sestini). According to Sestini, it slowly acquires a slight yellow colour, on exposure to light; according to Heldt, it is not altered by exposure to diffused daylight, but when exposed to sunshine, even in an atmosphere of hydrogen, it turns rusty-red, and afterwards becomes covered with a brown crust, but not so quickly as santonin. Alcohol removes the brown crust, leaving white crystals (the effect was perhaps partly due to the monochlorosantonin in Heldt's product). Dichlorosantonin is inodorous and tasteless in the solid state, but very bitter in alcoholic solution. It melts when heated, and solidifies again on cooling; but when heated above its melting-point, it decomposes, with evolution of hydrochloric acid. It dissoles in alcoholic potash, forming an orange-red liquid. (Heldt.)

Trichlorosantonin, $C^{15}H^{15}Cl^3O^3$, was obtained by exposing 60 grms. of santonin suspended in 2½ litres of water to a slow current of chlorine continued for several hours on four successive days, washing the product with tepid water, dissolving it in boiling alcohol, and leaving the solution to evaporate. It crystallises in transparent monoclinic prisms, which are not coloured even by prolonged exposure to sunshine (analysis 34·1 per cent. chlorine; calc. 30·5 per cent.). It is insoluble or nearly so in water, but dissolves with moderate facility in *alcohol*, *ether*, and *chloroform*; from the last-mentioned liquid it crystallises in long silky needles. It does not lose weight by prolonged exposure to air dried by oil of vitriol, or when heated to 100—110°: hence the crystals appear to be anhydrous. It melts at 213°, assuming a faint brown colour. *Alcoholic potash* converts it into colourless or slightly coloured oily drops; and boiling alcoholic solutions of caustic alkalis decompose it, converting it into a resinous substance. (Sestini.)

SANTORIN. An argillaceous mineral, occurring on the island of Santorin, which yields an excellent cement. According to Elsner, it contains 68·5 per cent. silica, 5·5 ferric oxide, 13·3 alumina, 0·7 manganous oxide, 2·3 lime, 3·1 potash, 4·7 soda, with traces of common salt, sodic sulphate, and organic matter.

SAORIA. The seed of *Maesa picta*, a primulaceous plant, used in Abyssinia as a remedy for tapeworm. According to Apoiger (Jahresb. 1857, p. 530), it contains a waxy substance, a soft resin, a fatty non-drying oil, an acrid substance, extractive matter, gum, pectin, albumin, sugar, an iron-greening tannin, lactic acid, citric acid, racemic acid (?), a volatile acid (?), and a volatile oil. The seed dried at 100° yielded 7·7 per cent. ash, containing 27·84 per cent. K^2O, 9·04 Na^2O, 8·76 CaO, 7·47 MgO, 0·98 Al^2O^3, 1·69 FeO, with trace of manganous oxide, 9·00 Cl, 3·73 SO^3, 9·93 P^2O^5, 6·09 SiO^2, 15·17 CO^2, and 0·30 B^2O^3.

SAPAN-RED. *Brazilin.* $C^{22}H^{20}O^7$. (Bolley, Zürich. Mittheil. 1865, p. 2; J. pr. Chem. xciii. 451.)—The colouring matter of sapan-wood (*Cæsalpinia echinata* or *C. Sapan*), appears from Bolley's investigations to be identical with Chevreul's brazilin* (i. 655), obtained from brazil-wood (*Cæsalpinia crista*, *C. brasiliensis*, &c.). It was prepared from a crystalline deposit, which had collected at the bottom of a cask filled with extract of sapan-wood, by dissolving the deposit in absolute alcohol, and leaving the filtrate to crystallise in a vessel excluded from light and air. It is not easily obtained in the pure state from brazil-wood.

Sapan-red, or brazilin, crystallises from absolute alcohol in amber-yellow or brownish rhombohedrons, or in short monoclinic prisms containing 66·66 per cent. carbon and 5·04 hydrogen (calc. 66·66 C, 5·04 H, and 28·28 O); from hydrated alcohol or from aldehyde, in small straw-yellow or golden-yellow monoclinic needles, containing $2C^{22}H^{20}O^7.3H^2O$, turning brown at 90°, and giving off 6·61 per cent. water; no more at 120° ($\frac{3}{2}$ at. H^2O = 6·39 per cent.). They gave by analysis 62·78 per cent. C and 5·48 H (calc. 62·41 C, 5·43 H, and 32·16 O).

Brazilin is soluble in water, alcohol, and ether. The reddish aqueous solution is coloured deep carmine-red by traces of ammonia, the fixed alkalis, or baryta-water. The alcoholic solution, slowly evaporated in contact with air containing ammonia, yields iridescent spangles, which give off ammonia when treated with potash. Brazilin dissolves also in aqueous acid sulphite of sodium, and the solution deposits colourless crystals containing sulphur.

---

* The statements respecting brazilin, given (i. 656) on the authority of Preisser, are not to be depended upon.

Brazilin differs from hæmatoxylin (iii. 4) by containing the elements of phenol in addition:

$$\underset{\text{Brazilin.}}{C^{22}H^{20}O^{7}} = \underset{\text{Hæmatoxylin.}}{C^{16}H^{14}O^{6}} + \underset{\text{Phenol.}}{C^{6}H^{6}O}.$$

Accordingly, brazilin treated with nitric acid yields picric acid, whereas hæmatoxylin thus treated yields nothing but oxalic acid.

SAPHIRE. Syn. with SAPPHIRE.

SAPOGENIN. The name given by Bolley (Ann. Ch. Pharm. xc. 211; xci. 117), to the product obtained by boiling saponin with dilute sulphuric or hydrochloric acid. Fremy (Ann. Ch. Phys. [2] lviii. 102), who first obtained this substance, designated it as æsculic acid (i. 59). See also SAPONIN (p. 194), and *Gmelin's Handbook*, xv. 53.

SAPONARIN. A bitter, neutral, crystallisable substance, occurring, according to Osborne (Ann. Phil. xi. 302), in the roots of *Saponaria officinalis*, before flowering time, but not afterwards. It dissolves in less than 2 pts. of water, is soluble also in alcohol and ether, insoluble in oil of turpentine.

SAPONIFICATION. This term was originally applied to the conversion of natural fats (glycerides) into soaps, by the action of alkalis or other metallic hydrates, the change consisting in the rearrangement of the elements of the acting substances in the form of a metallic salt of the fatty acid, and glycerin. It is now, however, used in a wider sense, being extended to the resolution of all ethers, and neutral substances of analogous composition, into acids and alcohols; sometimes even to the decomposition of glucosides under the influence of dilute acids. (See ETHERS, GLUCOSIDES, GLYCERIDES, SOAP.)

SAPONIN. *Struthiin. Githagin. Senegin. Polygalin. Polygalic acid.*—This substance, first observed by Schrade (Gehlen's N. Journ. d. Chem. viii. 548) in the common soapwort (*Saponaria officinalis*), and some time afterwards by Bley (Ann. Ch. Pharm. iv. 283) and Bussy (*ibid.* vii. 168) in the oriental soapwort (*Gypsophila Struthium*), appears to be very widely diffused in the vegetable kingdom. It has been found by O. Henry and Boutron-Charland (J. Pharm. iv. 249) in quillaja-bark (*Quillaja smegmadermos*), by Fremy (Ann. Ch. Pharm. xv. 187) in horse-chestnuts, in which, according to Malapert (J. Pharm. [3] x. 339), it exists chiefly in the ovaries during flowering-time, and in the pericarp of the fruit, immediately after the petals have fallen off. Malapert has also found it in the roots of pinks, in the corn-cockle (*Agrostemma Githago*), the white campion (*Lychnis dioica*), the scarlet lychnis (*L. chalcedonica*); also in *Lychnis Flos cuculi, Silene inflata, Silene nutans, Anagallis arvensis*, and *A. cærulea.*

Saponin is said also to be contained in *Arnica montana, Arum maculatum, Capsella Bursa Pastoris*, the bark of *Gymnoclodeis canadensis*, the root of *Polypodium vulgare*, the fruit of *Sapindus Saponaria, S. laurifolius*, and *S. rigidus*, of *Pircunia abyssinica*, and in many plants of the sapindaceous and mimoseous orders. The irritating extractive matter in the root of the cowslip is, perhaps, identical with saponin.

Senegin, or *Polygalin*, discovered by Gehlen in the root of *Polygala Senega*, which was associated with saponin by Bucholz and Pfaff, minutely examined by Quevenne, who named it *acide polygalique*, is, according to Bolley, probably identical with saponin.

Preparation: A. *From the root of Saponaria*, or of *Gypsophila Struthium.*—1. The chopped root is exhausted with boiling alcohol of specific gravity 0·824; the filtrate is cooled; and the deposit of saponin, which separates after 24 hours, is collected, washed with ether and alcohol, and dried at 100° (Rochleder and Schwarz).—2. The coarsely-pounded root is freed by ether from resin and fat, then boiled with alcohol, and the flocks which separate on cooling and concentration are collected. (Bley and Bussy.)

Saponin prepared from *Gypsophila* is sometimes contaminated with foreign substances. It is purified by dissolving it in the smallest possible quantity of water, and adding baryta-water, which precipitates saponin-baryta, leaving the foreign substances in solution. The white precipitate is washed with baryta-water, and dissolved in water; on passing carbonic acid through the solution, and heating it, carbonate of barium separates out; and after its removal, the saponin may be precipitated by ether-alcohol. (Rochleder and De Payr.)

B. *From Quillaja-bark.*—This, according to Le Beuf, is the best material for preparing saponin for technical purposes. The same process as in A 1 (Le Beuf); or the aqueous extract is boiled with alcohol; the liquid is filtered at the boiling heat; and the white flocks, which fall down on cooling and concentration, are purified by solution in alcohol, with aid of animal charcoal. (Henry and Boutron, Bley.)

C. *From the seeds of the Corn-cockle* (*Agrostemma Githago*).—1. The coarsely pulverised dry seeds are freed from fixed oil by repeated exhaustion with ether, then by once exhausting with cold alcohol of 92° Tralles; the residue is boiled several times with alcohol of 84° Tr.; the liquid is filtered at the boiling heat; and the saponin which separates on cooling is collected, an additional quantity being obtained by mixing the mother-liquor with absolute alcohol. The whole of the saponin thus obtained is dissolved in water; the solution is filtered to separate vegetable gelatin, then precipitated with neutral acetate of lead; the precipitate removed; the filtrate precipitated with basic acetate of lead; the latter precipitate, after thorough washing, decomposed under water by sulphydric acid; and the limpid filtrate evaporated to dryness, or precipitated with absolute alcohol (Scharling).—2. The aqueous extract of the seed is precipitated with sulphate of copper; sulphydric acid is passed through the filtrate; the liquid again filtered, then digested with carbonate of barium; the resulting barium-salts precipitated by alcohol and separated by filtration; and the filtrate either strongly concentrated (in which case the saponin is to be precipitated by absolute alcohol), or evaporated to dryness, and the residue boiled with alcohol of 93° Tr. Saponin thus prepared contains a small quantity of baryta (Scharling).—3. Crawfurd digests the pulverised seeds with warm aqueous alcohol, evaporates the liquid to a syrup, mixes it with wood-charcoal, and dries it completely. The saponin is extracted from the residue by boiling with alcohol.

D. *From Horse-chestnuts.*—The pulverised seeds are exhausted with cold alcohol, and the alcohol is distilled from the tinctures. The yellowish jelly which remains consists, for the most part, of saponin, mixed with fat, a bitter crystallisable substance, and yellow-colouring matter; the fat may be removed by exhaustion with ether. (Frémy.)

E. *From Senega-root:* Senegin, Polygalic acid.—1. The root is exhausted with cold water; the extract concentrated, and filtered from the separated flocks containing senegin and earthy salts; the filtrate precipitated with neutral acetate of lead; the liquid again filtered, freed from lead by sulphydric acid, and evaporated to an extract; this extract exhausted with alcohol of 36°; the tincture evaporated; the residue freed by ether from yellow-colouring matter and fat, then dissolved in water; the solution precipitated with basic acetate of lead; and the precipitate washed and decomposed by sulphydric acid. Part of the senegin then remains with the sulphide of lead, while another portion dissolves, so that:—*a.* The sulphide of lead is collected and boiled with alcohol; *b.* The liquid filtered from the sulphide of lead is evaporated to dryness, and the residue is boiled with alcohol. The hot-filtered tinctures cooled and left to evaporate, deposit senegin, which may be purified, if necessary, by re-solution in alcohol and treatment with animal charcoal (Quevenne). Senega-root exhausted with water still yields senegin when boiled with alcohol, the tincture depositing the senegin when cooled or concentrated. It is purified from fat by ether, then with basic acetate of lead, as above (Quevenne).—2. Bolley precipitates the aqueous solution of officinal extract of senega with neutral acetate of lead; collects and washes the precipitate; decomposes it with sulphydric acid; evaporates the filtrate to dryness; boils the residue with alcohol; evaporates the tincture; treats the residue with ether; dissolves the portion not taken up by the ether in water; precipitates the solution with basic acetate of lead; decomposes the thoroughly-washed precipitate under water with sulphydric acid; evaporates the filtrate; and purifies the senegin which remains by repeated solution in boiling alcohol and cooling.

Properties.—Saponin is a white or nearly white, noncrystalline, friable powder, having a peculiar aromatic odour (Quevenne), inodorous when dry, but having a disagreeable odour when dissolved in water (Scharling). The dust excites violent sneezing. It tastes sweetish at first, then burning and biting, and produces a persistent scratching sensation in the throat. A drop of the aqueous solution introduced into the eye produces violent burning pain, and dilatation of the pupil. Saponin is generally said to be neutral to vegetable colours; but senegin, according to Quevenne, is acid. It acts poisonously on the smaller animals.

The following are analyses of saponin:—

		Rochleder and Schwarz. at 100°.	Overbeck. *mean* at 100°.	Bolley. *mean.*	Crawford.	Rochleder. *mean* at 100°.	Payr. *mean* at 100° *in vacuo.*	Quevenne. *Senegin.*	Bolley. *Senegin.*
Carbon	50·0	52·54	46·81	49·10	50·72	52·64	53·17	54·62	53·58
Hydrogen	7·4	7·26	7·51	6·88	7·44	7·37	7·57	7·53	6·23
Oxygen	42·6	40·20	45·68	44·02	41·84	39·99	39·26	37·85	40·19
	100·0	100·00	100·00	100·00	100·00	100·00	100·00	100·00	100·00

From these discordant results, it is impossible to deduce a formula with certainty; and saponin does not form any definite compounds by the composition of which the analyses might be checked. Rochleder and Schwarz propose for saponin the formula $C^{12}H^{20}O^7$, which requires 52·17 C, 7·24 H, and 40·59 O; Rochleder and v. Payr give for saponin, dried at 100°, $C^{64}H^{106}O^{36}$, requiring 52·97 C, 7·31 H, and 39·72 O. The analyses of senegin agree more nearly with $C^9H^{12}O^5$, requiring 54 C, 6 H, and 40 O; but as neither this substance nor saponin from other sources has been obtained in a perfectly definite state, and as their properties and products of decomposition are essentially the same, it is most probable that senegin is identical with saponin.

Saponin dissolves in *water*, forming a frothy solution, more easily in dilute than in strong *alcohol*, and is insoluble in absolute alcohol, in ether, and in volatile oils: the alcoholic solution does not froth. It is not altered by cold dilute *acids*, and does not unite with them. It dissolves slightly in cold *ammonia* and *potash*, more easily in the same liquids when warm. A solution of saponin in 4 pts. of water forms with *baryta-water* a white precipitate, soluble in excess of saponin or of baryta-water (Bussy); insoluble or nearly so in baryta-water, but easily soluble in pure water (Rochleder and Schwarz). With *neutral acetate of lead*, saponin forms a gelatinous precipitate; and on boiling the filtrate, a further precipitate of pulverulent character is obtained, which swells up during washing. It likewise precipitates *basic acetate of lead*.

Decompositions.—1. Saponin submitted to dry distillation swells up, blackens, and yields a large quantity of acid empyreumatic oil.—2. Boiling *nitric acid* attacks it, forming a yellow resin, mucic acid, and oxalic acid.

Saponin is decomposed by *dilute mineral acids*, slowly in the cold, more quickly when heated, into a carbohydrate and a white precipitate, called sapogenin by Bolley, æsculic acid by Frémy, and regarded by Rochleder and Schwarz as identical with quinovin (p. 32). The composition of this substance has not been precisely ascertained, as its analyses give results varying from 56·9 to 63·2 per cent. carbon, and 8·5 to 8·9 hydrogen; and accordingly various equations have been proposed to explain its formation from saponin. According to Rochleder and Schwarz, the reaction is:—

$$\underset{\text{Saponin.}}{2C^{12}H^{20}O^7} = \underset{\text{Quinovin.}}{C^{12}H^{18}O^3} + \underset{\text{Carbohydrate.}}{C^{12}H^{22}O^{11}}$$

according to Overbeck:—

$$\underset{\text{Saponin.}}{C^{21}H^{38}O^{15}} = \underset{\text{Saporetin.}}{C^9H^{14}O^3} + \underset{\text{Carbohydrate.}}{C^{12}H^{24}O^{12}}$$

according to Bolley:—

$$\underset{\text{Saponin.}}{2C^{18}H^{24}O^{10}} + 5H^2O = \underset{\text{Sapogenin.}}{C^{12}H^{18}O^5} + \underset{\text{Carbohydrate.}}{4C^6H^{10}O^5}.$$

According to Rochleder and v. Payr (Wien. Akad. Ber. xlv. 7), saponin, when decomposed by acids, is capable of yielding various products of decomposition, according as, of the 6 at. carbohydrate which it may be supposed to contain, two, more than two, or the whole are separated. The products resulting from partial separation are obtained by the action of aqueous acids, but complete decomposition is produced only by the action of alcoholic hydrochloric acid (Rochleder and v. Payr). According to this, only the crystals described under *d* are the true sapogenin.

a. The product obtained from saponin, $C^{64}H^{106}O^{36}$, by elimination of 2 at. carbohydrate ($C^6H^{12}O^6$), is perhaps Frémy's æsculic acid (i. 59), as it agrees in amount of carbon with the formula $C^{52}H^{82}O^{24}$ (calc. 57·25 per cent. C and 7·52 H). (Rochleder.)

b. Saponin purified with baryta-water yields, when heated with aqueous hydrochloric acid, 53·1 per cent. sugar, and gelatinous flocks, which, when dried at 100°, contain, on the average, 65 per cent. C and 8·64 H, agreeing nearly with the formula $C^{40}H^{62}O^{14}$ (calc. 62·66 per cent. C and 8·09 H). In this case the decomposition takes place chiefly in the manner shown by the equation:

$$C^{64}H^{106}O^{36} + 2H^2O = C^{40}H^{62}O^{14} + 4C^6H^{12}O^6$$

(calc. 49·62 per cent. $C^{12}H^{12}O^{12}$).

c. By prolonged boiling with aqueous hydrochloric acid, 62·66 per cent. sugar and a $C^{34}H^{52}O^9$, are obtained (calc. 67·55 per cent. C and 8·61 H):

$$C^{64}H^{106}O^{36} + 3H^2O = C^{34}H^{52}O^9 + 5C^6H^{12}O^6,$$

(calc. 59·8 per cent. $C^{12}H^{12}O^{12}$).

d. When the flocks which separate on boiling saponin with aqueous hydrochloric acid, are dissolved in anhydrous alcohol, and hydrochloric acid gas is passed for several hours through the boiling solution, white crystals, $C^{28}H^{42}O^4$, are deposited, produced by complete resolution of the saponin (Rochleder and v. Payr):

$$C^{64}H^{106}O^{36} + 4H^2O = C^{28}H^{42}O^4 + 6C^6H^{12}O^6.$$

These crystals, after recrystallisation from alcohol and drying at 100°, contain, on the average, 75·78 per cent. C, 9·76 H, and 14·46 O (calc. for $C^{28}H^{42}O^4$, 76·02 per cent. C, 9·50 H, and 14·48 O). They are insoluble in water, dissolve sparingly in cold, easily in hot alcohol, and are nearly insoluble in aqueous potash. From the easily-produced solution in alcoholic potash, aqueous potash throws down almost the whole of the compound of sapogenin and potash, which gives up its potash during washing. (Rochleder and v. Payr.)

The carbohydrate produced together with sapogenin, is insoluble in alcohol at the moment of separation, and is converted into dextroglucose only by the prolonged action of hot acids. (Rochleder and v. Payr.)

When saponin from horse-chestnuts is treated with *potash-ley*, a compound of potash with a yellow-colouring matter contained in the saponin is first formed; afterwards sapogenin-potash (æsculate of potassium), from the solution of which the sapogenin is thrown down by acids (Frémy). Saponin from soapwort treated in like manner does not yield sapogenin (Frémy). Aqueous saponin boiled with potash-ley, then mixed with hydrochloric acid, yields a white, tolerably abundant, non-gelatinous precipitate of sapogenin (Quevenne). Saponin mixed with potash-ley and evaporated turns brown, and the residue forms, with water, a brown solution, from which acids do not precipitate Frémy's æsculic acid (Rochleder and Schwarz). By the action of potash upon saponin, a finely-crystallised acid and an amorphous substance are obtained, the latter being resolved by hydrochloric acid into two products. (Rochleder and v. Payr, Wien. Akad. Ber. xxiv. 42.)

Saponin boiled with an alkaline solution of *cupric oxide*, throws down a small quantity of cuprous oxide (Bolley). According to Scharling, it forms, with cupric sulphate and potash, a blue-green precipitate, without reducing the cupric oxide.

SAPONITE. Syn. with SOAPSTONE.

SAPORETIN. $C^9H^{14}O^2$? The substance produced, according to Overbeck, together with sugar, by boiling saponin with dilute acids (p. 194).

SAPPARE, SAPPARITE. Syn. with KYANITE (iii. 449).

SAPPHIRE. See CORUNDUM (ii. 86). Deville and Caron have produced sapphires artificially, by exposing a fluoride of aluminium mixed with a little fluoride of chromium to a white heat, in a crucible made of alumina and enclosing a small platinum dish containing boric anhydride. (Compt. rend. xlvi. 764; Jahresb, 1858, p. 2.)

SAPPHIRE-QUARTZ. Quartz from Gölling, in the Salzburg territory in Upper Austria, coloured blue by admixed crocidolite.

SAPPHIRIN. A hard blue mineral occurring, with mica and anthophyllite, at Fiskenaes, in Greenland Its structure is granular massive; hardness = 7·8; specific gravity = 3·42—3·48; lustre vitreous. It is translucent, and exhibits colours by polarised light: probably trimetric.—*Analyses: a.* by Stromeyer (Gilb. Ann. lxiii. 374); *b.* by Damour (Bull. Geolog. de Fr. [2], vi. 315):—

SiO^2.	Al^2O^3.	MgO.	FeO.	MnO.	CaO.	Loss by ignition.		
14·51	63·10	16·85	3·92	0·53	0·38	0·49	=	99·78
14·86	63·25	19·28	1·99				=	99·38

These results agree approximately with the formula $(2Al^2O^3.3SiO^2).6(MgO.Al^2O^3)$.

SAPROCHROME. *Saprocyanogen. Saprocyanin* (from σαπρός putrid, χρῶμα colour, κύανος blue). A blue or red colouring matter, produced by the putrefaction of certain *Oscillatoriæ*. (Nees v. Esenbeck, Ann. Ch. Pharm. xvii. 76; Handw. vii. 244.)

SAPUCAIA. *Lecythis urnigera.*—A Brazilian tree of the myrtaceous order, producing a bottle-shaped fruit. The juice (*sapucaia-wine*), which flows from incisions in old trees, contains in 1000 pts.: 91·2 pts. free acetic acid, 27·4 uncrystallisable sugar, 3·9 iron-blueing tannin, 40·0 gum and extractive matter, with traces of gallic acid, 9·9 potassic and calcic acetates. The shell of the fruit contains a tannin (lecythitannic acid), which appears to be related to quercitannic acid, and in the older fruits is converted into a brown substance (*sapucaia-brown*), soluble in hot water and in alcohol.

The fatty oil of sapucaia-nuts, amounting to about 39 per cent., is non-drying, and resembles oil of almonds. (Peckolt, J. Pharm. [4] i. 319.)

SARACENIA. The root and leaves of *Saracenia purpurea* (a plant of frequent occurrence in Canada and the northern states of the American Union, and recommended as a remedy against smallpox) contain, besides the usual plant-constituents, a volatile acid (acrylic acid) and 0·18 per cent. of a base (not yet examined) which smells like conine, and is volatile at ordinary temperatures. (Björklund and Dragendorff, Russ. Zeitschr. Pharm. ii. 317, 344, 369.)

SARCINE. $C^5H^4N^4O$. (Strecker, Ann. Ch. Pharm. cii. 294; cviii. 129.)—A weak organic base, existing in the juice of muscular flesh. It is isomeric with Scherer's hypoxanthine, and Scherer is of opinion that the two are identical. According to Strecker, however, sarcine is distinguished from hypoxanthine by its crystalline character, its greater solubility in water and in cold hydrochloric acid, and by not being decomposed when dissolved in nitric acid. Probably hypoxanthine is impure sarcine, or a mixture of that substance with xanthine (*q. v.*).

Sarcine is found in the mother-liquor of the preparation of creatine. It has hitherto been obtained only from the flesh of oxen and horses; 100,000 pts. of beef yield 22 pts. of sarcine. Human urine sometimes contains a body which is perhaps sarcine, and perhaps also guanine, $C^5H^5N^5O$ (= sarcine + NH).

Preparation.—Sarcine is separated from the hot dilute mother-liquors obtained in the preparation of creatine, by precipitation with cupric acetate (or better with silver-nitrate). The precipitate, which contains a compound of sarcine with the metallic oxide or salt, together with foreign substances, is washed on a filter with boiling water and decomposed by sulphydric acid; the filtrate is evaporated; and the coloured sarcine which separates is purified by solution in hot water, with addition of hydrate of lead, precipitation of the filtrate with sulphydric acid, and evaporation.

Properties.—Sarcine separates from aqueous solution as a white indistinctly crystalline powder, which does not melt at 150°, but decomposes at higher temperatures, giving off hydrocyanic acid and a white sublimate (cyanuric acid?) It dissolves in 300 pts. of cold and 78 pts. of boiling water, and in 900 pts. of boiling alcohol. The solutions do not redden litmus. In hydrochloric acid, potash, ammonia, and baryta-water, it dissolves more easily than in water. Strong sulphuric acid and nitric acid also dissolve it easily, without colouring or evolution of gas; but when evaporated with excess of nitric acid, and somewhat strongly heated, it yields a yellow residue, which is turned red by potash: this reaction is likewise exhibited by hypoxanthine, guanine, and xanthine.

Sarcine forms definite compounds, both with acids and with metallic bases. A solution of sarcine in boiling hydrochloric acid yields colourless, nacreous, tabular crystals of the *hydrochlorate*, $C^5H^4N^4O.HCl.H^2O$.—The *chloroplatinate*, $2(C^5H^4N^4O.HCl)PtCl^4$, is a yellow crystalline precipitate.—The *nitrate* forms transparent crystals, resembling acetate of sodium, which become opaque on exposure to the air, and are turned milk-white and decomposed by water. The *sulphate* is precipitated by alcohol from a solution of sarcine in strong sulphuric acid, in needle-shaped crystals, likewise decomposible by water.—*Urate of Sarcine*, $C^5H^4N^4O.C^5H^4N^4O^3$, is precipitated by urate of potassium from the solution of the hydrochlorate. It is distinguished from xanthine, $C^5H^4N^4O^2$, with which it is polymeric, by the behaviour of its nitric acid solution with nitrate of silver, forming therewith a copious white precipitate, which dissolves but slowly at the boiling heat, whereas the solution of xanthine in nitric acid is not precipitated by nitrate of silver.

A solution of sarcine in boiling *baryta-water* mixed with a cold-saturated solution of baryta, deposits the compound, $C^5H^4N^4O.Ba''H^2O^2$, in colourless crystals. From solution in caustic *potash*, sarcine is for the most part precipitated by carbonic acid. The compounds of sarcine with *zinc-oxide*, *cupric oxide*, and *mercuric oxide*, are flocculent precipitates, insoluble in water. With *nitrate of silver*, sarcine forms a white flocculent precipitate, insoluble in cold nitric acid, and crystallising from hot nitric acid in scales having the composition $C^5H^4N^4O.AgNO^3$. An ammoniacal solution of nitrate or chloride of silver forms with solution of sarcine, a gelatinous precipitate consisting of $C^5H^4N^4O.Ag^2O$, which contracts strongly in drying, and is insoluble in ammonia. These silver-precipitates may be used for the purification and quantitative estimation of sarcine.

SARCOCOLLA. A gum-resin collected in Ethiopia and at the Cape of Good Hope, probably from *Penacca mucronata*, *P. Sarcocolla*, and *P. squamosa*. It forms yellow irregular grains of various size, and more or less aggregated; is inodorous; has a sharp and sweetish-bitter taste; swells up strongly when heated, without completely melting; and burns with an odour like that of caramel. It consists chiefly of resin, gum, and **sarcocollin**, a body resembling glycyrrhizin, which may be separated by extracting the resin with ether and treating the residue with alcohol, which dissolves the sarcocollin and leaves the gum.

Sarcocollin remains, on evaporating the alcoholic solution, as a brownish, semitransparent, amorphous mass, which has a sweetish and afterwards bitter taste, softens without melting when heated, and finally burns away, almost without residue, emitting an odour of burnt sugar. It dissolves in 40 pts. of cold and 25 pts. of boiling water. Its solution, saturated when hot, deposits a syrupy liquid no longer soluble in water (a property which seems to indicate that sarcocollin is a mixture). Alcohol dissolves it in almost all proportions, forming a solution which is clouded but not precipitated by water. Sarcocollin contains, according to Pelletier (Ann. Ch. Pharm. vi. 32), 57·13 per cent. carbon, 8·34 hydrogen, and 34·31 oxygen. According to Johnston, it is a mixture of several resins, which may be separated by bases. Acetate of lead throws down from the alcoholic solution, a lead-salt containing the compound $C^{20}H^{30}O^{8}$; and the filtrate yields with ammonia a further precipitate, which has not been analysed.

SARCOCOLLIN. See the last article.

SARCOLITE. A mineral from Vesuvius, occurring in small flesh-coloured or reddish-white quadratic crystals, exhibiting the combination $P . \frac{1}{3}P . 3P . \infty P . P\infty . \infty P\infty . \infty P . 3P3 . P3$, the last occurring hemihedrally, as a pyramid of the third order. Angle $oP : P = 128° 45'$; $oP : P\infty = 138° 27'$ (Rammelsberg, Pogg. Ann. cix. 570). The crystals are translucent, and have a vitreous lustre. Hardness = 5·5 to 6·0. Specific gravity = 2·545 (Scacchi); 2·932 (Rammelsberg). Melts before the blowpipe to a white enamel, and is decomposed by acids, with separation of gelatinous silica.

Analyses: *a.* by Scacchi (Mem. min. e geol., Napoli, 1841—1843).—*b.* by Rammelsberg (*loc. cit.*):

	SiO^2	Al^2O^3	CaO	Na^2O	K^2O		
a.	42·11	24·50	32·43	2·93		=	101·97
b.	40·51	21·54	32·36	3·30	1·20	=	98·91

Rammelsberg's analysis may be represented by the formula $3[2(Ca''O ; Na^2O ; K^2O).SiO^2]$, $(2Al^2O^3.SiO^2)$ or $3(Ca'' ; Na^2 ; K^2)^2SiO^4.\overset{\prime\prime\prime}{Al^4}Si^3O^{12}$, included under the general formula of garnet, $3M^4SiO^4.\overset{\prime\prime\prime}{Al^4}Si^3O^{12}$. For 6 at. SiO^2, 2 at. Al^2O^3, 5·4 at. $Ca''O$, and 0·6 at. Na^2O, the formula requires 40·41 per cent. silica, 22·45 alumina, 33·05 lime, and 4·09 soda.

The name **sarcolite** was also applied by Vauquelin to gmelinite.

SARCOSINE. $C^3H^7NO^2$ = *Methyl-glycocine*, $C^2H^4(CH^3)NO^2$ = 
$$\left.\begin{matrix} H^2 \\ (C^2H^2O)'' \\ CH^3 \end{matrix}\right\} \begin{matrix} N \\ O \end{matrix}.$$

(Liebig, Ann. Ch. Pharm. lxii. 310.—Dessaignes, Compt. rend. xli. 1258.—Volhard, Ann. Ch. Pharm. cxxiii. 261.)—A weak organic base, metameric with alanine, lactamic acid, and urethane or ethylic carbamate. It is produced: 1. Together with urea (carbamide), by the action of baryta on creatine:

$$\underset{\text{Creatine.}}{C^4H^{11}N^3O^3} = \underset{\text{Sarcosine.}}{C^3H^7NO^2} + \underset{\text{Urea.}}{CH^4N^2O}.$$

The urea may be detected in the liquid during the progress of the reaction, but is almost immediately resolved into carbonic acid and ammonia (Liebig).—2. By the action of methylamine on monochloracetic acid, just as glycocine is formed by treating that acid with ammonia (Volhard):

$$C^2H^3ClO^2 + CH^5N = HCl + C^3H^7NO^2.$$

Preparation.—1. Ten parts of baryta-crystals (free from potash, soda, lime, chlorine, and nitric acid, which substances are difficult to separate from sarcosine) are added to a boiling saturated solution of 1 pt. of creatine in water, the mixture being kept boiling and the water and baryta renewed, as long as ammonia continues to escape, and a precipitate of barytic carbonate to form; the liquid is filtered from this precipitate; the caustic baryta precipitated by a stream of carbonic acid gas, and the filtrate evaporated to a syrup: this syrup, when set aside, solidifies to a heap of transparent and colourless crystalline laminæ. To purify the product, the mass is dissolved in excess of dilute sulphuric acid; the solution evaporated to a syrup over the water-bath; the syrup mixed with alcohol by stirring the two together with a glass rod, till the mixture is converted into a white cyrstalline powder of sulphate of sarcosine; the powder is washed with cold alcohol (which dissolves out a substance resembling urethane), dissolved in water, and heated with carbonate of barium till the liquid becomes neutral, and the filtrate is evaporated over the water-bath to a syrup, which crystallises in 24 to 36 hours.

2. Ethylic chloracetate is heated in a sealed tube to 120°—130°, with excess of concentrated aqueous methylamine, whereby the chloracetic acid is completely decomposed, and hydrochlorate of methylamine is produced, together with sarcosine. The liquid is then boiled with baryta-water till the whole of the methylamine is distilled off, and the remaining solution is freed from baryta by sulphuric acid, and evaporated to a syrup. Hydrochlorate of sarcosine then separates in a crystalline mass, which must be pressed between paper and dissolved in boiling alcohol, whence it separates in shining needles. On decomposing this salt with carbonate of silver, treating the filtrate with animal charcoal, and evaporating, sarcosine separates in crystals after a few days.

Properties.—Sarcosine forms trimetric crystals, $\infty P . \bar{P}\infty$, with the faces P and oP, less frequent and but slightly developed. Angle $\infty P : \infty P = 77°$ (Kopp). They are rather large, colourless, and perfectly transparent, very soluble in water, slightly soluble in alcohol, insoluble in ether. They preserve their appearance unaltered at 100°, but melt at a higher temperature and volatilise without residue.

Sarcosine heated with soda-lime gives off methylamine. The aqueous solution of the sulphate is decomposed by peroxide of lead, with brisk effervescence, yielding an alkaline solution, which contains methylamine. (Dessaignes.)

The aqueous solution of sarcosine is neutral to vegetable colours, and has an acrid, sweetish, slightly metallic taste. It does not precipitate a solution of silver-nitrate or mercuric chloride; but a crystal of sarcosine introduced into a cold saturated solution of *mercuric chloride* dissolves readily, and soon forms numerous delicate needles of a double salt, which ultimately converts the liquid into a solid mass. A solution of *cupric acetate* is coloured dark-blue by sarcosine in the same manner as by ammonia, and the liquid yields by evaporation thin laminæ of a double salt having the same colour.

Hydrochlorate of Sarcosine.—Sarcosine evaporated with hydrochloric acid yields a white mass, which crystallises from alcohol in small transparent needles. The solution mixed with excess of platinic chloride, yields, by spontaneous evaporation, large, honey-yellow, octahedral segments of a *platinum-salt*, which, when freed from excess of platinic chloride by washing with ether and alcohol, contains $2(C^3H^7NO^2.HCl).PtCl^4.2H^2O$: it gives off its water at 100°.

The *sulphate*, $2C^3H^7NO^2.H^2SO^4$, prepared as above (p. 198), dissolves in 10 to 12 pts. of boiling alcohol, and separates on cooling in transparent, colourless, highly lustrous, four-sided plates, resembling chlorate of potassium. It gives off its water (6·8 per cent.) at 100°, dissolves readily in water, forming an acid solution, very slightly in cold alcohol. From the aqueous solution it crystallises in large plumose laminæ. (Liebig.)

SARD. A deep brownish variety of chalcedony, of a blood-red colour by transmitted light.

SARDACHATES. The ancient name of a variety of agate, containing layers of sand or cornelian.

SARDONYX. Onyx consisting of layers of sand and white chalcedony.

SARSAPARILLA-ROOT. The root of the South American *Smilax Sarsaparilla*, *Sm. syphilitica*, or *Sm. officinalis*, and probably of other species of the same genus. It contains, besides gum, starch, &c., a peculiar substance, variously designated as parallin, pariglin, parallic acid, salsaparin, sarsaparillin, and smilacin.

SARSAPARILLIN. This substance, first extracted from sarsaparilla by Pallota (Schw. J. xliv. 147), and further studied by Poggiale (Ann. Ch. Pharm. xiii. 84), Thubeuf (*ibid.* xiv. 76), and Petersen (*ibid.* xv. 74; xvii. 166), is deposited in the crystalline form from the concentrated alcoholic extract of the root, previously decolorised by animal charcoal. and may be purified by recrystallisation. It forms colourless inodorous needles, very soluble in water and alcohol at the boiling heat, less soluble at ordinary temperatures, soluble also in ether and volatile oils, slightly soluble in fixed oils. The solutions froth when agitated. The crystals contain 8·56 per cent. water, which they give off at 100°. The dried substance gives by analysis from 62·1 to 63·6 per cent. carbon, and 8·4 to 9·8 hydrogen. Sarsaparillin is decomposed by nitric acid. Strong sulphuric acid dissolves it with deep red colour, changing to violet, and ultimately to yellow. Water precipitates it unaltered. (See PARIGLIN, *Handw. d. Chem.* vi. 94.)

SASSAFRAS-OIL. A volatile oil obtained from the bark and wood of the root of *Laurus Sassafras.* It has a faint yellow colour, a peculiar odour like that of fennel, and an acrid taste. Specific gravity = 1·09. When distilled, it begins to give off vapour at 115°, but the boiling-point quickly rises to 228°, where it remains stationary, and a slightly brown-yellow residue remains in the retort.

Oil of sassafras is a mixture of two bodies. When exposed to a freezing mixture (composed of 12 pts. ice, 5 pts. common salt, and 5 pts. nitrate of ammonium), it becomes filled with bulky crystals of a camphor or stearoptene, containing 73·9 per cent. carbon and 6·4 hydrogen, agreeing nearly with the formula $C^{10}H^{10}O^2$. Vapour-density of the crystals: obs. = 5·800—5·956: calc. = 5·67.

Bromine acts strongly on oil of sassafras, hydrobromic acid being copiously evolved, and a crystalline mass formed, consisting of $C^{10}H^8Br^2O^2$. The action of *chlorine* is less definite. According to Faltin (Ann. Ch. Pharm. lxxxvii. 376), it eliminates a large quantity of hydrochloric acid, and forms a viscous mass, which, when neutralised with milk of lime, yields a small quantity of common camphor (perhaps formed from the liquid which, together with the crystalline compound above mentioned, constitutes oil of sassafras).

Pentachloride of phosphorus attacks oil of sassafras strongly, and the product distilled in an oil-bath yields at 238° an oily liquid, holding in solution phosphoric oxychloride, from which it may be freed by washing. When purified by rectification over massicot in a current of carbonic anhydride, it contains $C^{10}HCl^9O^2$. (St. Evre, Ann. Ch. Phys. [3] xii. 107.)

Oil of sassafras is inflamed by *fuming nitric acid;* with acid of ordinary strength it forms a yellow resin; with dilute nitric acid it yields oxalic acid.

Sulphuric anhydride, or *strong sulphuric acid*, attacks the oil violently, often setting it on fire. The product is a red resin, often accompanied by deposited carbon (see SASSARUBRIN); on diluting with water, and saturating with carbonate of barium, a resinous salt is obtained. The oil subjected to the prolonged action of a current of *sulphurous anhydride*, turns yellow, and becomes hot, the colour afterwards changing to green, and finally to orange-yellow. Sulphur is then deposited, and the liquid, when left at rest, separates into two layers, the upper consisting of undecomposed sassafras-oil, and the lower of a new oil distilling at 235°, and consisting, according to St. Evre, of $C^{10}H^{10}O^3$.

When oil of sassafras is passed through a red-hot tube, or over potash-lime, naphthalene is produced, together with phenol. According to St. Evre, it may be distilled without alteration over phosphoric anhydride, chloride of zinc, potassium, or a mixture of sulphuric acid and dichromate of potassium.

SASSAFRAS-ROOT. The root-bark of *Laurus Sassafras*, a North-American tree, contains, according to Reinsch (Repert. Pharm. xxxix. 180), in 100 pts., 6·6 pts. of substances extractable by ether (light and heavy essential oil, camphoroïdal and tallow-like substance, balsamic resin and wax), 15·0 pts. by strong alcohol (consisting of 9·2 sassafrid and 5·8 tannic acid), 6·8 pts. by weaker alcohol (gum, sassafrid, and tannic acid), 3·6 by cold water, 5·4 by boiling water, 28·9 by potash-ley, and 33·7 pts. vegetable fibre. The wood of the root contains similar constituents, but in much smaller quantity.

SASSAFRID. A constituent of the root-bark of *Laurus Sassafras*, which may be extracted by alcohol, after the bark has been freed by ether from volatile oil, wax, &c. The sassafrid is separated from the alcoholic solution by water, and when recrystallised from alcohol, forms yellow-brown crystalline grains, which easily make marks like chalk, and have neither taste nor smell. When heated in the air it swells up, emitting a pungent odour; by distillation it gives off white vapours, condensing to a white powder, which forms a blue-green precipitate with ferric salts. Cold water has but little action on sassafrid; hot water forms a red-brown solution, which becomes turbid on cooling. In ether sassafrid dissolves slowly, with wine-yellow colour; nitric acid converts it into oxalic acid and an oily body. The concentrated solution of sassafrid is precipitated by lime-water, baryta-water, and various metallic salts; dilute sulphuric and nitric acids render its colour lighter; tincture of galls and ferrocyanide of potassium have no effect upon it.

SASSAFRIN. See SASSARUBRIN.

SASSA-GUM. *Pseudo-tragacanth.* A gum obtained from *Inga Sassa*, an Abyssinian plant. It swells up in water, like gum-tragacanth, but does not form so thick a mucilage. It is also mixed with a much greater proportion of starch-granules, so that it is coloured dark-blue by iodine.

SASSAPARILLA. Syn. with SARSAPARILLA.

SASSARUBRIN. A resin produced, according to Hare (Sill. Am. J. xxxiii.

285), by the action of sulphuric acid on sassafras-oil. When equal volumes of alcohol, sulphuric acid, and sassafras-oil are heated together, a red tumefied mass is formed, consisting of a compound of sassarubrin and sulphuric acid; and on treating this resin with ammonia, and washing, sassarubrin remains as a tasteless mass, which is soluble in alcohol and in ether, and colours sulphuric acid red, even in small quantity. Precisely similar actions are exhibited by the oils of cloves and cinnamon.

When the oily mixture of sulphuric acid, alcohol, and sassafras-oil is heated, there is evolved at first a yellowish liquid, designated by Hare as sassafrin, which, when freed from sulphurous acid by ammonia, and from admixed ether by heat, is neutral, and has an odour different from that of sassafras-oil.

SASSOLIN, or **SASSOLITE.** Native boric acid, BH^3O^3, occurring more or less pure in irregular six-sided laminæ belonging to the triclinic system, or as a crust, or in stalactitic forms composed of small scales. It is white, or yellowish (when tinged by sulphur), has a nacreous lustre, a specific gravity of 1·48, and is easily friable. It occurs, as a deposit from hot springs or ponds, in the lagunes of Tuscany, abundantly also in the cràter of Vulcano, one of the Lipari Isles, forming a layer on the sulphur; it was first found near Sasso, whence its name.

SATERSBERGITE. This name has been given to native arsenide of iron, $FeAs^2$, from Fossum in Norway.

SATURATION. A liquid is said to be saturated with a solid or a gas when it has taken up the maximum quantity of that solid or gas which it is capable of dissolving under the existing circumstances. The quantity of a salt, or other solid, which a given liquid is capable of dissolving, depends upon its temperature, and, for the most part, increases with the temperature, so that a solution saturated at a given temperature is no longer saturated at a higher temperature, and, on the other hand, deposits a portion of the dissolved solid when the temperature falls.

The quantity of a gas which a liquid can dissolve depends upon both temperature and pressure, increasing for the most part directly with the pressure, and diminishing as the temperature rises, so that a solution saturated at a given pressure and temperature gives off a portion of the gas when the pressure is diminished, or the temperature rises. (See Gases, Absorption of, ii. 790.)

With reference to the composition of salts, the word saturation is equivalent to neutralisation, an acid being said to be saturated with a base, when it unites with the quantity of that base required to form a neutral or normal salt.

SATURATION, CAPACITY OF. A term employed by Berzelius to denote the quantity of oxygen which must be contained in a base in order to form a neutral salt with 100 pts. by weight of an anhydrous oxygen-acid or anhydride. Thus, as in the neutral sulphates, the oxygen of the anhydrous acid is to that of the base as 3 : 1, in the neutral nitrates as 5 : 1, in the neutral carbonates as 2 : 1, in the acetates as 3 : 1, &c.; and as, moreover, 100 pts. of sulphuric anhydride contain 60 pts. oxygen, 100 pts. nitric anhydride 74·07 oxygen, 100 pts. carbonic anhydride 72·72 oxygen, 100 pts. acetic anhydride 47·06 oxygen, &c., it follows that the saturating capacity of sulphuric acid is $\frac{60}{3} = 20$; of nitric acid $\frac{74{\cdot}07}{5} = 14{\cdot}81$; of carbonic acid $\frac{72{\cdot}72}{2} = 36{\cdot}36$; of acetic acid $\frac{47{\cdot}06}{3} = 15{\cdot}69$.

SATURNUS. By this name the alchemists originally distinguished lead and its compounds, *Acetum Saturni, Saccharum Saturni, Cinis Saturni*, &c., probably because lead easily fuses with other metals, and devours them, as it were, as Saturn is said to have devoured his children.

SAUALPITE. Syn. with Zoisite.

SAULDAMMAR, or *Dhara Dammar*, is the name of a resin collected in the northern parts of Hindostan from the saul-tree, *Shorea robusta*.

SAUSSURITE. *Lemantite. Felsite. Jade tenace. Feldspath tenace. Albite compacte. Bitterstein.*—A mineral allied to labradorite, occurring in crystallo-granular or compact masses, sometimes with labradorite, sometimes in place of it, as a constituent of euphotide, hypersthenite, diabase, gabbro, and other similar rocks. It exhibits indistinct cleavage in two directions, parallel to the faces of a rhombic prism of 24° nearly. Hardness = 5·5 to 6·0. Specific gravity = 3·2 to 3·4. Colour grey, greenish, reddish, or bluish. Dull, or with a faint lustre. Subtranslucent. Fracture splintery to uneven. Extremely tough. Before the blowpipe it melts with great difficulty to a greenish-grey glass. It is not acted upon by acids.

Analyses.—*a.* From the Lake of Geneva (M. de Saussure, Journ. des Mines, xix. 205).—*b.* From the same (Klaproth, *Beiträge*, iv. 271).—*c.* From Mont Genevre: greenish-white; specific gravity = 2·65 (Boulanger, Ann. Min. [3] viii. 159).—*d.* From the Orezza valley, Corsica: easily fusible before the blowpipe (Boulanger). *e.* From Switzerland: bluish-white; specific gravity = 3·365 (Hunt, Sill. Am. J. [2] xxvii. 336).—*f.* From the euphotide of the Lake of Geneva: finely granulo-crystalline; greyish to bluish-white; specific gravity = 3·227 (Fikenscher, Jahresb, 1863, p. 811):

	SiO^2	Al^2O^3	Fe^2O^3	Mn^2O^3	CaO	MgO	Na^2O	K^2O	Loss by ignition		
a.	44·00	30·00	12·50	0·05	4·00	. .	6·00	0·25	. .	=	96·80
b.	49·00	24·00	6·50	. .	10·50	3·75	5·50	. .	. .	=	99·25
c.	44·6	30·4	. .	. .	15·5	2·5	7·5	. .	. .	=	100·5
d.	43·6	32·0	. .	. .	21·0	2·4	. .	1·6	. .	=	100·6
e.	43·59	27·72	2·61	. .	19·71	2·98	3·08	. .	0·35	=	100·04
f.	45·34	30·28	1·37	. .	13·87	3·38	4·73	. .	0·71	=	99·68

These analyses may be represented by the general formula $3(M^4;\overset{\prime\prime}{M}{}^2)SiO^4.2\overset{\prime\prime\prime}{M}{}^4Si^3O^{12}$, similar to that of mejonite, which however contains no alkali.

The name *Saussurite* has been extended to other constituents of the above-mentioned rocks, of similar character, but containing a larger proportion of silica (48 to 54 per cent.) (See *Rammelsberg's Mineralchemie*, p. 605; and Jahresb. 1861, p. 997.)

SAVINE, OIL OF. *Sädebaumol, Sevenbaumöl.*—A volatile oil obtained by distilling with water the berries and the herb of the savine (*Juniperus Sabina*). According to Dumas, it is polymeric with oil of turpentine, $C^{10}H^{16}$. It is a nearly colourless mobile oil, which partly resinises on exposure to the air, becoming yellow and somewhat viscid. It has a pungent disagreeable odour, and a sharp, aromatic, camphor-like taste. Specific gravity = 0·91 to 0·94. Absolute alcohol dissolves it in all proportions; with 2 pts. of highly rectified spirit it forms a clear solution; with 3 pts. or more, an opalescent solution. It detonates with iodine, and is converted by nitric acid into a reddish-yellow balsam. When mixed with an equal quantity of strong sulphuric acid, it yields, according to Winckler (Repert. Pharm. [2] xlii. 330), a fourth of its weight of an oil, which after distillation over potash, is very much like oil of thyme. According to Zeller (N. Jahresb. f. Pharm. xii. 1), the fresh herb of savine yields 1½ per cent. of the oil; the dry herb 2 per cent.; the fresh berries 10 per cent.

SAVITE. A mineral occurring in the gabbro of Tuscany, forming thin dimetric prisms [trimetric, according to Breithaupt, Berg- u. hüttenm. Zeit. 1855, p. 223] of 91° 41′, colourless, transparent, having a hardness = 3·3, and specific gravity = 2·450. Melts with great difficulty before the blowpipe. According to Bechi (Sill. Am. J. [2] xiv. 64), it contains 49·17 per cent. silica, 19·66 alumina, 13·50 magnesia, 10·52 soda, 1·23 potash, and 6·57 water (= 100·65), agreeing approximately with the formula $(\overset{\prime\prime}{M}g^2Na^2)Si^3O^9.\overset{\prime\prime\prime}{A}l^2SiO^5.2H^2O$. According to a new examination of the crystals by Quintino Sella (*N. Cimento*, March 1858), the formula agrees exactly with that of natrolite.

SAYNITE. Syn. with Bismuth-nickel (i. 596).

SCABIOSA. A genus of dipsaceous plants, three species of which have been chemically examined by Sprengel (J. f. techn. Chem. viii. 311, 373; ix. 1), with the following results:—

In 100 parts:	*Scabiosa succisa.*	*Scabiosa arvensis.*	*Scabiosa columbaria.*
Water	83·0	80·0	70·0
Substances soluble in water and in caustic potash	12·5	13·0	17·6
Ash	1·6	1·1	1·5

Composition of the Ash in 100 *parts.*

	K^2O	Na^2O	CaO	MgO	Al^2O^3	Fe^2O^3	SiO^2	SO^3	P^2O^5	Cl
Sc. succisa .	38·1	4·9	31·2	4·7	0·2	. .	3·1	5·4	10·4	1·8

SCALES OF FISHES AND AMPHIBIA. The chemical composition of the scales of fishes is similar to that of bone, but they contain a larger proportion of organic matter. The organic constituent has, according to Frémy, the same composition as ossein, and is likewise converted into gelatin by boiling with water. The following table exhibits the composition of fish-scales as determined by Chevreul:—

	Lepisostea.	*Perca labrax.*	*Chetodon.*
Animal matter	41·16	55·00	51·42
Basic calcic phosphate . .	46·20	37·80	42·00
Calcic carbonate . . .	10·00	3·06	3·68
Magnesic phosphate . .	2·20	0·90	0·90
Fat	0·40	0·40	1·00
Sodic carbonate . . .	0·10	0·90	1·00
Loss	. .	1·94	

The ash of fish-scales has been analysed by Frémy with the following results:—

	Ash per cent.	Basic calcic phosphate.	Magnesic phosphate.	Calcic carbonate.
Scales of Lepisostea . .	59·3	51·8	7·6	4·0
„ Umber-fish . .	41·9	36·4	0·7	2·0
„ Pike	43·4	42·5	trace	1·3
„ Carp	34·2	33·7	. .	1·1

Brummerstädt found in the scales of the carp, 60·352 per cent. cartilaginous substance (chondrin), and 39·468 inorganic matter, consisting of 34·074 calcic phosphate, 3·777 calcic carbonate, 1·060 magnesic carbonate, and 0·557 magnesic phosphate.

The colours of fish-scales appear to be due to interference. The silvery coating of the scales of the bleak (*Cyprinus alburnus*) is used for making artificial pearls. It is separated by agitating the fishes with water, then drenched with ammonia, and the liquid is preserved in a tightly-corked bottle. Part of the silvery substance dissolves in the ammonia, while the rest remains suspended. The liquid thus obtained, called *Essence d'Orient*, is poured into small glass beads, and then poured out again, leaving the inner surface covered with a thin film, which, as the ammonia evaporates, forms a shining pearly coating on the glass. The bead is then filled up with white wax.

The scales of amphibia are histologically similar to epithelial structures, and chemically to horny substance. The shell of the tortoise and other chelonians is of similar nature. The scales of serpents were found by Frémy to yield a small quantity of alkaline ash, and to consist of a substance resembling epidermis. (*Handw. d. Chem.* vii. 381.)

SCAMMONIC ACID. See JALAPIC ACID (iii. 436).

SCAMMONIN. See JALAPIN (iii. 438).

SCAMMONOLIC ACID. See JALAPINOLIC ACID (iii. 440).

SCAMMONY. *Scammonium.*—A purgative gum-resin, produced, according to Guibourt, by two species of *Convolvulus*, viz. *C. Scammonia* (L.) and *C. hirsutus* (Stev.), growing in Syria and Asia Minor. There are two sorts of it, known in commerce as Aleppo and Smyrna scammony. According to other authorities (*Handw. d. Chem.* vii. 275), Aleppo scammony is obtained from *Convolvulus Scammonia*, and perhaps from other species of the same genus, and Smyrna scammony from *Periploca Secamone*, a plant belonging to the apocyanaceous order.[*]

Aleppo scammony is the most esteemed. When of superior quality it forms flat masses, rather light, and somewhat hollow within, dull and blackish-grey on the fractured surfaces; thin fragments appear transparent when examined by a magnifying glass. It is friable, has a powerful odour, and is often covered with a grey powder resulting from the friction of the lumps. Inferior sorts have the form of flat orbicular lumps, compact, heavy, and without internal cavities. The fracture is then black and vitreous, and thin fragments are very transparent. This kind of scammony is also friable, and has an odour like that of the better sort, but fainter.

Smyrna scammony is dull-brown, heavy, not friable, and has a dull vitreous fracture. Its odour is faint but disagreeable.

The composition of commercial scammony is subject to considerable variations. In three specimens of genuine Aleppo scammony, Marquart (Arch. Pharm. vii. 236; x. 124) found 81·25, 78·5, and 77 per cent. resin soluble in alcohol (which is the active principle), the remainder being made up of wax, extractive matters, gum, starch, albumin, fibrin, and inorganic salts. In one specimen, evidently adulterated, the proportion of resin was as low as 8·5 per cent., the remainder being chiefly made up of starch, gum, gluten, and salts. Another specimen, in which the proportion of resin was 32·5

[*] There is also a false or spurious scammony, known as French or Montpellier scammony, which is prepared in the South of France from the expressed juice of an asclepiadaceous plant, *Cynanchum monspeliacum*, and mixed with various resins and other purgative drugs; but it is a dangerous purgative, and should never be used.

per cent., was found to contain 52 per cent. of gypsum. In four specimens of Smyrna scammony, Marquart found 25, 6, 6, and 7 per cent. resin soluble in alcohol (about $\frac{4}{5}$ of it being also soluble in ether), the rest being made up of extractive matter, gum, starch, woody fibre, and inorganic salts.

The chemical constitution of scammony has been further investigated by Keller and by Spirgatis, who agree very nearly in their analytical results, but differ in the formulæ by which they represent them. Spirgatis regards the resin of scammony as identical with that of spurious or fusiform jalap, which is also derived from the root of a convolvulaceous plant, *Convolvulus orizabensis.* Keller regards the two resins as very closely allied, but not as absolutely identical. (See JALAPIC ACID, JALAPIN, &c., iii. 436—442.)

SCAPOLITE. *Wernerite:* including *Paranthine, Ekebergite, Nuttalite, Tetraclasite, Glaucolite, Atheriastite, Terenite, Porcelain-spar, Stroganowite.*—A silicate of aluminium and calcium (the calcium being, however, more or less replaced by sodium, potassium, and magnesium), occurring in dimetric crystals of the same form as mejonite (iii. 865). Observed faces, oP, $\infty P\infty$, ∞P, P, $P\infty$, $\infty P2$, $\infty P3$. Length of principal axis = 0·4398. Angle $oP : P\infty = 156° 14\frac{1}{2}'$. Cleavage parallel to $\infty P\infty$ and ∞P rather distinct but interrupted. The minerals occur also massive, granular, or with a faint fibrous appearance, sometimes columnar, but most frequently in distinct crystals, occasionally of large size.

Hardness = 5 to 5·5; in a subtranslucent variety from Gouverneur, New York, it is nearly 6. Specific gravity = 2·612 to 2·749. Lustre vitreous to pearly, externally inclining to resinous; on the cleavage and cross-fracture, vitreous. Colour white, grey, blue, green, and red, usually light; streak uncoloured. Transparent to faintly subtranslucent. Fracture subconchoïdal. Brittle. Before the blowpipe it turns white, and melts with tumefaction to a blistered glass. It colours the flame yellow, and when heated in an open tube gives a faint reaction of fluorine. It is completely decomposed by hydrochloric acid without gelatinising.

The numerous analyses which have been made of scapolite exhibit considerable diversities of composition. The silica varies from 42 to above 60 per cent.; the greater number of the analyses, however, give 45, 50, or 60 per cent. The lime varies from 20 to about 3 per cent., those scapolites which are poorest in silica being richest in lime. These latter contain either no other strong base, or only small quantities of alkali, chiefly soda; but as the amount of lime diminishes, that of soda (also of potash) increases for the most part; in that case also magnesia is almost always present, though in small quantity. Lastly, nearly all scapolites contain water, generally less than 1 per cent., but sometimes more than 2 per cent. (For the individual analyses, see *Rammelsberg's Mineralchemie*, pp. 717—720). The oxygen-ratio of the protoxides, sesquioxides, and silica in scapolite, varies:

$$\text{from}\quad \overset{\mathrm{RO}}{1} : \overset{\mathrm{R^2O^3}}{1{\cdot}68} : \overset{\mathrm{SiO^2}}{3{\cdot}16} \quad\text{to}\quad \overset{\mathrm{RO}}{1} : \overset{\mathrm{R^2O^3}}{4{\cdot}47} : \overset{\mathrm{SiO^2}}{8{\cdot}83}$$

Most scapolites exhibit signs of decomposition, indicated by differences of specific gravity, transparency, and hardness, and by the presence of water. The least altered are those which contain the largest proportion of lime. Such are those having nearly the composition of mejonite, $3(2\mathrm{Ca''O.SiO^2}).2(2\overset{\prime\prime\prime}{\mathrm{Al}}{}^2\mathrm{O^3.3SiO^2})$, which in fact is regarded by Rammelsberg, Bischof, and G. Rose as the original scapolite. Among the least altered scapolites are nuttalite from Bolton, Massachusetts, a specimen of which, analysed by v. Rath, gave 44·40 per cent. $\mathrm{SiO^2}$, 25·52 $\mathrm{Al^2O^3}$, 3·79 $\mathrm{Fe^2O^3}$, 20·18 CaO, 1·01 MgO, 2·99 $\mathrm{Na^2O}$, 0·51 $\mathrm{K^2O}$, and 1·24 water (= 98·74), and certain scapolites from Arendal in Norway, and from Malsjö in Wermland, Sweden.

The name *scapolite* (or *wernerite*) includes the common greyish and white varieties of the mineral. *Nuttalite* is bluish, greyish, and dark-greenish. *Paranthine* includes certain compact varieties and crystals of white and pale-blue colour. *Ekebergite* (containing 51·02 per cent. silica, 26·87 alumina, 2·73 ferric oxide, 13·29 lime, and 4·64 soda, besides small quantities of manganous oxide, magnesia, and potash) is massive and subfibrous. The distinctions between these varieties are, however, not very well defined. *Porcelain-spar*, from Passau, is sometimes referred to labradorite: but its analyses give essentially the same oxygen-ratio as scapolite (49·20—50·29 $\mathrm{SiO^2}$, 27·30—27·90 $\mathrm{Al^2O^3}$, 13·53—15·48 CaO, 4·53—5·92 $\mathrm{Na^2O}$, with small quantities of potash and water). *Glaucolite*, which has a lavender-blue or greenish colour, and specific gravity = 2·72—2·9, and has nearly the composition of labradorite (iii. 450), is referred to scapolite by G. Rose, as its cleavages are those of the latter and not of labradorite, and its oxygen-ratio is included within the limits of scapolite.

The alterations of scapolite appear to be chiefly due to the action of carbonated waters, the carbonic acid taking up the lime. *Stroganowite*, from near the Sludänka river, in

Dauria, affords an example of this alteration, containing 40·58 per cent. SiO^2, 28·57 Al^2O^3, 11·05 CaO, 3·50 Na^2O, 0·89 FeO, and MnO, and 14·55 $CaCO^3$. Sometimes the action of the carbonic acid goes so far as to carry off nearly all the stronger bases, and reduce the mineral to a kaolin. Acid carbonate of magnesium in solution converts scapolite into soapstone. By alkaline carbonates in solution, alkalis may be introduced and lime removed, thus forming mica, algerite (i. 113), and perhaps also zeolites. By means of ferrous carbonate dissolved in carbonic acid, an oxide of iron may be introduced; and the iron being oxidised to ferric oxide during the process, epidote in the form of scapolite is produced. *Atheriastite*, a highly hydrated scapolite from Arendal (i. 430), is, according to Hausmann, the original wernerite of Haüy.

Scapolite is usually found in crystalline rocks and in granular limestones, most commonly near its junction with granite, also in beds of magnetic iron accompanying this rock. In the latter situation it occurs at Arendal in Norway and Wermland in Sweden; also in fine crystallisations in Pargas in Finland, &c. Paranthine occurs in the limestone quarries at Marlsjö in Wermland; porcelain-spar in granular limestone at Obernzell, in Bavaria; glaucolite near Lake Baikal in Siberia, in veins in granite. (Dana, ii. 202). The localities of other varieties have already been mentioned.

SCARBROITE. An argillaceous mineral from Scarborough, containing, according to Vernon (Berz. Jahresb. x. 169), 10·5 per cent. silica, 42·5 alumina, 0·25 ferric oxide, and 46·75 water.

SCHABASITE. Syn. with CHABAZITE (i. 843).

SCHAPBACHITE. Syn. with BISMUTH-SILVER (i. 597).

SCHEELE'S GREEN. Arsenite of copper (i. 376).

SCHEELETINE. Native tungstate of lead. (See TUNGSTATES.)

SCHEELITE. Native tungstate of calcium. (See TUNGSTATES.)

SCHEERERITE. This name has been applied to two fossil resins occurring at Uznach, near St. Gallen, in Switzerland: 1. A crystalline resin polymeric with marsh-gas, of specific gravity 0·65, and melting at 44°.—2. A hydrocarbon, polymeric with benzene, already described as retene (p. 97).

SCHEFFERITE. A mineral formerly regarded as a garnet, occurring in the iron mine of Langbanshyttan in Sweden. It has a red-brown colour; hardness = 5·6; specific gravity = 3·39; is slightly attacked by hydrochloric acid, with evolution of chlorine. Contains, according to Michaelson (Jahresb. 1863, p. 804), 52·31 per cent. silica, 19·09 lime, 10·86 magnesia, 10·46 manganous oxide, 1·63 ferrous oxide, and 3·97 ferric oxide (loss by ignition 0·60). The oxygen-ratio of the protoxides and silica is 1 : 2; hence Michaelson regards the mineral as an augite.

SCHLERETINITE. A fossil resin from the coal-mines of Wigan, in Lancashire. It forms black drops and granules, sometimes as big as nuts, brittle, and of conchoïdal fracture. Specific gravity = 1·136. Combustible. By dry distillation it yields water and a large quantity of empyreumatic oil, and leaves a residue of charcoal. It is insoluble in water, alcohol, ether, and alkalis, and is slowly decomposed by strong nitric acid. When it is reduced to fine powder and boiled with water, alcohol, and ether in succession, traces of oil are dissolved, after which it contains at 120°, on the average, 3·68 per cent. of ash, 76·95 per cent. C, 8·95 H, and 10·42 O, corresponding to the formula $C^{20}H^{28}O^2$ (Mallet, Phil. Mag. [4] iv. 261).—This body was erroneously regarded by Dana and Mallet as identical with Rochleder's pyroretin. (Kenngott.)

SCHNEIDERITE. A zeolite from the gabbro of Tuscany, having a confusedly lamino-radiate structure; hardness = 3; white and opaque. Contains, according to Bechi (Sill. Am. J. [2] xiv. 64), 47·79 per cent. silica, 19·38 alumina, 16·76 lime, 11·04 magnesia, 1·62 alkali, and 3·41 water. Breithaupt regards it as a decomposed laumontite.

SCHORLAMITE, or **SCHORLOMITE.** A calcio-ferric silico-titanate occurring on the Ozark Mountains, Magnet Cove, Arkansas, together with elæolite, brookite, and garnet; also embedded in phenolite at Oberschaffhausen, on the Kaiserstuhl. Hardness = 7·75. Specific gravity = 3·783—3·862. It is massive without cleavage, black and opaque, with semivitreous lustre. Before the blowpipe it melts with difficulty on the edges to a black vitreous mass, and exhibits with borax and phosphorus-salt the reactions of titanium. Acids decompose it imperfectly, with separation of gelatinous silica. (Shepherd, Sill. Am. J. [2] ii. 251.—Whitney, Journ. Bost. Nat. Hist. Soc. 1849, vi. 46.)

Analyses.—*a.* From Arkansas (Rammelsberg, *Mineralchemie*, p. 886).—*b.* From the Kaiserstuhl: specific gravity = 3·745 (A. Claus, Ann. Ch. Pharm. cxxix. 213):

	SiO^2	TiO^2	Fe^2O^3	FeO	CaO	MgO	K^2O Na^2O		
a.	26·24	21·34	20·11	1·57	29·38	1·36	. .	=	100
b.	29·55	21·18	18·08	. .	25·13	1·22	4·22	=	99·38

Rammelsberg deduces from his analysis, which agrees very nearly with those of Whitney and Crossley, the formula $3(2Ca''O.SiO^2).(2Fe^2O^3.3SiO^2).(2Ca''O.3TiO^2)$.

SCHORLITE. Syn. with Topaz.

SCHORLOMITE. Syn. with Schorlamite.

SCHREIBERSITE. A phosphide of iron and nickel, occurring in meteoric iron, and forming the principal part of the residue left on dissolving the iron in hydrochloric acid (Meteorites, iii. 978). Under the microscope it often appears in sharply-defined crystals. Its colour is sometimes steel-grey, sometimes yellowish or brownish. It is strongly magnetic, dissolves with difficulty in acids, and is often mixed with graphite and silica. Hardness = about 6·5. Specific gravity = 7·01—7·22. It varies greatly in composition, as the following analyses will show (*Rammelsberg's Mineralchemie*, p. 947):—

Faye (Compt. rend. lvii. 801), by exposing a mixture of 8 grms. ferric oxide, 3·7 grms. nickel-oxide, 10·1 sodic phosphate, 6 grms. silica, and 2 grms. charcoal, to a white heat in a graphite crucible, obtained a black slag, a metallic regulus of nickel and iron, and between the two a crust of yellowish metallic shining laminæ, exhibiting the characters of schreibersite.

SCHRÖTTERITE. An amorphous mineral, resembling allophane, from the Döllinger mountain, near Frankenstein in Styria, where it occurs in nests between clay-slate and granular limestone. Hardness = 3—3·5; specific gravity = 1·95—2·05. Colour greenish, yellowish, or sometimes spotted with brown. Contains, according to Schrötter (J. pr. Chem. xi. 380), 11·94 per cent. silica, 46·29 alumina, 2·80 ferric oxide, 1·16 lime, 0·25 cupric oxide, 0·63 sulphuric acid, and 35·85 water, which may be represented by the formula $5Al^2O^3.2SiO^2.20H^2O$. It is probably a mixture containing hydrate of aluminium.

SCHULZITE. Syn. with Cœlestin (i. 1069).

SCILLA MARITIMA. *Squill.* A liliaceous plant, growing wild on the shores of the Mediterranean. The fleshy bulbs, which are used in medicine, have been investigated by several chemists, but with somewhat discordant results. They contain a volatile oil, an acrid substance, a bitter principle, gum, sugar, and, according to Landerer, starch and fat, together with phosphate, citrate, and perhaps also tartrate of calcium.

The volatile oil, obtained by distilling the bulbs with water, is mobile, slightly coloured, has a pungent disagreeable odour (like that of garlic or mustard oil), and blisters the skin; so likewise does its alcoholic solution.

The investigations on scillitin, the active ingredient of the bulbs, have not determined whether it is to be classed with the resins, the alkaloïds, or the bitter principles. Mandet (Compt. rend. li. 87) distinguishes two peculiar bodies, the poisonous and irritating sculeïn, and the non-poisonous scillitin, but adds nothing further concerning them. Schroff (N. Repert. xiv. 241) also distinguishes a narcotic principle (*scillitin*) and an acrid non-volatile principle. Righini (Repert. lxiii. 87) regards scillitin as impure veratrin.

a. According to Tilloy (J. Pharm. xii. 635; *ibid.* [3] xxiii. 406), squill contains no volatile acrid principle, but crystals of calcic citrate [oxalate (Schroff)] which irritate and inflame the skin when rubbed upon it. The active constituents are an acrid resin and a bitter substance.

---

* With Magnesium.

Dried squill-powder gives up to ether an agreeably-smelling yellow fat (or fatty acid?) which may be freed from adhering bitter substance by means of hot water. When the powder which has been exhausted with ether is digested with alcohol, a very acrid and bitter tincture is obtained, leaving on evaporation an acrid resin, which is freed from adhering fat by ether, and from sugar by water. This resin is very poisonous; it softens in hot water, dissolves in alkalis and alcohol, and is not altered by acids.—The bitter substance is extracted by hot water from squill previously treated with ether and alcohol; it is precipitated from the liquid by charcoal, which gives it up again to boiling alcohol (Tilloy).

b. Vogel (Schw. J. vi. 101) and Lebourdais (Ann. Ch. Phys. [3] xxiv. 62) prepare the bitter substance as follows:—

1. Vogel exhausts the concentrated juice with alcohol, evaporates the tincture, dissolves the residue in water, precipitates tannic acid by neutral acetate of lead, removes excess of lead by means of sulphydric acid, again filters, and evaporates. There then remains scillitin, together with sugar and salts, in the form of a colourless friable mass, which has a very bitter, afterwards sweetish taste, and causes vomiting and purging. This mass softens quickly in the air, and dissolves easily in water and absolute alcohol, and in vinegar.—2. Lebourdais precipitates the highly coloured and very viscid decoction of squill with neutral acetate of lead, and agitates the cold filtrate with purified animal charcoal till it loses its colour and bitterness. The charcoal is then washed and dried, and boiled with alcohol, which takes up the scillitin, and leaves it behind on evaporation.—Scillitin thus obtained is an amorphous, neutral, non-hygroscopic mass, which decomposes easily when heated, dissolves with purple colour in oil of vitriol, afterwards blackening, and is decomposed by nitric acid.—A portion placed upon the tongue produces the sensation of a caustic.—Bley (N. Br. Arch. lxi. 141) operated in the same way as Lebourdais, avoiding too great heat, and obtained by spontaneous evaporation, long, colourless, flexible needles, having a very bitter taste, becoming amorphous when gently warmed, and not afterwards susceptible of crystallisation.—According to Wittstein (Repert. [3], iv. 200), the bitter of squill is not precipitated by basic acetate of lead, nor by hydrated oxide of lead, which latter, however, precipitates the acrid constituent.

c. Marais (J. Pharm. [3] xxx. 130) and Landerer (Repert. xlvii. 442) believed they had obtained an alkaloïd, which Tilloy was not able to isolate.

1. Marais exhausts either the dried squill with alcohol of 56 per cent., or the fresh bulbs with alcohol of 90 per cent., mixes the tincture with milk of lime, agitates with ether, separates the supernatant layer of liquid, and evaporates, whereupon scillitin and fat remain, the latter of which is removed by again dissolving the residue in alcohol.—The product is an amorphous, hygroscopic, pale-yellow mass, having a pungent bitter taste and an alkaline reaction.—It dissolves in oil of vitriol, forming a violet solution, from which water precipitates green flocks, and in nitric acid with red colour, which quickly disappears; it is insoluble in hydrochloric acid, but soluble in ammonia and caustic alkalis, becoming decomposed and losing its bitter taste. When heated with hydrate of potassium, it evolves ammonia. It does not dissolve in water; produces with ferric chloride an orange-yellow, and with platinic chloride a yellow precipitate, and combines with acetic acid. It dissolves in alcohol and ether. Taken internally, it acts as an emetic and violent purgative, and afterwards as a narcotic. (Marais.)

2. Landerer digests the crushed inner portions of squill with very dilute sulphuric acid, boils down the filtrate to one-half, saturates it with lime, and sets it aside for three days; then collects and dries the residue. When this residue is boiled with alcohol, the filtrate deposits on evaporation a very small quantity of extremely bitter needles, which are insoluble in water, and sparingly soluble in alcohol. The needles have an alkaline reaction and neutralise acids, forming therewith crystallisable salts, which melt when heated (evolving vapours which excite coughing) and carbonise, but do not leave a trace of lime. This body does not appear to be obtained from dried squill.

SCILLITIN. See the last article.

SCIRPUS. The ash of the bulrush (*Scirpus lacustris*) has been analysed by Fleitmann (Ann. Ch. Pharm. lviii. 391) and by Schulz-Fleeth (Pogg. Ann. lxxxiv. 80), with the following results (deducting the charcoal):

K^2O	Na^2O	CaO	MgO	Fe^2O^3	SO^3	SiO^2	CO^2	P^2O^5	$NaCl$	KCl	
15·3	. .	7·3	2·6	1·17	4·8	28·1	. .	9·5	27·3	3·9	= 99·37 (Fleitmann).
9·7	5·0	7·0	2·3	0·24	5·5	46·5	7·9	4·8	10·1	. .	= 99·04 (Schulz-Fleeth).

SCLEROGEN. A term applied to the incrusting matter deposited within the cells of woody fibre, also called *lignin.* This substance is said by Payen to be distinguished from cellulose by assuming an orange colour when treated with potash and iodine, whereas pure cellulose turns blue under the same circumstances. Schleiden, on the other hand, denies its existence as a distinct compound. (See *Gmelin's Handbook*, xv. 124.)

SCOLECITE. *Lime Mesotype, Needlestone, Poonahlite, Fibrous Zeolite:* including *Mesolite* or *Lime* and *Soda Mesotype.*—A hydrated calcio-aluminic silicate, in which the calcium is sometimes partly replaced by sodium. It forms monoclinic crystals, in which the ratio of the axes $a : b : c = 1{\cdot}0282 : 1 : 0{\cdot}6791$. Angle of inclined axes $b, c = 89°6'$. The crystals are prismatic or acicular, consisting of a prism of 91°35′, acuminated by four faces of a monoclinic pyramid composed of the hemipyramid P of 144° 40′ and the hemipyramid —P of 144°20′; they bear a strong general resemblance to the crystals of natrolite, which consists of the orthorhombic prism $\infty P = 91°$, acuminated by four faces of the pyramid P inclined to the lateral edges at angles of 143°20′ and 142°40′. Twins also occur parallel to the orthodiagonal. Cleavage nearly perfect, parallel to ∞P. The mineral likewise occurs fibrous, massive, and radiated. Hardness = 5—5·5. Specific gravity = 2·2—2·7. Lustre vitreous, or silky when fibrous. Transparent to subtranslucent. Pyrolectric. Before the blowpipe it curls up like a worm (hence the name, from σκώληξ, a worm), and finally melts to a bulky shining slag, which in the inner flame becomes a vesicular slightly shining bead.

A. Scolecite or Lime Mesotype.—*Analyses*: *a.* From the Berufiord, Iceland (Gibbs, Pogg. Ann. lxxi. 565).—*b.* Faröe Islands (Stephan, *Rammelsberg's Mineralchemie*, p. 795).—*c.* Staffa: fibrous (Fuchs and Gehlen, Schw. J. viii. 353; xviii. 1).—*d.* Isle of Mull: radiate, accompanied by epidote (Scott, Edin. N. Phil. J. Oct. 1852).—*e.* Auvergne (Guillemin, Ann. Min. xii. 8).—*f.* Niederkirchen, in Rhenish Bavaria (Riegel, Jahrb. pr. Pharm. xiii. 1).—*g.* East Indies: spherical aggregates having a radiate structure (Taylor, J. pr. Chem. lxiii. 467).—*h.* Cachapual Valley, in Chili; in porphyry (Domeyko, Ann. Min. [4], ix. 3):—

	99·84	100·76	100·95	100·30	100·87	100·21	100·03	100·63

Rammelsberg represents the analyses *b, c, d* by the formula:

$$3[(Na^2O.SiO^2).(Al^2O^3.2SiO^2).2H^2O] + 7[(Ca''O.SiO^2).(Al^2O^3.2SiO^2).3H^2O]$$

and the rest by the formula:

$$[(Na^2O.SiO^2).(Al^2O^3.2SiO^2).2H^2O] + 2[(Ca''O.SiO^2).(Al^2O^3.3SiO^2).3H^2O].$$

These two formulæ, however, give very nearly the same percentage composition, the first requiring 46·92 SiO^2, 26·05 Al^2O^3, 9·95 CaO, 4·75 Na^2O, and 12·33 H^2O; the second, 46·96 SiO^2, 26·09 Al^2O^3, 9·48 CaO, 5·28 Na^2O, and 12·19 H^2O.

Scolecite occurs also in Greenland, at Pargas in Finland, in Auvergne, and in veins in the Kilpatrick Hills.

Poonahlite, a variety from Poonah in Hindostan, has the angle $\infty P : \infty P = 91° 49'$ (Kenngott). Gmelin (Pogg. Ann. xlix. 428) found it to contain 45·12 per cent. silica, 30·44 alumina, 10·20 lime, 0·66 soda (with a trace of potash), and 13·89 water (= 99·81).

Antrimolite occurs in white fibrous stalactites at Antrim, four miles east of the Giant's Causeway. Angle of prism = 92° 13'; outer edges bevelled by a prism of 150° 30'. Hardness = 3·75. Specific gravity = 2·096.

SCOLEXEROSE. A mineral from Pargas in Finland, regarded by Nordenskiold as a variety of labradorite (iii. 451), by others as a scapolite.

SCOPARIN. $C^{21}H^{22}O^{10}$. (Stenhouse, Phil. Trans. 1851, p. 422; Ann. Ch. Pharm. lxxviii. 15.)—A substance contained in *Spartium Scoparium*, and apparently constituting the diuretic principle of that plant.

Preparation.—The decoction obtained by boiling the plant for six or eight hours with water, when evaporated to one-tenth of its bulk, and left at rest for 24 hours, solidifies to a jelly, containing scoparin together with chlorophyll and a small quantity of sparteïne. The jelly is washed with a little cold water, dissolved in boiling water containing a few drops of hydrochloric acid, filtered, and set aside till it solidifies; and the jelly again formed is purified by washing, pressing, drying over the water-bath, and dissolving in boiling water, which now leaves most of the chlorophyll undissolved. The chlorophyll may also be precipitated from the aqueous solution by long-continued boiling; it is deposited from a moderately concentrated solution before the scoparin, and may be separated by filtration at the proper point.

Scoparin thus obtained forms, after drying in a vacuum, a pale-yellow, brittle, amorphous mass, tasteless, inodorous, and neutral. By precipitating its cold ammoniacal solution with hydrochloric acid, dissolving the somewhat more solid jelly in boiling water, and cooling slowly, a small quantity of pale-yellow crystalline stars is obtained, together with gelatinous scoparin. The solution in hot alcohol likewise yields a jelly on partial evaporation, and crystals in the cold. When an attempt is made to recrystallise the latter from hot alcohol, there remains a residue which dissolves with difficulty in water and alcohol, and is obtained as a jelly having the original degree of solubility only by dissolving it in ammonia-water, and precipitating with hydrochloric acid. The crystals and the jelly have the same composition when dry.

Scoparin puffs up when *heated*, carbonises without subliming, and burns with bright flame. A solution in *potash* or in *acids* is decomposed by boiling, with formation of a greenish-brown resin.—Scoparin assumes a blue-green colour with *bromine*, and a dark-green with *solution of chloride of lime*.—With *nitric acid* it forms picric acid.

Scoparin is sparingly soluble in cold, more freely soluble in hot water, forming pale-yellow solutions. It dissolves also in cold *alcohol*, more freely in boiling alcohol. It dissolves slightly in strong *acids*; very easily, with deep yellowish-green colour, in *caustic ammonia*, the *fixed alkalis*, and *alkaline carbonates*, less easily in lime- and baryta-water. The ammoniacal solution leaves, on spontaneous evaporation, a green jelly, nearly free from ammonia.

Scoparin throws down greenish-yellow flocks from *neutral* and *basic acetate of lead*. It does not precipitate *mercuric chloride* or *nitrate of silver*.

SCORDEÏN. A yellow aromatic substance obtained from *Teucrium Scordium*. (Winckler, Repert. Pharm. xxviii. 352.)

SCORILITE. A mineral from Juan del Rio Cara del Calvaxio, in Mexico, containing, according to R. Thomson (J. pr. Chem. viii. 506), 58·0 per cent. silica, 16·8 alumina, 13·3 ferrous oxide, 8·6 lime, and 2·0 water. It occurs in brown slag-like masses, with numerous cavities. Streak white. Hardness = 2·0. Specific gravity = 1·70. Before the blowpipe it becomes lighter in colour, but does not fuse. With fluxes it gives the iron reaction.

SCORODITE. *Neoctese. Cupreous Arsenate of Iron.*—A hydrated ferric arsenate occurring in trimetric crystals, which exhibits the combination $\infty\breve{P}\infty \,.\, \infty\bar{P}\infty \,.\, P \,.\, \infty\breve{P}2$, sometimes with ∞P and $\frac{1}{2}P$. Axes $a : b : c = 1 : 1·1511 : 1·0977$. Angle $\infty P : \infty P = 98° 2'$. Cleavage parallel to $\infty\breve{P}2$ imperfect, parallel to $\infty\bar{P}\infty$ and $\infty\breve{P}\infty$ in traces. The crystals are sometimes single, sometimes implanted in groups or grown together in granular aggregates. The mineral also occurs in botryoïdal, kidney-shaped, tubular, and other forms, also as an incrustation (arsenical sinter). Hardness = 3·5—4. Specific gravity = 3·1—3·3. Lustre vitreous, subadamantine, and subresinous. Colour pale leek-green or liver-brown. Streak white. Subtransparent to translucent. Fracture uneven. Before the blowpipe on charcoal it emits an alliaceous odour (hence the name, from σκόροδον, garlic), and fuses to a reddish-brown or black scoria, magnetic after all the arsenic is expelled. The mineral is not acted upon by nitric acid, but dissolves easily in hydrochloric acid.

Analyses:—*a*. Graul, near Schwarzenberg in Saxony (Damour, Ann. Ch. Phys. [3] x. 412).—*b*. Vaubry, Dept. Haute-Vienne: crystallised; specific gravity = 3·11 (Damour).—*c*. Cornwall (Damour).—*d*. Antonio Pereira in Brazil: specific gravity = 3·18 (Berzelius, Jahresbericht, v. 205).—*e*. From the same (Damour).—*f*. Loaysa, near Marmato, New Granada (Boussingault):

	a.	*b*.	*c*.	*d*.	*e*.	*f*.
Arsenic anhydride	52·16	50·95	51·06	50·78	50·96	49·6
Phosphoric „	. .	. .	. .	0·67		
Ferric oxide	33·00	31·89	32·74	34·85	33·20	34·3
Water	15·58	15·64	15·68	15·55	15·70	16·9
	100·74	98·48	99·48	101·85	99·86	100·8

These analyses lead to the formula $Fe^2O^3.As^2O^5.4H^2O$, or $\left.\begin{matrix}As^{v}\\Fe'''\end{matrix}\right\}O^4.2H^2O$, requiring 49·84 As^2O^5, 34·60 Fe^2O^3, and 15·56 water.

An iron sinter from Nertschinsk in Siberia, containing, according to Hermann (J. pr. Chem. xxxiii. 95), 48·05 As^2O^5, 36·41 Fe^2O^3, and 15·54 water, is an amorphous scorodite.

Scorodite occurs altered to limonite.

SCORZA. A variety of epidote.

SCORZONERA. The roots of *Scorzonera hispanica*, a plant belonging to the cichoraceous tribe of *Compositæ*, contain starch. According to Witting (Arch. Pharm. [2] cv. 286), the expressed juice of the plant contains mannite.

SCROPHULARIA. Two species of this genus of plants have been examined chemically by Walz (Jahrb. pr. Pharm. xxvi. 296; xxvii. 12). *S. nodosa* contains a bitter substance called by Walz α-scrophularin, which dissolves very slowly in water, and is precipitated in white flocks by tannin; also a resin insoluble in water, soluble in alcohol and ether.

Sc. aquatica contains a bitter substance, β-scrophularin, differing in taste and solubility from α-scrophularin; an irritating resinous substance, scrophulacrin, soluble in alcohol and ether; and a resinous substance, scrophularesin, soluble in alcohol, insoluble in water and in ether.

100 pts. of *Sc. aquatica* yielded 7·8 pts., and 100 pts. of *Sc. nodosa* 7·5 pts. of ash, composed as follows:—

	K^2O	Na^2O	CaO	MgO	Fe^2O^3	NaCl	SO^3	P^2O^5	CO^2	SiO^2	Charcoal and sand		
Sc. aquatica	2·3	. .	15·2	5·8	1·3	24·3	4·1	25·3	8·0	7·0	7·0	=	100·3
Sc. nodosa	4·4	13·1	25·5	13·1	1·0	6·2	3·1	13·0	15·2	4·5	0·8	=	99·9

SCURVY-GRASS. See COCHLEARIA (i. 1062).

SCUTTELLARIN. A bitter substance contained in *Scutellaria laterifolia*. (Cadot de Gassicourt, J. Pharm. v. 432.)

SCYLLITE. A neutral substance occurring in cartilaginous fishes, chiefly in the kidneys of the sharks and rays, in the milt and liver of the former, and in the liver and gills of the latter. It does not contain either nitrogen or sulphur, and is probably isomeric with inosite; but its composition has not been exactly determined.

To prepare it, the organs just mentioned are triturated with pounded glass, then stirred up repeatedly with alcohol, and pressed; the filtered extracts are evaporated; the residue is exhausted with water; and the filtrate is again evaporated. The syrupy residue is then treated with absolute alcohol; the portion insoluble therein is dissolved in water; and the solution is left to evaporate, whereupon it deposits crystals of taurine and scyllite. These crystals are separated from the mother-liquor by filtration, then dissolved; and the somewhat concentrated solution is treated with basic acetate of lead, whereby a lead-compound of scyllite is precipitated, from which the lead may be separated by sulphydric acid.

Scyllite crystallises in anhydrous monoclinic prisms having a vitreous lustre, less soluble in water than inosite, insoluble in absolute alcohol. It has a faint sweetish taste, and is precipitated by basic acetate of lead, from its perfectly neutral aqueous solution, in a pasty form, like inosite. It does not, however, exhibit the reactions of inosite with nitric acid, ammonia, or chloride of calcium. Nitric acid, of specific gravity 1·3, dissolves it only at the boiling heat, and even then but slowly, and without evolution of gas. The solution contains unaltered scyllite, which may be separated by alcohol. Scyllite is dissolved by strong sulphuric acid also, only at high temperatures;

it is not coloured by boiling with strong soda-ley, and does not reduce an alkaline cupric solution. (Frerichs and Städeler, J. pr. Chem. lxxiii. 48.)

SEA-SALT. Chloride of sodium more or less mixed with other salts, obtained by evaporation of sea-water. (See SODIUM, CHLORIDE OF.)

SEA-WATER. See WATER.

SEAWEEDS. These plants, which occur abundantly in the open sea, and are often heaped up in vast quantities on the shore, are used for various purposes—viz., as food and medicine, in certain manufactures, but more extensively as manure, and for the sake of their ash (called kelp or varee), which is valuable as a source of potassium-salts, and as the principal source of iodine.

1. *Seaweed as Food and Medicine.*—Many seaweeds contain large proportions of gelatinous or mucilaginous matter, and afford demulcent and nutritive jellies; the proportion of nitrogen in them is also very considerable. The following table exhibits the proportions of dry matter and nitrogen contained in some of the species most used, as food for men or as fodder for cattle, in the British Islands and the North of Europe, according to the determinations of J. Davy and Apjohn:—

Percentage of Dry matter and Nitrogen in Seaweed.

Plants.	Water.	Dry matter.	Nitrogen per cent. in dry matter.
Chondrus crispus (Carragheen or Irish moss), bleached	17·92	82·08	1·534
„ „ „ unbleached.	21·47	78·53	2·142
Gigartina mammillosa	21·55	78·45	2·198
Laminaria digitata, or dulse tangle	21·38	78·62	1·588
„ black tangle	31·05	68·95	1·396
Rhodomenia palmata, or dylisk	16·56	83·44	3·465
Porphyra laciniata, or laver	17·41	82·59	4·650
Iridæa edulis	19·61	80·39	3·088
Alaria esculenta, or murlins	17·91	82·09	2·424

The proportion of nitrogen in these plants appears, from these analyses, to be larger than in most other vegetable esculents: the best wheat-flour (dried at 100°) containing, according to Apjohn, 1·817 per cent. nitrogen, potatoes 0·541, beetroot 1·848, mangolds 1·781, and Swedish turnips 1·843. This large proportion of nitrogen has been supposed to account for the high nutritive value attributed to many kinds of seaweed; but the mere percentage of nitrogen existing in a substance cannot be taken as a certain indication of its nutritive value, as the form in which the nitrogen exists is likewise of great importance in determining whether the nitrogenous constituent of the plant is capable of ready assimilation in the body of an animal: moreover, the nutritive power of a substance cannot be determined without taking account also of its non-nitrogenous constituents.

The use of seaweed as food is most extensive in China and Japan. *Laminaria saccharina*, sweet tangle or sea-tape, highly esteemed in these countries, has been found by Stenhouse to contain large quantities of mannite.

Plocaria candida (called *Agar-Agar* by the Malays, and *Bulung* in Java) is imported into this country as commercial Ceylon Moss. It is a small delicate white fucus, containing about 70 per cent. of starch and vegetable jelly. The edible birds'-nests, esteemed as a delicacy in China, are probably constructed from this plant by a species of swallow, the *Hirundo esculenta.*—*Gelidium corneum* is the *algue de Java*, which is made into an iced jelly, and sold in Ningpo under the name of *Nin-mau* (ox-hair vegetable). Payen has extracted from it 27 per cent. of a peculiar vegetable substance, called gelose, which he finds to possess ten times the gelatinising power of the best isinglass. The same substance is obtained from *Plocaria lichenoïdes*, a seaweed from the Mauritius, and in small quantity from several European seaweeds; it is said also to be obtained from certain lichens growing on trees in the South of China, and in the southern islands of the Philippine Archipelago (ii. 829).—*Fucus saccharinus*, the *Kambon* of the Japanese and the *Sea-cabbage* of the Russians, which is found in great abundance on the islands and shores of Eastern Asia, is used as an ingredient of soap, and eaten with fish, or boiled and eaten merely with salt. *Laminaria potatorum* furnishes the natives of Australia with food, and serves also as a material for their tools and vessels; other species of the same genus constitute an important resource to the poor on the west coast of South America, to the Fuegians, and the inhabitants of the country near the Straits of Magellan. Under the name of *bull-kelp*, it is largely eaten in New Zealand and Tasmania.—*Durvillia utilis* is used as food in Valparaiso, and by the poorer inhabitants of the west coast of South America.—*Eucheuma speciosum* and *Gigartina speciosa* are eaten in Australia.

The use of seaweed as medicine depends partly on the gelatinous matter, partly on the iodine contained in it. Carragheen moss has been found useful in pulmonary complaints.—*Fucus vesiculosus*, bladder-wraïk or lady-wrack, is used externally as a friction in glandular enlargements, and the juice has been given internally with advantage for the same purpose.—*Sargassum bacciferum* is the celebrated gulf-weed of the Atlantic, the stems of which are said to constitute the *gôîtresticks* chewed in South America, where that disease is prevalent, but they more probably come from the stems of the *Laminaria digitata*.—*Plocaria helminthocortos* (also called *Gracilaria lichenoïdes* or *Sphærococcus*, *Gigartina lichenoïdes*, and Corsican moss) has long been used by the Corsicans as an anthelmintic.

2. *Use in Manufactures.*—A process has been recommended by Dr. Stenhouse for the manufacture of acetic acid from seaweeds by fermentation. His experiments were conducted with some of the fuci; these were mixed with lime, and kept moist at a temperature of 90° F. He obtained by distillation with sulphuric acid, an average of 1·5 per cent. of anhydrous acetic acid, contaminated with butyric acid. This might, however, be separated and turned to account in the manufacture of butyric ether or essence of pine-apple. The best method would be to ferment the plants in pits with lime or chalk, at the ordinary temperature in the summer, leaving each portion in for two or three months, and supplying its place by a fresh load until the lime was saturated; the liquid would then be pumped out, evaporated to dryness, the residue sold as crude acetate of calcium, and the weed carried to the manure-heap. The whole process might be roughly and economically carried on by an agriculturist near the sea.

Seaweeds are used as substitutes for horn, shell, whalebone, indurated leather, &c., in the manufacture of various articles. One process consists in immersing the weed, from which all extraneous matters have previously been removed, in a lye of caustic lime for three hours, then steeping it in very dilute sulphuric acid, and afterwards in a solution of common salt, after which it may be moulded into any desired form. Or the dry material is ground to powder and mixed with glue, to which some alum and powdered resin are added, or with coal-tar or bitumen, and baked, then rolled out, or pressed in moulds. The stems of *Laminaria digitata* (tangle or sea-girdle) make excellent handles for knives, files, &c. If the blade is inserted when the stem is fresh cut, and the weed then allowed to dry, it contracts, holding the blade firmly, and presenting a brown wrinkled appearance, somewhat like buck-horn.

A kind of soap may be made by treating some of the common seaweeds with alkalis.

Attempts have been made to use seaweeds in the manufacture of paper, and for the production of textile fabrics; but the true algæ are not adapted for this purpose, as they are destitute of fibrous structure. The seawrack, *Zostera marina*, which is not an alga, but contains fibre resembling that of the grasses, promises better results when used for such purposes.

Many seaweeds exhibit very brilliant colours, but it does not appear that any attempts have hitherto been made to utilise them. Several varieties of *Griffithsia* yield to pure water a brilliant crimson colour, which is precipitated by soluble chlorides, and appears to combine with alumina and other metallic oxides.

3. *Seaweed as Manure.*—The value of seaweed as manure is most appreciated in the Channel Islands; the "varec" or "vraic," as the weed is there called, is considered so valuable that special laws are enforced for its regular collection and fair distribution amongst the agriculturists, many of whom use no other manure. "Point de vraic, point de hangard" has passed into a local proverb. The weed is either thickly spread on the land, and ploughed in fresh with a deep plough, or dried on the beach, and burnt on the cottagers' hearths as fuel; the charred ash thus produced sells at 6*d*. per bushel for manure. "Driftweed" is also largely used in Ireland, as the only manure for the potato crop; this is interesting, because the potato requires a considerable supply of potash. This alkali can hardly, however, be required in the Channel Islands, as the granitic subsoil would, in disintegration, furnish it in abundance; it is probably the earthy phosphates that render the weed so fertilising there. This is borne out by the fact that the lixiviated seaweed ash, from which the alkalis have been removed, meets with a ready sale in Guernsey, and is esteemed indeed richer, no doubt on account of the increased percentage of phosphates. The residual seaweed ash from the iodine factories in France is highly valued as a manure, and carried for that purpose a distance of thirty miles from the factory.

Seaweed is also much used as manure in the Hebrides, the Isle of Thanet, Cornwall, and the Isle of Man.

100 pts. of decomposed and dried seaweed contain, according to Way, 65·62 per cent. organic matter, 13·65 soda, 16·00 soluble salts, and 3·23 nitrogen (= 4 of ammonia).

4. *For the production of Kelp or Varec, as sources of Iodine and Potassium-salts.*—This part of the subject has already been treated under the head of "POTASSIUM-SALTS, MANUFACTURE OF" (iv. 714). We here give a table of the composition of the ash of several kinds of seaweed, as determined by Schwitzer, Forchhammer, and Godecheus:—

Ash of Seaweed.

Constituents of the Ash.	*Laminaria saccharina,* North Sea.	*Fucus serratus,* North Sea.	*Laminaria latifolia,* Hoffmansgave.	*Furcellaria fastigiata,* Cattegat.	*Chondrus crispus,* Cattegat.	*Iridaea edulis,* Cattegat.	*Polysiphonia elongata,* Hoffmansgave.	*Delesseria sanguinea,* Cattegat.	*Fucus digitatus,* from the mouths of the Clyde.	*Fucus nodosus,* from the mouths of the Clyde.	*Fucus serratus,* from the mouths of the Clyde.

	Schwitzer.		Forchhammer.						Godecheus.		

The high temperature to which the seaweed is exposed in the ordinary process of incineration gives rise to the loss by volatilisation of at least half of the iodine, and of a certain portion of the potassium-salts, and likewise enables the carbon to reduce the sulphates to sulphites, hyposulphites, and sulphites, which accumulate in the mother-liquors, and necessitate the consumption of a large quantity of sulphuric acid to reconvert them into sulphates.

To obviate these and other disadvantages attending the ordinary process, and further to economise the products, Mr. E. C. Stanford proposes to subject the seaweed, previously dried, to destructive distillation in iron retorts, whereby they yield the usual products of the dry distillation of organic bodies—such as hydrocarbons, naphtha, ammonia, acetic acid, and illuminating gas. The residual charcoal then yields, on lixiviation, a colourless solution, which is nearly free from sulphides, and leaves on evaporation a crop of pure salts and a nearly colourless mother-liquor, containing all the iodine and bromine of the seaweed. (For details, see a paper read before the Society of Arts, February 14, 1862; also Pharm. J. Trans. [2] iii. 495; also Richardson and Watts's Chemical Technology, i. [3] 529.)

SEBACIC ACID. $C^{10}H^{18}O^4 = \left.\begin{matrix}C^{10}H^{16}O^2\\H^2\end{matrix}\right\}O^2$. *Pyroleic acid, Sebacylsäure, Fettsäure.* (Thénard, Ann. Chim. xxxix. 193.—Dumas and Péligot, Ann. Ch. Phys. lvii. 332.—Redtenbacher, Ann. Ch. Pharm. xxxv. 188.—Bouis, *ibid.* lxxx. 303; xcvii. 34.—W. Mayer, *ibid.* lxxxiii. 143; xcv. 160.—Rowney, *ibid.* lxxxii. 103.—Carlet, J. Pharm. [3] xxiv. 176.—Arppe, Ann. Ch. Pharm. cxxiv. 98; Jahresb. 1862, p. 283; 1864, p. 377.—Gm. xiv. 494.)—This acid, the highest known term of the oxalic series, $C^nH^{2n-2}O^4$ (i. 52), is produced:—1. By the dry distillation of oleic acid, and of hog's-lard and other fats containing oleic acid or olein (Thénard, Berzelius, Redtenbacher).—2. Together with other acids of the oxalic series, by the oxidising action of nitric acid on fats. Spermaceti thus treated yields sebacic and azelaic acids.—3. Together with heptylic or octylic alcohol, and other products, by distilling castor-oil or ricinoleic acid with excess of caustic alkali. (Bouis and others, 1·98; iii. 144; v. 110.)

Preparation.—Sebacic acid is best prepared from castor-oil by distillation with

fused potash. Delfs (Jahresb. 1862, p. 320) allows 2 pts. of castor-oil to flow into 1 pt. of caustic potash, fused and mixed with a small quantity of water, continuing the heat till the mass assumes a faint yellowish colour. On dissolving the residue in boiling water, and mixing it at the boiling heat with hydrochloric acid, the filtrate, as it cools, yields sebacic acid in bulky needles.

The residue left in the retort in the preparation of heptylic or octylic alcohol from castor-oil, may also be made available for the preparation of sebacic acid. This residue is decomposed by hydrochloric acid, and the sebacic acid is extracted by boiling water from the mixture of insoluble acids thereby separated (Bouis). Petersen (Ann. Ch. Pharm. ciii. 184) boils the residue with water; strains the liquid; precipitates the other fatty acids by adding a small quantity of hydrochloric acid; then, after separating these by filtration, precipitates the sebacic acid by excess of hydrochloric acid, and purifies it by recrystallisation from hot water, with aid of animal charcoal.

The quantity of sebacic acid obtained from fats by dry distillation or by oxidation of nitric acid is very small, and it is difficult to separate the sebacic acid from the other solid acids produced at the same time. According to Arppe, spermacetic and stearic acids yield sebacic acid in larger quantity than other fats.

Properties.—Sebacic acid crystallises in white, nacreous, very light needles or laminæ resembling benzoic acid. It has an acid taste, reddens litmus strongly, does not lose weight at 100°, melts at 127°, solidifies to a crystalline mass on cooling, and sublimes at a higher temperature. The melted acid has a specific gravity of 1·317. Its vapour irritates the palate, and has the odour common to all fatty bodies. It is slightly soluble in cold, very soluble in hot *water*, dissolves very easily also in *alcohol*, *ether*, and *fat oils*.

Decompositions.—1. Sebacic acid heated with strong *nitric acid* dissolves slowly, and is converted into pyrotartaric acid (Schlieper, Ann. Ch. Pharm. lxx. 121); succinic acid (Carlet); succinic, pimelic, and perhaps also adipic acid (Wirz, Ann. Ch. Pharm. civ. 280); succinic and oxypyrolic acids (Arppe, Ann. Ch. Pharm. xcv. 242); according to later experiments, also adipic acid (Jahresb. 1862, p. 377).—2. Sebacic acid is attacked by *pentachloride of phosphorus*, with formation of hydrochloric acid gas, phosphoric oxychloride, and sebacic anhydride (Gerhardt and Chiozza, Compt. rend. xxx. 1050).—3. *Chlorine* acts on sebacic acid only in sunshine, forming two yellow substitution-products, $C^{10}H^{17}ClO^4$ and $C^{10}H^{16}Cl^2O^4$, which are pasty at mean temperature (Carlet).—4. The *calcium-salt* of sebacic acid, subjected to *dry distillation*, gives off hydrogen gas, and yields an oil boiling between 80° and 200°.—On rectifying this oil, a liquid passes over between 85° and 90°, which has a pleasant ethereal odour, and appears to be propionic aldehyde,—then, between 156° and 200°, œnanthol (xii. 446) distils over (Calvi). When sebate of calcium is distilled with *excess of lime*, sebacin (p. 214) is obtained, together with an oil boiling between 80° and 280°. The latter, when rectified, first yields a product which, when treated with nitric acid, forms nitrobenzene, and is therefore probably benzene—then, between 90° and 100°, propionic aldehyde—and at 160° œnanthol, inasmuch as the portions which distil at these temperatures form, with nitric acid, propionic and œnanthylic acids (Petersen, Ann. Ch. Pharm. ciii. 184). By distillation with *excess of baryta*, sebacic acid yields carbonate of barium and a hydrocarbon, $C^{10}H^{18}$, boiling between 125° and 130°, chiefly at 127° (A. Riche, Rép. Chim. pure, ii. 127).—5. When alcoholic sebacic acid is treated with *hydrochloric acid gas*, an oil is produced, which when treated with ammonia forms sebamide and sebacic acid, and is therefore probably a mixture of neutral and acid ethyl-sebacic ether. (Rowney.)

Sebates.—Sebacic acid is dibasic, forming acid and neutral salts. The sebates of the alkali-metals and alkaline earth-metals are soluble in water; the rest are obtained by double decomposition. All the acid sebates, excepting the ammonium-salt, decompose with great facility.

The *neutral ammonium-salt* is very soluble in water, crystallises confusedly, and gives off ammonia in drying. By dry distillation it yields sebamic acid (Kraut).—The *acid salt* forms plumose crystals, slightly soluble in alcohol.—The *potassium-salt*, $C^{10}H^{16}K^2O^8$, crystallises from concentrated solution in small nodules, very soluble in water, non-deliquescent, slightly soluble in absolute alcohol.—The *sodium-salt* is similar, but less soluble in water.—The *calcium-salt*, $C^{10}H^{16}Ca''O^4$ (at 100°) is but slightly soluble in water, and is obtained by precipitation. From a dilute solution it crystallises by spontaneous evaporation, in white, shining, very thin scales.—The *copper-salt* is a greenish-blue precipitate. The mother-liquor, when left to evaporate, yields, on the surface a green crust of crystalline grains. The salt, when heated, melts before decomposing.—The *ferric salt* is a flesh-coloured precipitate, which is decomposed by carbonate of ammonium, part dissolving with red colour, while the rest is changed into an insoluble basic salt. The neutral salt melts when heated, and then decomposes with intumescence.—The *lead-salt* is a white precipitate, converted by ammonia into a basic salt. –

The *mercurous salt* is obtained, as a precipitate, by treating mercurous nitrate either with sebacic acid or an alkaline sebate.—The *silver-salt*, $C^{10}H^{16}Ag^2O^4$, is a white, curdy, nearly insoluble precipitate, obtained with nitrate of silver and an alkaline sebate. When heated in a tube it yields metallic silver and a white crystalline sublimate.

Ipomæic acid. An acid, isomeric with sebacic acid, produced by the action of moderately strong nitric acid on convolvulic acid, convolvulinolic acid, jalapin, jalapic acid, or jalapinolic acid. It resembles sebacic acid in most of its properties and reactions, but melts at a lower temperature, viz. at 104°. The acid and its salts become electric by friction. The precipitate formed by ipomæate of ammonium with chloride of calcium is amorphous at first, and becomes crystalline only after standing for some time, whereas the corresponding precipitate formed by sebate of ammonium, is crystalline when first formed. (W. Mayer, Ann. Ch. Pharm. lxxxiii. 143; xcv. 160.)

SEBACIC ETHERS. *Methylic Sebate*, or *Methyl-sebacic Ether*, $C^{12}H^{22}O^4 = C^{10}H^{16}(CH^3)^2O^4$, is obtained by gradually adding methylic alcohôl to a solution of sebacic acid in strong sulphuric acid, agitating the liquid, and cooling the vessel with cold water. The ether is then precipitated by addition of water, washed first with alkaline, then with pure water, and crystallised from alcohol. It melts at 25·5°, and crystallises in fine needles on cooling. It is heavier than water when solid, but lighter in the melted state. It has a very faint odour; boils without alteration at 285°; is decomposed by potash into potassic sebate and methylic alcohol; and is converted by ammonia into sebamide. (Carlet, Compt. rend. xxxvii. 130.)

Ethylic Sebate, or *Ethyl-sebacic ether*, $C^{14}H^{26}O^4 = C^{10}H^{16}(C^2H^5)^2O^4$, is easily prepared by dissolving sebacic acid in a small quantity of alcohol, and saturating the solution with hydrochloric acid gas. The chloride of ethyl formed at the same time is expelled by a moderate heat; and the product is washed with water containing sodic carbonate, then dried over chloride of calcium, and rectified. It is liquid above —9°, lighter than water, has an agreeable odour, and boils at 308°. It is insoluble in cold water, but dissolves easily in alcohol. Ammonia converts it into sebamide. (Redtenbacher, Ann. Ch. Pharm. xxxv. 193.)

The acid sebates of ethyl and methyl have not been prepared; but they are doubtless formed, together with the neutral ethers, by the action of hydrochloric acid gas on the alcoholic solutions of sebacic acid, inasmuch as these solutions, when treated with ammonia, yield sebamic acid as well as sebamide.

Diglycerylic Sebate or *Sebin*, $C^{16}H^{30}O^8 = \left.\begin{matrix}(C^3H^5)^3\\(C^{10}H^{16}O^2)''\\H^4\end{matrix}\right\}O^6$. — Produced in small quantity as a crystallisable solid, by heating sebacic acid with glycerin to 200°:

$$C^{10}H^{18}O^4 + 2C^3H^8O^3 = C^{16}H^{30}O^8 + 2H^2O;$$

more abundantly, together with chlorhydrin, by the action of hydrochloric acid gas on a mixture of sebacic acid and glycerin heated to 100°. As thus obtained, it is liquid at first, but after drying at 120°, solidifies partially after a few days, and completely at —40°. It gives off acrolein when heated. Oxide of lead converts it into sebacic acid and glycerin. With alcoholic hydrochloric acid, it yields ethylic sebate and glycerin. (Berthelot, Ann. Ch. Phys. [3] xli. 293.)

SEBACIN. $C^{10}H^{18}$.—A hydrocarbon obtained, together with propionic aldehyde, œnanthol, and a small quantity of benzene, by the dry distillation of calcic sebate mixed with excess of lime. It partly condenses, as a solid fatty mass, on the sides of the receiver and the neck of the retort, and partly separates from the liquid product when left at rest. When purified by solution in oil of vitriol, precipitation with water, and recrystallisation from alcohol, it forms nearly colourless laminæ, which easily cake together. It is tasteless and inodorous, lighter than water, melts at 55°, and volatilises at a temperature above 300°. It is insoluble in water, easily soluble in alcohol and ether, dissolves with red colour in oil of vitriol, and is precipitated in its original state by water. It is scarcely altered by nitric acid or caustic potash. (Petersen, Ann. Ch. Pharm. ciii. 187.)

SEBAMIC ACID. $C^{10}H^{19}NO^3 = \left.\begin{matrix}H^2\\(C^{10}H^{16}O^2)''\\H\end{matrix}\right\}\begin{matrix}N\\O.\end{matrix}$ (Rowney, Chem. Soc. Qu. J. iv. 334.—Kraut, *Gmelin's Handbook*, xiv. 501.)—Produced: 1. By the action of ammonia on ethyl-sebacic acid (Rowney).—2. By the dry distillation of neutral sebate of ammonium. (Kraut.)

Preparation.—1. The oily mixture of neutral sebacic ether and ethyl-sebacic acid, obtained by the action of hydrochloric acid gas on alcoholic sebacic acid, is digested with strong aqueous ammonia for several weeks in a closed vessel, or till the oil is converted into a granular mass, the sebamide which separates from the liquid containing sebamic acid being removed by filtration, and washed to free it from mother-liquor. The several portions of liquid are then united and concentrated over the water-bath; the sebamic acid is precipitated by hydrochloric acid, washed with cold water, and dissolved in dilute aqueous ammonia, which still leaves a small quantity of sebamide undissolved; the solution filtered therefrom is again precipitated by hydrochloric acid; and the resulting precipitate, after being washed, is purified by recrystallisation from water (Rowney).—2. Neutral sebate of ammonium yields by simple distillation, first a colourless, then a yellowish empyreumatic distillate, which is to be dissolved in ammonia, filtered from a small quantity of oil which separates, and precipitated with hydrochloric acid. The precipitate is washed with cold water, and recrystallised from boiling water. (Kraut.)

Properties.—Sebamic acid forms rounded granules (Rowney); a white, crystalline, pulverulent mass (Kraut). Has an acid reaction (Rowney). It is sparingly soluble in cold, easily in warm water, alcohol, and ammonia. When boiled with calcic carbonate, it gives off carbonic acid, and forms a calcium-salt, slightly soluble in water (Kraut). The solution of sebamic acid in ammonia does not precipitate the alkaline earths; it precipitates *acetate of lead*, and forms, with *nitrate of silver*, a precipitate soluble in ammonia and in nitric acid. (Rowney.)

Sebamic acid gives off ammonia when boiled with *potash* (Rowney).—The sodium-salt brought in contact with *chloride of benzoyl*, yields chloride of sodium and an oil, which may be dissolved out by ether, is left behind when the ether evaporates, gives off ammonia when fused with hydrate of potassium, is insoluble in water and ammonia, and when washed with ammonia, gives up to it only a small quantity of free acid. (Kraut.)

SEBAMIDE. $C^{10}H^{20}N^2O^2 = \left.\begin{matrix}(C^{10}H^{16}O^2)'' \\ H^4\end{matrix}\right\} N^2$. (Rowney, *loc. cit.*—Carlet, Compt. rend. xxxvii. 128.)—Produced as just described from ethylic sebate, or in like manner from methylic sebate, and purified by two recrystallisations from alcohol. It is neutral, and forms hard rounded granules composed of microscopic needles, insoluble in cold, moderately soluble in boiling water; insoluble in ammonia, slightly soluble in cold alcohol, very soluble in boiling alcohol. By water it is gradually converted into sebate of ammonium. It is not attacked by potash in the cold, but gives off ammonia when boiled therewith.

SEBIN. Diglycerylic Sebate. (See SEBACIC ETHERS, p. 214.)

SECALE CEREALE. Rye. See CEREALS (i. 823).

SECALE CORNUTUM. *Ergot.*—These names are applied to several fungi growing on the ears of grasses. They differ in structure and in chemical composition according to the plant on which they grow. Ramdohr (Arch. Pharm. cxxxi. 179) has examined the ergots from rye, from barley, and from *Bromus secalinus*; and finds that they differ in the proportions of organic substance, water, and ash contained in them—also in the composition of the organic substance and of the ash, but the differences are not important. (See *Handw. d. Chem.* vii. 732). Respecting the detection of ergot in rye, see RYE (p. 141).

SECONDARY ALCOHOLS. This term, with its correlatives, primary and tertiary alcohols, has been employed by Kolbe to express certain differences in the manner in which the carbon is linked together in the alcohols. These three terms are borrowed from the nomenclature of the compound ammonias (Ann. Ch Pharm. [1864] lvi. 102). Thus we have:—

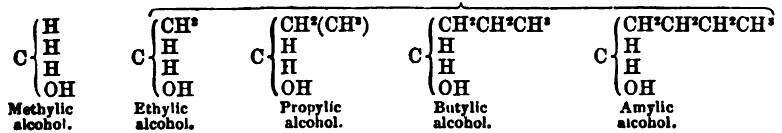
$N\left\{\begin{matrix}H\\H\\H\end{matrix}\right.$	$N\left\{\begin{matrix}R\\H\\H\end{matrix}\right.$	$N\left\{\begin{matrix}R\\R\\H\end{matrix}\right.$	$N\left\{\begin{matrix}R\\R\\R\end{matrix}\right.$
Ammonia (type).	Primary amine.	Secondary amine.	Tertiary amine.
$C\left\{\begin{matrix}H\\H\\H\\OH\end{matrix}\right.$	$C\left\{\begin{matrix}R\\H\\H\\OH\end{matrix}\right.$	$C\left\{\begin{matrix}R\\R\\H\\OH\end{matrix}\right.$	$C\left\{\begin{matrix}R\\R\\R\\OH\end{matrix}\right.$
Methylic alcohol (type).	Primary alcohol.	Secondary alcohol.	Tertiary alcohol.

Just as in ammonia there are three atoms of hydrogen capable of replacement by radicles, so in methylic alcohol there are three atoms of hydrogen capable of replacement by radicles. This parallel must not, however, be followed too far, inasmuch as whereas NH^3 takes up HCl (equal to H^2), CH^3 can only take up Cl or OH (equal to H.)

The alcohols obtained by fermentation, the so-called normal alcohols, are believed to be of the primary class. The alcohols obtained by the addition of hydrogen to the ketones are secondary. A tertiary alcohol appears to have been obtained by Buttlerow and by Wanklyn.

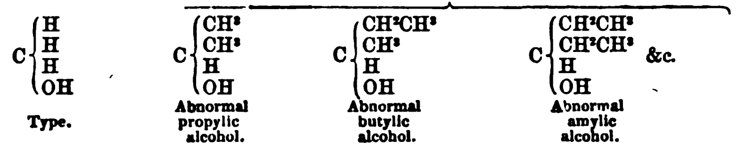
The following formulæ exhibit the structural differences in the three classes of alcohols:—

Primary Alcohols.



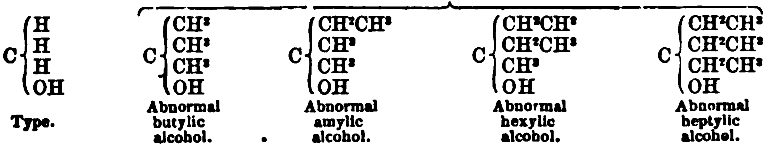
$$C\left\{\begin{matrix}H\\H\\H\\OH\end{matrix}\right. \quad C\left\{\begin{matrix}CH^3\\H\\H\\OH\end{matrix}\right. \quad C\left\{\begin{matrix}CH^2(CH^3)\\H\\H\\OH\end{matrix}\right. \quad C\left\{\begin{matrix}CH^2CH^2CH^3\\H\\H\\OH\end{matrix}\right. \quad C\left\{\begin{matrix}CH^2CH^2CH^2CH^3\\H\\H\\OH\end{matrix}\right.$$

Secondary Alcohols.



$$C\left\{\begin{matrix}H\\H\\H\\OH\end{matrix}\right. \quad C\left\{\begin{matrix}CH^3\\CH^3\\H\\OH\end{matrix}\right. \quad C\left\{\begin{matrix}CH^2CH^3\\CH^3\\H\\OH\end{matrix}\right. \quad C\left\{\begin{matrix}CH^2CH^3\\CH^2CH^3\\H\\OH\end{matrix}\right. \quad \&c.$$

Tertiary Alcohols.



Type.
Abnormal butylic alcohol.
Abnormal amylic alcohol.
Abnormal hexylic alcohol.
Abnormal heptylic alcohol.

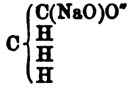
$$C\left\{\begin{matrix}H\\H\\H\\OH\end{matrix}\right. \quad C\left\{\begin{matrix}CH^3\\CH^3\\CH^3\\OH\end{matrix}\right. \quad C\left\{\begin{matrix}CH^2CH^3\\CH^3\\CH^3\\OH\end{matrix}\right. \quad C\left\{\begin{matrix}CH^2CH^3\\CH^2CH^3\\CH^3\\OH\end{matrix}\right. \quad C\left\{\begin{matrix}CH^2CH^3\\CH^2CH^3\\CH^2CH^3\\OH\end{matrix}\right.$$

On inspecting these formulæ, it appears that there cannot be a secondary ethylic alcohol, and that neither ethylic nor propylic alcohol is possible in the tertiary series.

The experimental evidence of the existence of these different kinds of structure in different alcohols may be set forth as follows:

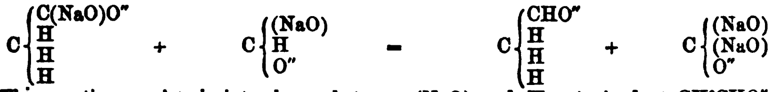
Genesis of the Alcohols of the Primary Type.

Starting with CH^3Na and CO^2 we get—



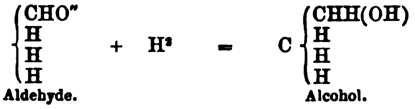
$$C\left\{\begin{matrix}C(NaO)O''\\H\\H\\H\end{matrix}\right.$$

wherein the sodium which saturates one quarter of the one atom of carbon is replaced by an equivalent of the other carbon, whilst the sodium goes to saturate half of one of the atoms of oxygen which existed in combination in the carbonic anhydride. On distilling together $CH^3C(NaO)O''$ and formate of sodium, there is produced aldehyde and carbonate of sodium:



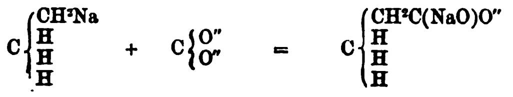
$$C\left\{\begin{matrix}C(NaO)O''\\H\\H\\H\end{matrix}\right. + C\left\{\begin{matrix}(NaO)\\H\\O''\end{matrix}\right. = C\left\{\begin{matrix}CHO''\\H\\H\\H\end{matrix}\right. + C\left\{\begin{matrix}(NaO)\\(NaO)\\O''\end{matrix}\right.$$

This reaction consists in interchange between (NaO) and H. Arrived at CH^3CHO'' (aldehyde), we add nascent hydrogen, and get:



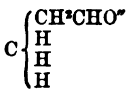
$$\left\{\begin{matrix}CHO''\\H\\H\\H\end{matrix}\right. + H^2 = C\left\{\begin{matrix}CHH(OH)\\H\\H\\H\end{matrix}\right.$$

From alcohol we get iodide of ethyl; from iodide of ethyl we get zinc-ethyl, and then sodium-ethyl, CH^3CH^2Na. Acting upon sodium-ethyl with carbonic anhydride we get:—



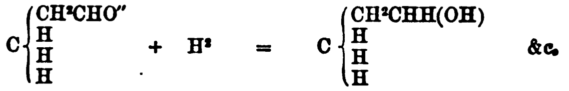
$$C\left\{\begin{matrix}CH^2Na\\H\\H\\H\end{matrix}\right. + C\left\{\begin{matrix}O''\\O''\end{matrix}\right. = C\left\{\begin{matrix}CH^2C(NaO)O''\\H\\H\\H\end{matrix}\right.$$

Whence, as before, by means of formiate:—



$$C\left\{\begin{matrix}CH^2CHO''\\H\\H\\H\end{matrix}\right.$$

Then on addition of hydrogen:—



$$C\left\{\begin{matrix}CH^2CHO''\\H\\H\\H\end{matrix}\right. + H^2 = C\left\{\begin{matrix}CH^2CHH(OH)\\H\\H\\H\end{matrix}\right. \quad \&c.$$

The compound last formulated is the primary propylic alcohol. Now, if the mechanism of these reactions be studied, it will be apparent that the last atom of carbon which is joined on to the group is that which is ultimately combined with the peroxide of hydrogen. We add CO^2, which goes through the stages, $C\overset{''}{O}(ONa)\frac{C}{4}$, $C\overset{''}{O}H\frac{C}{4}$, and $CH(OH)H\frac{C}{4}$.

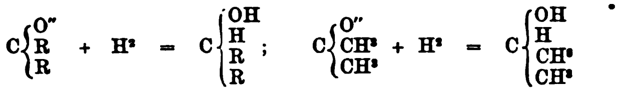
If the formulæ of the primary alcohols be examined, it will appear that one of the chief characteristic structural features of these alcohols is that the atom of carbon which is in combination with the peroxide of hydrogen is in combination with *only one* atom of carbon. This condition is satisfied by the alcohol resulting from the series of reactions above given. It is supposed, but has not been proved, that the alcohols resulting from the fermentation of sugar are identical with those given by the synthetical method.

Genesis of the Alcohols of the Secondary Type.

The formula of a secondary alcohol requires that the same atom of carbon which is in combination with peroxide of hydrogen should be in union with *two* atoms of carbon. This condition is satisfied by forming an alcohol by the addition of hydrogen to a ketone. The constitution of a ketone is this—$C\left\{\begin{matrix}R\\R\\O''\end{matrix}\right.$ as is shown by the general history of the ketones, but most decisively by their formation from carbonic oxide and the compounds of the alkali-metals with the alcohol-radicles:

$$CO + 2NaR = Na^2 + CORR.$$

If then we take a ketone and operate upon its oxygen with nascent hydrogen, the resulting alcohol must contain an atom of carbon which is in direct union with peroxide of hydrogen, and with two atoms of carbon: *e.g.*—

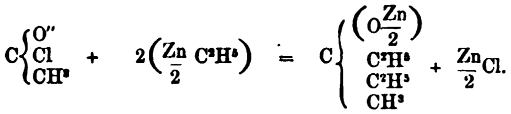


$$C\left\{\begin{matrix}O''\\R\\R\end{matrix}\right. + H^2 = C\left\{\begin{matrix}OH\\H\\R\\R\end{matrix}\right. ; \quad C\left\{\begin{matrix}O''\\CH^3\\CH^3\end{matrix}\right. + H^2 = C\left\{\begin{matrix}OH\\H\\CH^3\\CH^3\end{matrix}\right.$$

The known examples of secondary alcohols are a pseudo- or abnormal propylic alcohol, obtained from acetone and nascent hydrogen, and by attacking glycerin with hydriodic acid, and then decomposing the resulting abnormal iodide of isopropyl with appropriate reagents—a pseudo-butyric alcohol, a pseudo-amylic, and a pseudo-hexylic alcohol, the last-named being obtained from glycerin.

Genesis of the Alcohols of the Tertiary Type.

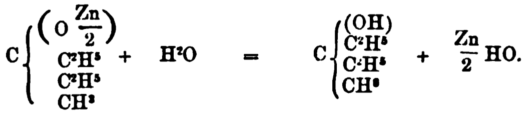
Inspection of the formula of a tertiary alcohol will reveal the fact that a tertiary alcohol must contain an atom of carbon which is in union with *one* atom of peroxide of hydrogen, and *three* of carbon. This structural peculiarity has been realised by Buttlerow, who made chloride of acetyl act on zinc-ethyl as follows:—



$$C\left\{\begin{matrix}O''\\Cl\\CH^3\end{matrix}\right. + 2\left(\frac{Zn}{2}C^2H^5\right) = C\left\{\begin{matrix}\left(O\frac{Zn}{2}\right)\\C^2H^5\\C^2H^5\\CH^3\end{matrix}\right. + \frac{Zn}{2}Cl.$$

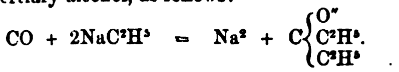
Chloride
of acetyl.

The action of water upon the latter compound gives hydrate of zinc, and the tertiary of alcohol:—

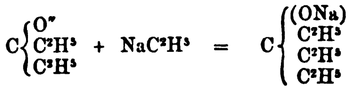


$$C\left\{\begin{matrix}\left(O\frac{Zn}{2}\right)\\ C^2H^5\\ C^2H^5\\ CH^3\end{matrix}\right. + H^2O = C\left\{\begin{matrix}(OH)\\ C^2H^5\\ C^2H^5\\ CH^3\end{matrix}\right. + \frac{Zn}{2}HO.$$

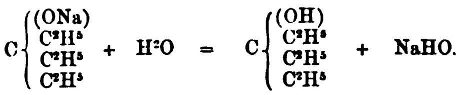
In the reaction between carbonic oxide and sodium-ethyl there appears to result a certain quantity of a tertiary alcohol, as follows:—



$$CO + 2NaC^2H^5 = Na^2 + C\left\{\begin{matrix}O''\\ C^2H^5.\\ C^2H^5\end{matrix}\right.$$



$$C\left\{\begin{matrix}O''\\ C^2H^5\\ C^2H^5\end{matrix}\right. + NaC^2H^5 = C\left\{\begin{matrix}(ONa)\\ C^2H^5\\ C^2H^5\\ C^2H^5\end{matrix}\right.$$



$$C\left\{\begin{matrix}(ONa)\\ C^2H^5\\ C^2H^5\\ C^2H^5\end{matrix}\right. + H^2O = C\left\{\begin{matrix}(OH)\\ C^2H^5\\ C^2H^5\\ C^2H^5\end{matrix}\right. + NaHO.$$

The characters of the tertiary alcohols are almost unknown. The secondary alcohols boil at lower temperatures than the corresponding primary alcohols, and oxidise into ketones instead of into aldehydes. They are apt to evolve their olefine.

J. A. W.

SECONDARY AMIDES and **AMINES.** Compounds derived from a single or multiple molecule of ammonia, by the replacement of two-thirds of the typic hydrogen by acid and basylous radicles respectively (i. 170, 174).

SEIGNETTE SALT. Sodio-potassic tartrate. (See Tartaric Acid.)

SELADONITE. Syn. with Green Earth (ii. 944).

SELBITE. An ash-grey or black silver ore from Wolfach in Baden and the Mexican mines, where it is called *Plata Azul.* It is said to consist mainly of silver-carbonate, but is probably only a mixture.

SELENALDINE. $C^6H^{13}NSe^2$. (Wöhler and Liebig, Ann. Ch. Pharm. lxi. 14.)—A base analogous to thialdine, produced by the action of selenhydric acid on aldehydate of ammonium. To prepare it, the gas is passed into a rather concentrated aqueous solution of the aldehydate, in an apparatus from which the air has been expelled by a current of hydrogen; and when the liquid has deposited crystals of selenaldine, the excess of selenhydric acid gas is likewise expelled by a current of hydrogen. The supernatant liquid containing selenhydrate of ammonium is then displaced by a stream of cold de-aërated water, and the crystals are collected on a filter, pressed, and dried over oil of vitriol.

Selenaldine forms small colourless crystals, probably isomorphous with thialdine, having a faint disagreeable odour, and slightly soluble in water, easily soluble in alcohol and ether, but not crystallisable by evaporation in a vacuum. It is easily decomposed by heat, giving off a fetid gas; when boiled with water it also gives off a very fetid substance, and deposits a yellow powder. Its solution in water, alcohol, or ether yields aldehydate of ammonium on exposure to the air, and deposits an orange-coloured amorphous powder, which is insoluble in alcohol and ether, melts to a yellow-red mass in boiling water, and yields by distillation a very fetid oil containing selenium. Selenaldine dissolves in dilute hydrochloric acid, forming a liquid which is precipitated by ammonia and decomposes quickly, depositing a yellow powder, and emitting an offensive odour.

SELENARSIN. Syn. with Selenide of Cacodyl (i. 408).

SELENETHYL. $(C^2H^5)^2Se$. Already described as Selenide of Ethyl (ii. 544).

SELENHYDRIC ACID. H^2Se. Described as Selenide of Hydrogen (iii. 202). It may also be prepared by heating selenium in a slow stream of pure dry hydrogen gas, forming easily as soon as the selenium assumes the form of vapour. It decomposes at higher temperatures; remains gaseous at —15°. (Uelsmann, Ann. Ch. Pharm. cxvi. 122.)

SELENIC ACID. See Selenium, Oxygen-acids of.

SELENIDES and **SELENHYDRATES.** Selenium unites with metals and with alcohol-radicles, forming compounds analogous in composition, properties, and mode of formation to the sulphides.

Metallic Selenides are obtained in the dry state:—1. By directly fusing the metal with selenium, the combination being often attended with development of light and heat, not so vivid, however, as in the combination of sulphur with the same metals; also by heating the metal in vapour of selenium.—2. By precipitating most of the heavy metallic oxides dissolved in acids, by means of selenhydric acid, or of a disssolved selenide of an alkali-metal, or by heating a hydrated metallic selenide.—3. By heating selenium with metallic oxides or their carbonates, whereby part of the selenium is converted into selenious oxide: thus, the alkalis fused with selenium produce an alkaline selenite and a metallic selenide (Berzelius).—4. By igniting selenites or selenates with hydrogen or charcoal.

The selenides of the alkali-metals have a red or, if they contain excess of selenium, a dark red-brown colour, and the hepatic taste and smell of the corresponding sulphides. Their aqueous solutions, which may be obtained by passing selenhydric acid gas into solutions of the caustic alkalis, are colourless when pure, but are gradually coloured red by free selenium held in solution. On exposure to the air, they decompose, with deposition of crystalline selenium. When selenhydric acid gas is passed to saturation into a solution of caustic alkali, a **selenhydrate** of the alkali-metal, *e.g.* KHSe, is produced.

The selenides of the alkaline earth-metals are flesh-coloured, insoluble in pure water, but soluble in aqueous selenhydric acid; in their other characters they resemble the selenides of the alkali-metals. The selenides of the earth-metals and of manganese and zinc are also flesh-coloured and insoluble in water. The other metallic selenides are mostly dark-coloured, and exhibit the metallic lustre: they are generally more fusible than the metals which they contain. When they are heated to redness in the air, the selenium burns slowly with a reddish-blue flame, and an odour of horseradish. Selenium is, however, more difficult to drive off by roasting than sulphur. The selenides are less easily soluble in nitric acid than the pure metals; selenide of mercury, almost insoluble. Chlorine, with the aid of heat, converts them into chloride of selenium and metallic chloride. Heated in hydrochloric acid gas, they yield metallic chloride and selenhydric acid.

Some metallic selenides occur in nature as rare minerals, or as impurities in sulphides. Selenide of copper occurs as berzelianite at Skrikerum in Sweden, and near Lehrbach in the Hartz; selenide of lead, and selenide of lead and copper, as clausthalite, at Clausthal, Tilkerode, Lehrbach, and other localities in the Hartz; selenide of lead and mercury as lehrbachite at Lehrbach; selenide of silver as naumannite at Tilkerode; selenide of silver and copper, as eucairite, at Skrikerum.

The selenides and selenhydrates (selenium-mercaptans) of the **alcohol-radicles** are volatile fetid liquids resembling the corresponding sulphur-compounds. The ethyl- and methyl-compounds are the only ones yet obtained (ii. 544; iii. 990).

SELENIOCYANATES. $CNMSe = CyMSe$ and $C^2N^2M''Se^2 = Cy^2M''Se^2$.—These compounds, the analogues of the sulphocyanates, were discovered in 1820 by **Berzelius** (Schw. J. xxxi. 60), and have been more fully examined by **Crookes** (Chem. Soc. Qu. J. iv. 12). The potassium-salt is obtained by fusing ferrocyanide of potassium with selenium. The solution of this salt mixed with acetate of lead yields a precipitate of seleniocyanate of lead, which when decomposed by sulphydric acid, yields a solution of hydric seleniocyanate, or seleniocyanic acid; and the other seleniocyanates are obtained by neutralising the acid with bases, or by precipitation, according as they are soluble or insoluble.

Seleniocyanate of Ammonium is a soluble very deliquescent salt, crystallising in minute needles like the potassium-salt.

The *barium-salt* is obtained, but not in definite crystalline form, by dissolving carbonate of barium in the aqueous acid, and evaporating in a vacuum.—The *calcium-salt* crystallises in groups of stellate needles; the *strontium-salt* in fine prisms.

Cupric Seleniocyanate.—Seleniocyanate of potassium added to cupric sulphate throws down a brownish precipitate, which is probably cupric seleniocyanate. It is rapidly decomposed, even at ordinary temperatures, yielding black selenide of copper, with separation of selenhydric acid. (**Crookes**.)

Hydric Seleniocyanate, or *Seleniocyanic Acid*, $CNHSe = CyHSe$, is prepared by passing a rapid stream of sulphydric acid gas through a warm aqueous solution of seleniocyanate of lead in which the same salt is suspended in a state of fine division; heating the filtrate nearly to boiling to expel the excess of sulphydric acid; and again filtering, to separate a small quantity of precipitated selenium. The solution thus obtained is strongly acid, and easily decomposed by boiling or by exposure to the air. It cannot be concentrated without decomposition even in a vacuum over oil of vitriol.

The addition of almost any acid causes an immediate precipitation of selenium, hydrocyanic acid remaining in solution. It dissolves zinc and iron, with evolution of hydrogen, and decomposes carbonates.

Ferric Seleniocyanate.—The rapid decomposition which seleniocyanic acid undergoes in contact with stronger acids, prevents the formation of any red colour with ferric salts by double decomposition. Neither, according to Crookes, is a ferric seleniocyanate obtained by treating ferric oxide with seleniocyanic acid, selenium being immediately precipitated. On one occasion, however, in preparing seleniocyanate of potassium by the process described below, the fused mass having been treated with absolute alcohol in a well-closed flask, a deep blood-red filtrate was obtained, the colour of which soon disappeared on exposure to the air, with deposition of selenium. On other occasions no colour was obtained, the iron always remaining as a black powder, chiefly consisting of carbide of iron.

Seleniocyanate of Lead, $C^2N^2Pb''S^2 = Cy^2Pb''S^2$.—Seleniocyanate of potassium forms, with acetate of lead, a lemon-yellow precipitate, which dissolves, with slight decomposition, in boiling water. The filtered solution, which is neutral to test-paper, deposits, on cooling, beautiful lemon-coloured needles, which are insoluble in alcohol. The salt may be heated to 100° without decomposition, but assumes, when moist, a slight pink tint. The crystals are extremely light. (Crookes.)

Seleniocyanate of Magnesium is soluble, and dries up to a gummy mass apparently destitute of crystalline structure.

Mercuric Seleniocyanate with *Mercuric Chloride*, $C^2N^2Hg''S^2.Hg''Cl^2$.—Obtained by adding an excess of mercuric chloride to seleniocyanate of potassium. When strong solutions are used, the whole immediately solidifies into a felt-like mass of yellowish crystals; these, after washing with water, are purified by recrystallisation from alcohol. The crystals are but sparingly soluble in cold water, but dissolve more readily in hot water, still more in alcohol and in dilute hydrochloric acid; the latter, however, separates selenium after a while. Nitric acid and aqua-regia dissolve the double salt entirely, the liberated selenium being immediately oxidised. The crystals are anhydrous, and may be heated to 100° without decomposition; above that temperature they are decomposed, intumescing in a remarkable manner (Crookes). All attempts to produce the simple seleniocyanate of mercury failed, the double salt just described being always produced

Seleniocyanate of Potassium, $CNKSe = CyKSe$.—Prepared by fusing 1 pt. of selenium with 3 pts. of dry ferrocyanide of potassium in a small retort; digesting the resulting greenish-black mass with absolute alcohol; and passing carbonic anhydride through the solution to decompose cyanide and cyanate of potassium, and precipitate the potassium in the form of acid carbonate (a salt which is quite insoluble in absolute alcohol). The alcohol is then distilled off, together with the hydrocyanic and cyanic acids; and the watery extract of the residue is left to crystallise *in vacuo* over oil of vitriol. The formation of the salt is expressed by the following equation:

$$C^6N^6K^4Fe'' + Se^4 = 4CNKSe + FeC^2 + N^2.$$

The residue in the retort consists chiefly of carbide of iron, together with undecomposed yellow prussiate, and traces of selenium (Crookes). The salt may also be prepared by dissolving selenium in aqueous cyanide of potassium. (Wiggers. Wöhler.)

Seleniocyanate of potassium crystallises in needles, having the same form and taste as the sulphocyanate. It is very deliquescent, and even more soluble than the sulphocyanate. Its solution is decomposed even by weak acids, depositing selenium and giving off hydrocyanic acid. The crystals are strongly alkaline to test-paper, and produce great reduction of temperature when dissolved in water. They may be heated without decomposition in close vessels; but if the air has access to them, they alter when heated a little above 100°.

The *sodium-salt*, obtained by neutralisation, is very soluble, and when evaporated in a vacuum, crystallises in small foliated crystals.

Seleniocyanate of Silver, $CNAgSe$.—The potassium-salt forms with nitrate of silver a curdy precipitate resembling chloride of silver; but if the silver-solution be previously mixed with ammonia, the seleniocyanate of silver is precipitated in beautiful, minute, satiny crystals. This salt blackens readily on exposure to light; is insoluble in water, and very sparingly soluble in cold dilute acids. It is instantly decomposed by boiling with strong acids; and unless oxidising acids are used, selenium is precipitated. (Crookes.)

Seleniocyanate of Zinc, obtained by dissolving either the metal or its oxide in seleniocyanic acid, forms groups of prismatic needles, which are not deliquescent.

SELENIOCYANIC ACID. Syn. with HYDRIC SELENIOCYANATE (p. 219).

SELENIOCYANIC ANHYDRIDE. $C^2N^2Se = \left.\begin{matrix}Cy\\Cy\end{matrix}\right\}Se$.—Produced by the action of iodide of cyanogen on seleniocyanate of silver. It is a volatile crystalline body, closely analogous in all its properties and reactions to sulphocyanic anhydride (*q.v.*). (Linnemann, Ann. Ch. Pharm. cxx. 36.)

SELENIOCYANIC ETHERS. The only one known is the allylic ether, $CN(C^3H^5)Se$, analagous to volatile oil of mustard, which is obtained, though not quite pure, by cohobating 1 at. seleniocyanate of potassium in alcoholic solution with 1 at. allylic iodide for twelve hours, then distilling, and mixing the distillate with water. Allylic seleniocyanate then separates as a heavy yellow oil, which may be obtained colourless by treatment with chloride of calcium and rectification, but does not exhibit a constant boiling-point (150°—184°). The portion boiling at 150° gave by analysis 38·5 per cent. carbon and 42 per cent. selenium, whereas the formula requires 32·6 and 54·4. The compound has an extremely offensive alliaceous odour, and when exposed to the air, gradually turns red from separation of selenium. It differs from the sulphocyanate in not inflaming the skin, and not forming a crystalline compound with ammonia. (Wöhler, Ann. Ch. Pharm. cix. 125).

SELENIOUS ACID. See SELENIUM, OXYGEN-ACIDS OF (p. 226).

SELENITE. Crystallised native sulphate of calcium. (See GYPSUM, ii. 962.)

SELENITES. See SELENIUM, OXYGEN-ACIDS OF (p. 226).

SELENIUM. *Atomic weight*, 79·5. *Symbol*, Se.—An elementary substance belonging to the oxygen-group, and occupying the intermediate place between sulphur and tellurium. It is closely allied in its properties to sulphur, and often associated with that element in the mineral kingdom. It was discovered by Berzelius in 1817, in the refuse of a sulphuric acid manufactory at Gripsholm near Fahlun, in Sweden. Though not an abundant element, it enters into the composition of many minerals. It occurs in the free state at Culebras in Mexico, in crystals, which, according to Mitscherlich, are monoclinic, and in greyish or brownish-black incrustations having a submetallic lustre.* Selenites of cadmium, copper, iron, cobalt, nickel, lead, silver, and mercury, are also found native (p. 219). Selenium frequently occurs as an impurity in native sulphur, as at Vulcano, one of the Lipari Islands, and in metallic sulphides. It occurs to a greater or less extent in the iron pyrites of certain localities, particularly at Fahlun in Sweden, and at Kraslitz and Luckawitz in Bohemia; also in some forms of copper pyrites, those from Rammelsberg and Anglesea, for instance; and occasionally in small quantities associated with the sulphides of lead and molybdenum; also in tellurium-ores, and in pitchblende from Johangeorgenstadt and Schneeberg. The principal sources of selenium are the double selenide of lead and copper found at Clausthal and other places in the Hartz, and the deposit which occurs in the leaden chambers of certain vitriol works, where seleniferous sulphur or pyrites is burned.

Preparation.—1. From the cuproplumbic selenides of the Hartz. The pulverised ore is treated with hydrochloric acid, to dissolve the earthy carbonates, and the washed and dried residue is ignited for some time with an equal quantity of black flux. The selenium is thereby converted into selenide of potassium, which by treatment with boiling water is dissolved away from the oxides formed at the same time. This solution, when exposed to the air, absorbs oxygen, and yields the selenium as a grey deposit, which is washed, dried, and distilled.

2. The seleniferous deposit from certain vitriol works, as those near Fahlun, is mixed with nitrate and carbonate of potassium, and deflagrated in a red-hot crucible. The residue, containing selenate of potassium, is treated with hydrochloric acid, and the whole is evaporated down to a small bulk, whereby a reducing action is set up, and selenious acid is liberated; and on saturating the liquid with sulphurous acid, and heating it to the boiling-point selenium is deposited in red amorphous flakes. For further details respecting both these processes, see *Gmelin's Handbook*, ii. 232.

Another method of obtaining selenium from the deposit of the sulphuric acid chambers, recommended by Liebe (Arch. Pharm. ci. 25), is to treat the deposit with nitromuriatic acid; expel the excess of this acid by heat, after addition of sulphuric acid; wash the residue when cold with water; neutralise the solution with sodic carbonate; evaporate to dryness; roast the residue at a gentle heat with an equal weight of sal-ammoniac, till it becomes red-brown (nitrogen and sal-ammoniac being then given off, but no appreciable quantity of selenium); and treat the red-brown mass with water, which leaves the selenium undissolved.

3. Böttger has shown that the flue-dust of the roasting furnaces in the desilverising works at Mansfeld, in Saxony, contains uncombined selenium in quantity sufficient for profitable extraction (9 per cent. according to Kemper, Arch. Pharm. [2] ci. 25).

---

* This native selenium is sometimes called *Riolite*, from Del Rio, who discovered it; but that name is also applied to selenide of silver, found by the same mineralogist at Tasco in Mexico (p. 111).

To separate the selenium, Böttger levigates the flue-deposit; washes out the heavier parts with water containing hydrochloric acid, and with pure water; then fuses it with crude sodic or potassic carbonate; pulverises the fused mass, lixiviates it, and leaves the brown-red liquid exposed to the air; then separates the deposited selenium by filtration, and distils it. (J. pr. Chem. lxxi. 512.)

Properties.—Selenium, like sulphur, occurs in different allotropic states, both amorphous and crystalline. These modifications have been especially studied by Hittorf (Pogg. Ann. lxxxiv. 214; Jahresb. 1851, p. 318), Mitscherlich (J. pr. Chem. lxvi. 301; Jahresb. 1855, p. 314), and Regnault (Ann. Ch. Phys. [3] xlvi. 257; Jahresb. 1856, p. 44.)

1. *Amorphous.*—Selenium, precipitated from a solution of selenhydric acid by exposure to the air, or by electrolysis (electronegative selenium), is amorphous, and soluble in sulphide of carbon; that which is deposited from aqueous selenious acid, either by electrolysis or by the reducing action of sulphurous acid (electropositive selenium), is likewise amorphous, but insoluble in sulphide of carbon.

Amorphous selenium softens when heated, becomes semifluid at 100°, and perfectly fluid at a somewhat higher temperature (Berzelius, *Traité de Chimie* [1846], ii. 190). On cooling, the selenium remains soft for a long time, and may be drawn out, like sealing-wax, into long thin flexible threads, which when flattened are transparent, and of a deep ruby colour by transmitted light. When quickly cooled from fusion, it forms a brittle solid, having a glassy fracture, almost metallic lustre, and deep brown colour. This *vitreous* selenium has a specific gravity of 4·3, is nearly insoluble in sulphide of carbon, does not conduct electricity, but becomes slightly electrical by friction in a dry atmosphere.

2. *Crystalline.*—*a.* Selenium, when very slowly cooled from the fused state, forms a lead-grey mass having an irregular granular surface and fine-grained fracture (Berzelius). Vitreous selenium remains unaltered at ordinary temperatures, but at temperatures between 80° and 217°, most quickly between 125° and 180°, it becomes crystalline, the change being attended with considerable rise of temperature (Hittorf). According to Regnault, vitreous selenium remains unaltered, even when heated to 90° for several hours; but at 96° or 97° it passes quickly, and with great evolution of heat, into the crystalline state, acquiring a bluish-grey colour, metallic lustre, and granular fracture. According to Mitscherlich, the change from the vitreous to the crystalline state is most easily effected by melting the selenium in a flask, heating it above 217°, then quickly cooling it to 180°—190°, and keeping it for some time at this temperature. This crystallo-granular selenium is quite insoluble in sulphide of carbon. According to Hittorf, it melts at 217° without previous softening; but according to Regnault, it gradually softens when heated, and does not become completely fluid till heated above 250°.

β. Selenium deposited from a solution of selenide of ammonium, potassium, or sodium, on exposure to the air, is likewise crystalline, and has a specific gravity of 4·808 at 15° (Hittorf); 4·760—4·788 at 15° (Mitscherlich). It is likewise insoluble in sulphide of carbon, and, according to Mitscherlich, is identical in every respect with the crystallo-granular variety obtained by the transformation of vitreous selenium. Crystalline selenium conducts electricity better than the vitreous modification, and the more easily as its temperature is higher.

γ. Selenium is deposited from solution in sulphide of carbon in small but distinct crystals, which, according to Mitscherlich, are monoclinic, exhibiting the dominant faces, oP, 0+P, −P, together with numerous secondary faces. Axes $a : b : c = 0·6170 : 1 : ·9622$. Angle $b : c = 75° 34'$; oP : +P = 112° 36′; oP : −P = 124° 48′ : ∞P∞ : +P = 111° 48′; ∞P∞ : − P = 123° 63′. These crystals dissolve easily, though sparingly, in sulphide of carbon, 100 pts. of that liquid dissolving 1 pt. of selenium at the boiling heat, and 0·016 pt. at 0°. They retain their solubility after being heated to 100°, but if heated to 150°, becomes nearly black and quite insoluble in sulphide of carbon; the selenium thus modified regains its solubility by melting and rapid cooling. The crystals before being heated have a specific gravity of 4·46 to 4·509 at 15°; after heating, it increases to 4·7°, being then nearly equal to that of the variety deposited from solutions of alkaline selenides. Crystalline selenium appears indeed to be dimorphous, the two varieties being probably related to one another in the same manner in monoclinic and rhombic sulphur (ii. 332). Native selenium (p. 221) appears to be monoclinic (Mitscherlich); its specific gravity is 4·3—4·2, and hardness 2·0.

Amorphous and crystalline selenium exhibit, according to Regnault, a considerable difference of specific heat at comparatively high temperatures. He found the specific heat of crystalline selenium between 98° and 20° to be = 0·0762; that of amorphous selenium considerably greater—viz., 0·1036 between 87° and 19°, and 0·1026 between 77° and 18°. At lower temperatures, however, as between −20° and 7°, the specific heats of the two modifications are sensibly equal. The change from the amorphous to the crystalline state is attended with the evolution of a quantity of heat sufficient, according to Regnault, to raise the temperature of the selenium 200 degrees. Mitscherlich, however, found the rise of temperature to be much smaller, viz. 20°; and according to Hittorf, it is only 5° (the thermometer rising from 210° to 215°).

Selenium heated in close vessels boils below a red heat, and is converted into a deep yellow vapour, which condenses in scarlet flowers or black lustrous drops, according to the size of the condenser. At temperatures not much above its boiling-point, the density of its vapour, like that of sulphur under similar circumstances, is anomalous; but at higher temperatures it diminishes, and ultimately the vapour occupies a bulk nearly equal to that of an equivalent quantity of oxygen. According to Deville and Troost (Ann. Ch. Pharm. cxxvii. 274), the vapour-density of selenium is 7·67 at 860°, 6·37 at 1040°, and 5·68 at 1420°, the calculated density for a two-volume condensation being 5·54.

Selenium is quite insoluble in water, whether cold or hot. It dissolves to a slight amount in oil of vitriol, but is precipitated on dilution. Its relations to sulphide of carbon have already been mentioned. Monoclinic selenium and the amorphous variety deposited from selenhydric acid are soluble in that liquid; the vitreous modification is very slightly soluble; and the crystallo-granular variety, the crystalline selenium deposited from alkaline selenides, and the amorphous variety deposited from selenious acid, are quite insoluble.

Selenium does not take fire very readily, but when thoroughly heated in contact with air, it burns with a blue flame, forming selenious anhydride, giving off yellowish-red vapours of unoxidised selenium, and emitting an odour like that of decayed horseradish, probably due to a protoxide of selenium formed at the same time. When heated in a current of oxygen gas, it is wholly converted into selenious anhydride. It unites directly with bromine and chlorine, and, when heated, also with iodine, sulphur, phosphorus, and metals. It is oxidised and dissolved by nitric and nitromuriatic acid, yielding selenious acid.

SELENIUM, BROMIDE OF. When pulverised selenium is dropped by small quantities into bromine, combination takes place, attended with loud hissing and considerable evolution of heat; and the compound instantly solidifies to a brown-red or orange-red mass, which fumes in the air and smells like chloride of sulphur. It volatilises when heated, part being resolved into selenium and bromine, while the rest sublimes as a yellow mass. Water dissolves and decomposes it, forming hydrobromic and selenious acids. (Serullas.)

SELENIUM, CHLORIDES OF. There are two chlorides of selenium, both formed by direct combination. The *dichloride*, Se^2Cl^2, or *perselenide of chlorine*, analogous to persulphide of chlorine, S^2Cl^2, and persulphide of hydrogen, H^2S^2, was discovered by Berzelius, who obtained it by heating the tetrachloride with selenium. According to Sacc (Ann. Ch. Phys. [3] xxiii. 124), it may be obtained by passing a slow stream of dry chlorine through an inclined glass tube filled with fragments of fused selenium. The heat evolved by the reaction volatilises the chloride of selenium, which condenses in the colder parts of the tube, and flows in thick drops through the open end into a perfectly dry receiver.

Dichloride of selenium is a dark-yellow oily liquid, having a pungent odour, not very volatile according to Berzelius, extremely volatile according to Sacc. It is slowly decomposed by cold, quickly by hot water, into hydrochloric acid, selenious acid, and free selenium; but the decomposition is seldom complete, because a portion of the dichloride generally becomes mechanically enclosed in the solid selenium.

Tetrachloride of Selenium, $SeCl^4$, is produced by passing chlorine gas over fused selenium, contained in a bulb-tube. The liquid dichloride is at first produced, and is afterwards converted into a white solid mass of the tetrachloride, which when further heated, volatilises as a yellow vapour, and sublimes on the colder parts of the apparatus in small thin crystals. By prolonged heating, the crystals aggregate into a white semi-fused mass, which becomes fissured on cooling. Tetrachloride of selenium dissolves in water with rise of temperature and slight effervescence, forming a solution of hydrochloric and selenious acids: $SeCl^4 + 3H^2O = 4HCl + H^2SeO^3$ (Berzelius, Ann. Ch. Phys. [2] ix. 225). When decomposed by a small quantity of water, or by exposure to moist air, it yields oxychloride of selenium, $SeCl^2O$ or $SeCl^4.SeO^2$ (p. 224).

When a selenate is heated with common salt and sulphuric acid, tetrachloride of selenium mixed with free chlorine passes over first, and then green vapours, which condense to an oily mixture of selenious and sulphuric acids. (H. Rose, Pogg. Ann. xxvii. 575.)

Tetrachloride of selenium gradually absorbs vapour of sulphuric anhydride, especially when the two substances are enclosed in a closely-corked vessel and placed in a warm room; they then unite, without disengagement either of sulphurous anhydride or of chlorine, and form a very dense greenish-yellow syrup, the excess of sulphuric anhydride remaining in the crystalline form. On distilling the syrup at a gentle heat, the excess of sulphuric anhydride passes over first, and the residue in the retort solidifies on cooling to a white crystalline mass. This, when more strongly heated, melts to a light-brown liquid, and evolves (with disengagement of chlorine, but not of sulphurous anhydride) a reddish-yellow vapour resembling nitric peroxide, which condenses to a colourless syrup, and finally to a white mass resembling wax. The latter substance is freed from adhering chlorine by a second distillation. After this treatment, it boils constantly at 187°, and may be redistilled without leaving any residue or undergoing further decomposition. It contains, on the average, 12·895 per cent. of selenium and 36·885 of chlorine; and, according to H. Rose, may be regarded as $2(SeCl^6.5SO^3) + 5(SeCl^4.SeO^2)$. Berzelius, on the other hand, regards it as consisting mainly of the compound $SeCl^4.SO^3$, analogous to the compounds of sulphuric anhydride with other chlorides. It deliquesces rapidly in the air, exhaling the odour of hydrochloric acid; and dissolves readily in water, without first sinking to the bottom in oily drops; the solution, which is generally coloured red, from the presence of a small quantity of free selenium, contains hydrochloric, sulphuric, and selenious acids (no selenic acid). (H. Rose, Pogg. Ann. xliv. 315.)

SELENIUM, CYANIDES OF. Syn. with SELENIOCYANIC ANHYDRIDE (p. 220).

SELENIUM, DETECTION AND ESTIMATION OF. 1. *Blowpipe-reactions.*—Metallic selenides heated in the outer flame, and selenites or selenates heated in the inner flame, on charcoal, give off a characteristic odour, like that of decayed horseradish. When a metallic selenide is heated in the outer flame on charcoal, the charcoal generally becomes covered, at some distance from the bead, with a steel-grey, slightly metallic deposit of selenium, which may be easily driven by the oxidising flame from one part to another. Selenium-compounds heated on charcoal with carbonate of sodium yield a residue of selenide of sodium, which when placed on a clean silver surface and moistened with a drop of water, produces a black stain. When a metallic selenide is heated in an inclined glass tube open at both ends, part of the selenium is volatilised in the free state, and forms a red sublimate on the upper part of the tube, the metal being at the same time oxidised. Sometimes also selenious oxide is formed, and deposited on the colder part of the tube in a network of crystals.

2. *Reactions in Solution.*—Selenhydric acid and solutions of alkaline selenides deposit selenium on exposure to the air, the former yielding it in red amorphous flakes, the latter as a grey crystalline film (p. 222). Selenides heated with *acids*, give off selenhydric acid gas, which is inflammable, has a peculiar fetid odour, and forms dark-coloured precipitates with most metallic solutions (iii. 202).

Soluble selenites give with *sulphurous acid* and other reducing agents, a red precipitate of free selenium, and with *sulphydric acid*, a lemon-yellow precipitate of sulphide of selenium. Soluble selenates give with *chloride of barium*, a precipitate of barytic selenate, which is insoluble in cold dilute acids; but when heated with hydrochloric acid, gives off chlorine and is reduced to selenite of barium, which dissolves.

3. *Estimation and Separation.*—The methods adopted for the quantitative estimation of selenium vary according to the nature of the compound to be analysed. When the selenium is contained in a solution in the form of selenious acid or a selenite, the solution is acidulated with hydrochloric acid, and mixed with an *alkaline sulphite*. The selenium is thereby reduced and precipitated as a red powder, which, on heating the liquid, cakes together and turns black. The treatment with alkaline sulphite must be repeated till no more red coloration is produced. The precipitate is then to be collected on a weighed filter, washed, dried at a gentle heat, and weighed. If the solution likewise contains nitric acid, this acid must be decomposed by boiling with hydrochloric acid before adding the alkaline sulphite.

When selenium is present in solution as selenic acid, the liquid must be boiled with *hydrochloric acid* to convert the selenic into selenious acid, from which the selenium may then be precipitated by an alkaline sulphite as above. The precipitation of selenic acid as a barium-salt does not give very exact results, because selenate of barium is not quite insoluble in dilute acids, and, moreover, has even a greater tendency than the sulphate to carry down other salts, which cannot be separated from it by washing with hot water. Insoluble selenates, like selenate of barium, which are but slowly reduced to selenites by boiling with hydrochloric acid, must first be decomposed by digestion with a solution of alkaline carbonate. If, however, the selenate of barium be mixed with sulphate, the decomposition of the former by aqueous alkaline carbonates is never complete; hence sulphate and selenate of barium cannot be separated by this method (H. Rose, Pogg. Ann. cxiii. 472, 621; Jahresb. 1861, p. 828). The quantities of these two salts in a mixture may, however, be ascertained by an indirect method.

A weighed quantity of the mixed barium-salts is fused with a mixture of potassic and sodic carbonates in equivalent proportions; the soluble salts are washed out; and the residual barium-carbonate is weighed. If now the weight of barium-sulphate equivalent to this weight of carbonate be subtracted from the weight of the mixture of sulphate and selenate, and the difference be multiplied by $\frac{140{\cdot}5}{140{\cdot}5 - 116{\cdot}5} = \frac{140{\cdot}5}{24}$ (since $BaSO^4 = 140{\cdot}5$ and $BaSO^4 = 116{\cdot}5$), the product will give the quantity of barium-selenate in the mixture. (Wohlwill, *Handw. d. Chem.* vii. 800.)

Selenites and selenates may also be analysed by fusing them with 7 or 8 pts. of *potassium-cyanide* in an atmosphere of hydrogen. The whole of the selenium is thereby converted into seleniocyanate of potassium, the aqueous solution of which when boiled for some sime (to convert any selenide of potassium that may be present into seleniocyanate), and supersaturated when cold with hydrochloric acid, deposits the whole of the selenium in the course of 12 to 24 hours. The selenium may then be dried at 100° and weighed. Free selenious or selenic acid in solution may be neutralised with an alkaline carbonate, the solution evaporated to dryness, and the residue treated as just described. (Oppenheim, J. pr. Chem. lxx. 266; H. Rose, *loc. cit.*)

Selenium may also be separated from sulphur and tellurium by fusing the mixture, in which the selenium and tellurium may both exist as oxygen-acids, with 10 pts. of cyanide of potassium in a long-necked flask through which a stream of hydrogen is passed. The selenium and sulphur are thereby converted into seleniocyanate and sulphocyanate, and the tellurium into telluride of potassium; and on passing a stream of air through the aqueous solution of the product, the whole, of the tellurium is precipitated in the free state, and the filtrate, treated with hydrochloric acid as above, deposits the selenium, while the sulphur remains in solution. From a finely-pulverised mixture of sulphur and selenium, the whole of the selenium may be dissolved out by digestion with a warm solution of potassium-cyanide, which also takes up part of the sulphur. The undissolved sulphur is then collected and weighed, the selenium precipitated from the filtrate by hydrochloric acid, the dissolved sulphur oxidised by chlorine to sulphuric acid, and precipitated by a barium-salt (H. Rose). Small quantities of selenium may be detected in sulphur by boiling with aqueous potassium-cyanide, the solution, if selenium is present, exhibiting a reddish turbidity when treated with hydrochloric acid.

Metallic Selenides are best analysed by heating them in a stream of *chlorine*, the selenium then volatilising as di- and tetrachloride, while the metallic chloride in most cases remains behind. The chlorides of selenium are collected in water, whereby a solution of selenious and selenic acids is formed. This is heated with hydrochloric acid, to reduce the selenic to selenious acid, and the selenium is precipitated therefrom by an alkaline sulphite as above. In applying this method to the selenides of lead and zinc, care must be taken not to apply too strong a heat, as the chlorides of these metals are somewhat volatile. The chlorides of mercury, arsenic, and antimony pass over into the receiver, and are dissolved together with the chlorides of selenium. The presence of arsenic or antimony does not interfere with the precipitation of the selenium by sulphurous acid; but mercury would be precipitated at the same time, in the form of calomel. In this case, therefore, the whole of the selenious acid must be converted into selenic acid by saturating the liquid with chlorine; the selenic acid precipitated by a barium-salt, the excess of barium removed by sulphuric acid, and the mercury precipitated as calomel by an alkaline formate.

4. *Atomic Weight of Selenium.*—Numerous attempts have been made to determine the atomic weight of selenium by the analysis of selenites and selenates, but the results are by no means accordant (*Handw. d. Chem.* 2^{te} Auflage, ii. [2] 500). Berzelius found that 100 parts of selenium heated in a current of chlorine yielded 279 pts. of tetrachloride, $SeCl^4$: whence $Se = \frac{4Cl \times 100}{179} = 79{\cdot}32$. Dumas (Ann Ch. Pharm. cxiii. 31), by a similar method, taking care to condense the chloride of selenium completely by passing the excess of chlorine through a tube cooled to −20°, and then through another filled with asbestos, obtained, as a mean of seven experiments, $Se = 79{\cdot}46$.

SELENIUM, FLUORIDE OF. Obtained, according to Knox, by heating fluoride of lead in selenium-vapour, selenide of lead then remaining, while the fluoride of selenium sublimes in crystals. It volatilises undecomposed at higher temperatures, dissolves in strong hydrofluoric acid, but is immediately decomposed by water into hydrofluoric and selenious acids.

SELENIUM, IODIDES OF. Not known with certainty. Equivalent quantities of iodine and selenium melt together when heated, to a blackish-grey mass, from which the whole of the iodine is extracted by absolute alcohol. (Trommsdorff.)

SELENIUM, OXIDES AND OXYGEN-ACIDS OF. The only oxide of selenium whose composition is exactly known is the dioxide or selenious anhydride, SeO^2, the hydrate of which is selenious acid, H^2SeO^3. A lower oxide is produced by the imperfect combustion of selenium in air or oxygen, but its composition has not been ascertained. It is a colourless gas, which is the source of the peculiar horseradish odour evolved in the combustion of selenium; it is sparingly soluble in water, but has no acid reaction. The trioxide, or anhydride of selenic acid, $H^2O.SeO^3$, has not been isolated.

Dioxide of Selenium, Selenious Oxide or **Anhydride,** SeO^2.—This compound, the analogue of sulphurous oxide, SO^2, is produced by burning selenium in a stream of oxygen; or by evaporating the solution of selenious acid to dryness. In the latter case it is obtained as a white mass which does not melt, but, at a heat somewhat below redness, volatilises in the form of a yellow vapour, which condenses in white four-sided needles. It absorbs water rapidly, producing selenious acid.

Selenious Acid, $H^2SeO^3 = \left.\begin{matrix}(SeO)''\\H^2\end{matrix}\right\}O^2$.—This acid is produced by the hydration of selenious oxide, or by the action of nitric or nitromuriatic acid on selenium. From its hot aqueous solution, it is deposited, on slow cooling, in prismatic crystals like those of saltpetre, which readily absorb water, but effloresce in dry air. When heated it splits up into water and the anhydride, which sublimes at a higher temperature. Its solution has an acid taste, and is reduced, especially at the boiling heat, by *sulphurous acid* or a *sulphite*, with deposition of red amorphous selenium; also by *stannous chloride*, and by all *metals*, except gold, palladium, and platinum, but not by ferrous sulphate. *Sulphydric acid* throws down from its solution a yellow precipitate, usually regarded as disulphide of selenium, but consisting, according to H. Rose (Pogg. Ann. cvii. 186), merely of a mixture of selenium and sulphur:

$$H^2SeO^3 + 2H^2S = 3H^2O + Se + S^2$$

Selenious acid is not decomposed by boiling with hydrochloric acid. It is oxidised to selenic acid by *chlorine* in presence of water, by *potassic chromate*, *peroxide of manganese*, and *peroxide of lead*, and by fusion with *saltpetre*.

Selenious acid is a very powerful acid, approximating to sulphuric acid in the energy of its reactions. It reddens litmus, neutralises alkalis completely, effervesces with carbonates, and being non-volatile, decomposes chlorides and nitrates with aid of heat. Its aqueous solution precipitates the neutral salts of lead and silver.

Selenites.

Selenious acid is dibasic, forming neutral salts, M^2SeO^3 and $M''SeO^3$, and acid salts, $HMSeO^3$ and $H^2M''Se^2O^6$. The acid selenites of the alkali-metals also form double or hyperacid salts, with an additional quantity of selenious acid: *e.g.* $HKSeO^3.H^2SeO^3$. The neutral selenites have a purely saline taste. They are decomposed by heating with *charcoal*, yielding selenides, or metallic oxide and selenium. When heated with *carbonate of sodium* in the inner blowpipe-flame, they emit the characteristic horseradish odour. The fused mass moistened with water produces a brown stain on silver. Heated with *chloride of ammonium*, out of contact with the air, they yield a sublimate of metallic selenium. The selenites of the alkali-metals are soluble in water, and their solutions, acidulated with hydrochloric acid, behave like the free acid with sulphurous acid, sulphydric acid, &c. The other selenites are insoluble in water, but soluble in nitric acid; the lead- and silver-salts, however, dissolve but slowly. The selenites have been examined chiefly by Berzelius and by Muspratt. (Chem. Soc. Qu. J. ii. 52.)

SELENITES OF ALUMINIUM.—The *neutral salt*, $Al^2O^3.3SeO^2 = \left.\begin{matrix}(Se''O)^3\\(Al''')^2\end{matrix}\right\}O^6$, obtained by precipitating an aluminium-salt with neutral selenite of potassium, is a white powder insoluble in water, and decomposing when strongly heated, giving off first water and then the whole of its acid (Berzelius).—An *acid salt* is formed by dissolving the neutral salt or aluminium-hydrate in selenious acid, and is obtained by evaporation as a colourless, gummy, transparent mass, having a harsh taste and easily soluble in water. (Berzelius.)

SELENITES OF AMMONIUM.—The *neutral salt*, $(NH^4)^2SeO^3$, is obtained in shining deliquescent crystals, by saturating alcoholic selenious acid with ammonia-gas (Muspratt); also by leaving a solution of the acid in excess of aqueous ammonia to evaporate in a warm place. When heated it gives off water and ammonia, and afterwards water and nitrogen, together with a small quantity of the hyperacid salt, and leaves a residue of fused selenium:

$$3(NH^4)^2SeO^3 \quad = \quad 9H^2O \; + \; 2NH^3 \; + \; 2N^2 \; + \; Se^3.$$

The *acid salt*, produced, with evolution of ammonia, by leaving an aqueous solution of the neutral salt to evaporate, forms needles permanent in the air (Berzelius).—The *hyperacid salt*, obtained by evaporating a solution of the preceding, with aid of heat, or with addition of selenious acid, is deliquescent and uncrystallisable. (Berzelius.)

Selenites of Barium.—The *neutral salt*, $Ba''SeO^3$, separates from a mixture of barium-chloride and neutral potassium-selenite, as a white precipitate, insoluble in water, easily soluble in acids. It does not fuse even at the melting-point of glass (Berzelius). According to Muspratt, it separates from a mixture of barium-nitrate and potassium-selenite, in delicate, shining, feathery crystals.—The *acid salt* is obtained by dissolving barium-carbonate in selenious acid, and leaving the solution to evaporate, in crystalline granules, sparingly soluble in water. Ammonia added to the solution throws down the neutral salt (Berzelius). When strongly heated it gives off white fumes of selenious oxide. (Muspratt.)

Selenite of Cadmium, $Cd''SeO^3$, is a white precipitate, which becomes orange-yellow on exposure to the air, and yields a yellowish sublimate when heated in a glass tube. It is anhydrous, and soluble in selenious acid. (Muspratt.)

Selenites of Calcium.—The *neutral salt*, $Ca''SeO^3$, separates as a soft crystalline powder from a solution of calcium-carbonate in selenious acid. It is sparingly soluble in water, and melts at a bright red heat (Berzelius).—An *acid salt* crystallises from a solution of the neutral salt in excess of selenious acid, in very small prisms, which are permanent in the air at ordinary temperatures, but give off half their acid when heated, or in contact with ammonia. (Berzelius.)

Selenites of Cerium.—The *neutral cerous salt* is a white powder, insoluble in water, soluble in selenious acid.—The *neutral ceric salt* is a lemon-yellow powder, which when heated gives off its acid and leaves ceric [? ceroso-ceric] oxide. It dissolves in selenious acid, forming an *acid salt*, which dries up on evaporation to a yellow varnish, and when heated gives off water, becoming opaque and crystalline. (Berzelius.)

Chromic Selenite, $Cr^2O^3.3SeO^2 = \left.\begin{matrix}(Se''O)^3\\(Cr''')^2\end{matrix}\right\}O^6$, is obtained by precipitating chromic chloride with selenite of ammonium, as a green amorphous powder, the solution of which in selenious acid leaves a green varnish on evaporation. (Muspratt.)

Selenite of Cobalt.—The *neutral salt*, $Co''SeO^3$, is a pale-red powder, insoluble in water.—The *acid salt* is soluble, and remains on evaporation as a purple-red varnish. (Berzelius.)

Selenites of Copper.—The *neutral cupric salt*, $Cu''SeO^3$, is precipitated on adding the acid ammonium-salt to a warm solution of cupric sulphate, in bulky, curdy, yellowish flocks, quickly converted by heat into small, silky, greenish-blue crystals, which at a higher temperature give off water and turn liver-brown, then melt, and ultimately give off all their acid. The salt is insoluble in water and in selenious acid (Berzelius). According to Muspratt, it turns blue over oil of vitriol, and has the composition $3Cu''SeO^3.H^2O$.—A *basic cupric selenite* is precipitated on mixing cupric sulphate with ammonium-selenite containing excess of ammonia, as a pistachio-brown powder, insoluble in water but soluble in ammonia. When heated it first loses water, then froths up, and gives off all its acid. (Berzelius.)

Cuprous Selenite is a white insoluble powder, obtained by digesting cuprous hydrate with selenious acid. (Berzelius.)

Selenites of Glucinum.—The *neutral salt* is a white insoluble powder, which leaves glucina when ignited. The acid salt is gummy and soluble in water. (Berzelius.)

Selenites of Iron.—The *neutral ferric salt*, $Fe^2O^3.3SeO^2 = \left.\begin{matrix}(Se''O)^3\\(Fe''')^2\end{matrix}\right\}O^6$, obtained by double decomposition, is a white insoluble powder, which becomes somewhat yellowish on drying, gives off water at a higher temperature, then turns red, and gives off all its acid (Berzelius).—An *acid ferric selenite* crystallises on cooling from a solution of iron in an excess of mixed selenious and nitric acids, in pistachio-green laminæ. When heated it gives off water, gradually blackens and gives off its acid, and ultimately leaves a residue of ferric oxide. It is insoluble in water, but dissolves with orange-yellow colour in hydrochloric acid (Berzelius).—A *basic ferric selenite*, insoluble in water, is obtained by treating either of the preceding salts with ammonia. (Berzelius.)

Neutral ferrous Selenite, $Fe''SeO^3$, is a white precipitate, gradually turning grey, and ultimately yellow, on exposure to the air. Its solution in selenious acid yields an *acid salt*, $Fe''SeO^3.SeO^2$, slightly soluble in water; the solution, when heated, yields a brown precipitate, consisting of selenium and ferric selenite. (Berzelius.)

Selenites of Lead.—The *neutral salt*, $Pb''SeO^3$, obtained by precipitating aqueous chloride of lead with excess of ammonium-selenite, is a white heavy powder, nearly insoluble in water, slightly soluble in nitric acid, and melting, almost as easily as chloride of lead, to a yellowish transparent liquid, which solidifies to a white opaque mass having a crystalline fracture. By exposure to a strong red heat, or by treatment with ammonia, it is converted into a *basic salt*, which forms a translucent, friable, fusible mass, also having a crystalline fracture.—According to Kersten (Pogg. Ann. xlvi. 277), neutral selenite of lead occurs native; but, according to H. Rose, the mineral thus characterised is a selenate (p. 232).

Selenites of Magnesium.—The *neutral salt*, $Mg''SeO^3.3H^2O$ (Muspratt), remains, on treating carbonate of magnesium with selenious acid, as a granular powder, insoluble in cold, slightly soluble in hot water, and separating therefrom, on evaporation and cooling, in small four-sided prisms or tables. At a higher temperature it gives off its water, and acquires a fused appearance, but without actually melting or giving off acid, and attacks the glass strongly (Berzelius).—The *acid salt* is precipitated by alcohol from a solution of the neutral salt in selenious acid, as a crystallisable, pasty, deliquescent mass. (Berzelius.)

Selenites of Manganese.—The *neutral salt* is, according to Berzelius, a soft, white, easily fusible powder, which melts and decomposes when heated, and, in the fused state, attacks glass strongly. It is insoluble in water. Muspratt, by dissolving carbonate of manganese in selenious acid, obtained a white sandy powder having the composition $Mn''SeO^3.2H^2O$, which formed a colourless solution with cold, and a pale-red solution with hydrochloric acid.—The *acid salt* is crystallisable, very soluble in water, and gives off half its acid when heated out of contact with the air.

Selenites of Mercury.—The *neutral mercuric salt*, $Hg''SeO^3$, obtained by double decomposition, or by bringing mercuric oxide in contact with aqueous selenious acid, is a white powder, insoluble or very slightly soluble in water.—The *acid mercuric salt*, formed by adding mercuric oxide to aqueous selenious acid till the neutral salt begins to separate out, then filtering and evaporating, crystallises in large prisms, longitudinally striated, having the taste of corrosive sublimate, and containing a large quantity of water. The crystallised salt melts in its water of crystallisation when heated, then solidifies, and finally sublimes unaltered. It dissolves easily in water, very slightly in alcohol; the aqueous solution is not precipitated by ammonia, and very slowly by alkaline carbonates; potash also throws down only part of the oxide. Sulphurous acid precipitates white mercurous selenite, which soon acquires a scarlet colour, from the presence of reduced selenium (Berzelius).—A *basic salt*, $3Hg''O.4Hg''SeO^3$, is obtained, according to Köhler, by boiling precipitated mercuric oxide with selenious acid. It is pale-yellow and insoluble in water.

Neutral mercurous Selenite, Hg^2SeO^3, obtained by precipitating mercurous nitrate with selenite of sodium, is a white powder, melting when heated to a dark-brown substance, which becomes lemon-yellow on cooling; at a stronger heat, it boils, and passes over in brown drops, which become amber-yellow and mostly transparent on cooling. Hydrochloric acid converts it into mercuric chloride, the selenious acid being partly reduced to the state of free selenium, and partly remaining dissolved in the liquid. The salt gives up all its acid to caustic potash. It is not soluble either in water or in aqueous selenious acid (Berzelius).—A *mercurous anhydro-salt*, $3Hg^2SeO^3.SeO^2$, is obtained, according to Köhler, as a dark, brick-red, opaque, crystalline mass, by melting the neutral salt at 180°, and raising the temperature a little higher.

Selenite of Nickel.—The *neutral salt*, obtained by precipitation, is insoluble in water, white when moist, but becomes apple-green on drying (Berzelius). According to Muspratt, on the contrary, it is precipitated, on adding selenite of potassium to sulphate of nickel, as a greenish powder, containing $Ni''SeO^3.H^2O$, which becomes white when dry.—The *acid salt* is a green gummy mass, soluble in water. (Berzelius.)

Selenites of Potassium.—Selenious acid and potash form three different salts, which are obtained by mixing the acid with potash or potassium-carbonate in the required proportions.—The *neutral salt*, K^2SeO^3, obtained by saturating carbonate of potassium with selenious acid, separates on evaporation, but not on cooling, in crystalline grains. It melts, when heated, to a yellow mass, which again becomes white on cooling; it attracts moisture from the air, and dissolves in nearly all proportions in water, but is insoluble in alcohol. It has a disagreeable taste, and strong alkaline action to test-paper.—The *acid salt*, $KHSeO^3$, crystallises with difficulty on cooling from a solution evaporated to the consistence of syrup, or from a slightly acid solution by evaporation over oil of vitriol, in feathery crystals (having a satiny lustre according to Muspratt), which unite at last to a compact mass. It slowly parts with the half of its acid when ignited. It is deliquescent, slightly soluble in alcohol.—The *hyperacid salt*, $KHSeO^3.H^2SeO^3$, is uncrystallisable and highly deliquescent. (Berzelius.)

Selenite of Silver, Ag^2SeO^3.—Selenious acid added to nitrate of silver, throws down this salt in the form of a white powder. The same salt crystallises in needles, from a nitric acid solution diluted with hot water. It is not blackened by light. Melts almost as easily as horn-silver, forming a clear liquid, which, on cooling, solidifies in a white opaque mass, friable, and having a crystalline fracture. When more strongly ignited, it gives off selenious oxide and oxygen gas, and becomes covered with metallic silver. Dissolves very sparingly in cold water, somewhat more freely in hot water, and easily in nitric acid, from which it may be precipitated by cold water (Berzelius.)

Selenites of Sodium.—The *neutral salt*, Na^2SeO^2, does not crystallise on cooling, but only by evaporation of an aqueous solution *in vacuo*; it then forms small grains, which are permanent in the air, taste like borax, and dissolve very easily in water, but not in alcohol. According to Muspratt, it forms radiated crystals, which fuse without decomposition.—The *acid salt*, $NaHSeO^3.2H^2O$ (Muspratt), crystallises during the slow cooling of a syrupy solution, in needles united together in tufts, which do not effloresce in the air, but melt when heated, with loss of their water of crystallisation, to a liquid which is yellow while hot, and solidifies, on cooling, to a white mass of a fibrous texture. At a red heat, the salt loses half its acid.—The *hyperacid salt*, $2NaH^3Se^2O^6.H^2O$ or $Na^2SeO^3.3H^2SeO^3.H^2O$ (Muspratt), first obtained by Berzelius, is prepared by dissolving the acid salt in selenious acid, and crystallises by spontaneous evaporation in needles, which are permanent in the air. It melts easily to a yellowish-red liquid, which gives off selenious oxide, leaving a residue of neutral sodium-selenite with traces of selenate. (Muspratt.)

Selenites of Strontium.—The *neutral salt*, $Sr''SeO^3$, is a white powder, infusible, and not soluble in water.—The *acid salt*, obtained like the corresponding barium-salt, separates as a milk-white amorphous crust, on evaporating the aqueous solution. It melts in the fire; swells up and evolves water at first, and then one half of its acid, so that the neutral selenite remains in a spongy form. It is nearly insoluble in cold water, and dissolves but slowly even in boiling water. (Berzelius.)

Selenites of Thallium.—The *neutral salt*, Tl^2SeO^3, is produced by oxidising selenide of thallium with nitric acid, or more easily by treating selenious acid with excess of thallium-carbonate. It has an alkaline reaction, is easily soluble in water, insoluble in alcohol and ether, and crystallises in very thin micaceous laminæ (Kuhlmann, Bull. Soc. Chim. [2] i. 330).—The *acid salt*, $TlHSeO^3$, is more soluble in water than the neutral salt, and crystallises most readily from a solution mixed with alcohol. (Kuhlmann.)

Selenites of Tin.—Stannic selenite is a white powder, insoluble in water, soluble in hydrochloric acid, and precipitated therefrom by water. When strongly heated, it first gives off water, and then the whole of its acid.

Selenites of Uranium.—*Neutral uranic selenite* is a lemon-yellow powder, which is decomposed at high temperatures, giving off oxygen and selenious oxide, and leaving uranoso-uranic oxide. It dissolves in excess of selenious acid, forming an *acid salt*, which dries up to a white, opaque, crystalline mass, soluble in water (Berzelius). According to Muspratt, the crystalline salt thus obtained is *neutral uranic selenite*, $U^2O^3.3SeO^2$.

Selenite of Yttrium is precipitated in curdy white flocks, which dry up to a white powder. It is insoluble in water and in selenious acid, and when strongly heated, first gives off water, and then the whole of its acid. (Berzelius.)

Selenites of Zinc.—The *neutral salt*, $Zn''SeO^3.H^2O$ (Muspratt), is a white powder, insoluble in water. When heated, it gives off water, and melts to a yellow transparent liquid, which on cooling forms a white mass, having a crystalline fracture. At an incipient white heat, it enters into ebullition, and is converted, with sublimation of selenious oxide, into an infusible basic salt, no longer decomposible by heat.—The *acid salt*, obtained by dissolving the neutral salt in selenious acid, is a transparent, fissured, gummy mass, easily soluble in water. (Berzelius.)

Hyperacid Salt, $Zn''H^6Se^4O^{12} = Zn''SeO^3.3H^2SeO^3$.—When clean zinc-turnings or plates of zinc are immersed in a somewhat concentrated aqueous solution of selenious acid the metal soon becomes covered with a thin red layer of reduced selenium, and a solution is formed containing hyperacid zinc-selenite, which, when the solution is evaporated to a syrupy consistence *in vacuo* over oil of vitriol, and then left at rest for about a week, separates in large yellow crystals, very much like those of neutral potassium-chromate. They are oblique rhombic prisms, having their terminal edges, and frequently also the obtuse lateral edges, replaced by planes: generally associated in twins. The salt is permanent in the air, soluble in water. The solution is colourless; has a strong sour taste; is not decomposed by acids; becomes turbid when heated, the salt being resolved into selenious oxide and neutral zinc-selenite. A crystal heated to 30° or 40° undergoes the same change, becoming white and opaque; on increasing the heat, the crystal melts, and is resolved into water which distils over, selenious oxide which sublimes, and a neutral or basic salt which remains behind. (Wöhler, Ann. Ch. Pharm. lix. 279.)

SELENITE OF ZIRCONIUM is a white powder, insoluble in water, soluble in selenious acid, decomposed by heat, leaving a residue of zirconia. (Berzelius.)

Selenic Acid, $H^2SeO^4 = H^2O.SeO^3 = \left.\begin{matrix}(SeO^2)''\\H^2\end{matrix}\right\}O^2$.—This acid, the analogue of sulphuric acid, was discovered in 1827 by Mitscherlich (Pogg. Ann. ix. 623), and has been further examined by Wohlwill (Ann. Ch. Pharm. cxiv. 162) and v. Hauer (Wien. Akad. Ber. xxxix. 299; Jahresb. 1860, p. 85).

Selenic acid (or a metallic selenate) is formed: 1. By fusing selenium, selenious oxide, or a selenite with nitrate of potassium or sodium.—2. By the action of chlorine and water, or of hypochlorous acid, on selenium, selenious acid, or selenites.—3. By heating selenious acid with peroxide of lead, peroxide of manganese, or chromate of potassium. (Wohlwill.)

Preparation.—Aqueous selenic acid is usually prepared by fusing an alkaline selenite with nitrate of potassium or sodium, precipitating the solution of the resulting alkaline selenate with a lead-salt, and decomposing the precipitated selenate of lead with sulphydric acid. According to Wohlwill, however, this process is not advantageous, because a portion of the selenate of lead obstinately resists decomposition. The following is more convenient and productive. Selenious acid is first prepared by dissolving selenium in nitric acid; and the solution, after moderate concentration, is finally evaporated down in a retort provided with a receiver, whereupon, after the excess of nitric acid and the water have been driven off, the liquid suddenly becomes briskly agitated, and a considerable quantity of the selenious acid volatilises and condenses in the receiver to a snowy mass. The solution of this sublimed selenious acid, or cupric selenite (prepared therefrom with cupric carbonate suspended in water), is treated with chlorine gas; the excess of chlorine is allowed to evaporate from the liquid by exposure to the air at the ordinary temperature; the liquid is saturated with pure cupric carbonate; and the cupric selenate contained in the liquid (filtered from unaltered cupric selenite) is separated from cupric chloride by precipitation with alcohol (which leaves the chloride in solution), or by repeated crystallisation. The cupric selenate is then suspended in a small quantity of water, and decomposed by sulphydric acid; and the filtered aqueous acid is concentrated by evaporation over the water-bath. The formation of selenic acid by oxidising selenious acid with chlorine may be used for the preparation of selenates, but not for the direct preparation of the aqueous acid, because the hydrochloric acid formed at the same time reconverts the selenic acid, unless neutralised, into selenious acid, slowly in the cold, quickly when heated. (Wohlwill.)

Von Hauer precipitates a solution of potassium-selenite with calcium-nitrate; purifies the resulting calcium-selenate by solution in water and precipitation by heat (it is less soluble in hot than in cold water); then decomposes it by boiling with excess of cadmium-oxalate and water, till the liquid is free from calcium; precipitates the cadmium from the filtered liquid with sulphydric acid; expels the excess of that acid from the filtrate by heat, and concentrates by evaporation.

Properties.—Selenic acid is a transparent colourless liquid, which in the most concentrated state boils at 280°, and has a specific gravity of 2·6. The liquid in this state is not quite pure selenic acid, H^2SeO^4, but contains a little water in addition, which cannot be driven off without further decomposition of the acid into selenious oxide, water, and oxygen. The concentrated acid resembles sulphuric acid in many of its properties. It is very hygroscopic, and its admixture with water is attended with considerable rise of temperature. The strong or dilute acid boiled with *hydrochloric acid* eliminates chlorine, and is reduced to selenious acid:

$$H^2SeO^4 + 2HCl = Cl^2 + H^2O + H^2SeO^3.$$

On the other hand, it resists the action of many reducing agents which decompose selenious acid. Thus, it is not decomposed by sulphurous or sulphydric acid, and its solution dissolves *zinc* and *iron*, with simple substitution of the metal for hydrogen, not with precipitation of selenium, as is the case with selenious acid (p. 226). The free acid precipitates *barium-salts*, even in presence of other mineral acids. By this property, taken in connection with its reduction to selenious acid, with evolution of chlorine by boiling with hydrochloric acid, selenic acid may be distinguished from all other acids.

Selenates.

Selenic acid is dibasic like sulphuric acid, and capable of forming acid as well as neutral salts. Only one acid selenate has, however, yet been prepared, viz. that of potassium, $KHSeO^4$. The neutral selenates have the composition, M^2SeO^4 or $M''SeO^4$. Many double selenates are also known, represented by the general formulæ, $M''X^2Se^2O^8$ and $M'''XSe^2O^8$, the last being analogous to the alums.

The selenates of the alkali-metals are prepared by igniting selenium, selenides, or selenites with nitrate of potassium or sodium; other selenates by dissolving metallic oxides, hydrates, or carbonates in selenic acid; the selenates of barium, strontium, and lead, which are insoluble in water, and even in nitric acid, by precipitation. The selenates correspond very closely in their properties to the sulphates, with which they are isomorphous. Most of them sustain a red heat without decomposition. Heated in a current of *hydrogen*, they are readily converted into selenides. Heated with *charcoal* or with *carbonate of sodium* in the reducing flame, they are also reduced to selenides, emitting the characteristic horseradish odour. When boiled with *hydrochloric acid*, they evolve chlorine, and leave selenious acid, from which selenium may be precipitated by sulphurous acid.

Selenate of Aluminium resembles the sulphate, and yields corresponding basic salts under similar circumstances (see Sulphates).—*Selenium-alums*, viz. $Al'''KSe^2O^8.12H^2O = \left.\begin{matrix}(Se\overset{''}{O}{}^2)^2\\ Al'''K\end{matrix}\right\}O^4.12H^2O$, and the corresponding ammonium- and sodium-salts, are obtained, by dissolving aluminium-hydrate in excess of selenic acid and neutralising with an alkaline carbonate, in monometric crystals (O with ∞O∞ and ∞O), which effloresce slightly in the air. They are all easily soluble in cold water; the sodium-salt crystallises only from very concentrated solutions, and even in presence of a considerable excess of aluminium-selenate, only in small crystals mixed with selenate of sodium (Wohlwill). The crystals of the potassium-salt have a specific gravity of 1·971. (Weber, Pogg. Ann. cviii. 615.)

Selenate of Barium, $Ba''SeO^4$, obtained by precipitation, is a white powder insoluble in water and in nitric acid, but converted into selenite and dissolved by boiling with hydrochloric acid, being thereby distinguished from the sulphate. Specific gravity = 4·67 at 22°. (Schafarik, Jahresb. 1863, p. 15.)

Selenate of Cadmium, $Cd''SeO^4.2H^2O$, prepared as above (p. 230), crystallises by cooling or spontaneous evaporation in small transparent tables, which are permanent in the air, very soluble in water, give off half their water at 100°, and the rest considerably below a red heat. (v. Hauer.)

Selenate of Calcium, $Ca''SeO^4.2H^2O$, prepared by precipitation (p. 230), separates on warming its aqueous solution, in transparent crystals, which resemble those of gypsum, and may be obtained of considerable size by slow evaporation. The dehydrated salt hardens with water, like burnt gypsum. (v. Hauer.)

Selenate of Chromium and Potassium, or *Selenic Chrome-alum*, crystallises after some time from the liquid obtained by treating a concentrated solution of acid potassium-chromate with selenic acid and alcohol at a moderate heat. (Wohlwill.)

Selenate of Cobalt, $Co''SeO^4.7H^2O$, resembles the sulphate (Mitscherlich). —*Potassio-cobaltous selenate*, $Co''K^2Se^2O^8$, resembles the corresponding nickel-salt. (v. Hauer.)

Selenate of Copper, $Cu''SeO^4.5H^2O$, prepared by dissolving copper or cupric oxide in selenic acid, or by oxidation of the selenite (p. 230), is isomorphous with the sulphate (Mitscherlich). A mixture of cupric and ferrous selenates yields, according to Wohlwill, in a number of successive crystallisations, nothing but different combinations of the form of cupric sulphate (triclinic, ii. 158); crystals having the form of ferrous sulphate (monoclinic) are obtained only when the latter is in considerable excess, as observed by Wohlwill in a mixed salt containing 3 at. Fe to 1 at. Cu. A solution of magnesium-selenate mixed with comparatively very small quantities of cupric selenate yields crystals having the form of ferrous sulphate, and containing $Cu''\overset{''}{Mg}{}^3Se^4O^{16}.28H^2O$. Selenate of zinc yields with cupric selenate a similar salt, containing $Cu''\overset{''}{Zn}{}^3Se^4O^{16}.28H^2O$.

Ferrous Selenate, $Fe''SeO^4.7H^2O$ (or $5H^2O$).—This salt, obtained by dissolving iron wire in selenic acid, and evaporating in an atmosphere of hydrogen or carbonic anhydride, crystallises with 7 at. water and the form of ferrous sulphate, only at temperatures a little above 0°. The monoclinic crystals thus obtained become opaque, and give off part of their water even on slight rise of temperature; and at temperatures not much above 5°, the salt crystallises with only 5 at. water, and in the form of cupric sulphate. (Wohlwill.)

Selenate of Lead, $Pb''SeO^4$, is obtained by precipitating selenate of sodium with nitrate of lead, as a white powder insoluble in nitric acid. Specific gravity = 6·37 at 22° (Schafarik). This salt occurs native, with selenide of lead and antimony, malachite, &c., at the Friederichsglück mine, near Hildburghausen, and at Eisfeld, in small, brittle, sulphur-yellow spheres and botryoïdal masses, cleaving distinctly in one direction. This mineral was regarded by Kersten (Pogg. Ann. xlvi. 277) as a selenite of lead; but according to H. Rose's analysis, it is a selenate of lead containing a little copper. (Dana, ii. 375.)

Selenate of Magnesium, $Mg''SeO^4.7H^2O$, exactly resembles the sulphate in form and solubility.

Selenate of Nickel, $Ni''SeO^4.6H^2O$, obtained by dissolving the carbonate in selenic acid, forms quadratic crystals, isomorphous with the sulphate containing the same quantity of water (Mitscherlich). According to v. Hauer, it crystallises from neutral solutions by spontaneous evaporation in quadratic pyramids, which give off 4 at. water at 100°, but cannot be completely dehydrated without further decomposition. A mixture of this salt and cupric selenate in nearly equivalent quantities, yields crystals having the form of ferrous sulphate. (Wohlwill.)

Nickel-potassium Selenate, $Ni''K^2Se^2O^8.6H^2O$, forms monoclinic crystals, isomorphous with the corresponding double sulphate. It cannot be dehydrated without decomposition, but gives off nearly 4 at. water at 100°, whereas the sulphate remains unaltered at that temperature. [Respecting the crystalline form, see also G. v. Rath (Pogg. Ann. cxv. 487; Jahresb. 1862, p. 215)]. The corresponding double salts formed by combination of the selenates of cobalt, magnesium, and copper with the selenates of potassium and ammonium, crystallises in the same form, are permanent in the air, more soluble than the corresponding double sulphates, and cannot be completely dehydrated without decomposition. (v. Hauer.)

Selenates of Potassium.—The *neutral salt*, K^2SeO^4, is prepared by fusing selenium or selenite of potassium, or native selenide of lead, with saltpetre, dissolving the fused mass in hot water, and leaving the concentrated solution to crystallise. The excess of nitrate then crystallises out first, and afterwards the selenate, in crystals exactly resembling the neutral sulphate. It deflagrates on glowing coals like saltpetre, and is equally soluble in hot and in cold water (Mitscherlich).—The *acid salt*, $KHSeO^4$, exactly resembles the acid sulphate. (Mitscherlich.)

Selenate of Silver, Ag^2SeO^4, prepared by dissolving silver in selenic acid, agrees with the sulphate in form and properties.

Selenate of Sodium, Na^2SeO^4, is prepared like the potassium-salt, and crystallises from aqueous solution above 40° in anhydrous crystals; at lower temperatures, or by spontaneous evaporation, in crystals containing $Na^2SeO^4.10H^2O$, exactly resembling those of Glauber's salt, and exhibiting, like the latter, a maximum solubility at about 33°. (Mitscherlich.)

Selenate of Thallium, Tl^2SeO^4, prepared by dissolving the metal or its carbonate in selenic acid, crystallises in long, white, prismatic needles, isomorphous with sulphate of potassium, sparingly soluble in cold water, insoluble in alcohol and in ether. (Kuhlmann, Bull. Soc. Chim. 1864, i. 330.—Oettinger, Zeitschr. Ch. Pharm. 1864, p. 440.)

Selenate of Zinc, $Zn''SeO^4.7H^2O$, is isomorphous with the sulphate. According to Mitscherlich, it crystallises also with 2 at. and 6 at. water, the dehydrated salt separating at temperatures above 30°, the hex-hydrate between 20° and 15°. The solution mixed with ferrous sulphate deposits, according to Wohlwill, crystals having the form of cupric sulphate. When a solution of zinc-selenate is mixed with cupric selenate, the former being in considerable excess, the crystals which first separate have the form of cupric sulphate; and it is only the last that exhibit the quadratic form of zinc-selenate (Wohlwill).—*Selenate of zinc and thallium*, $Zn''Tl^2Se^2O^8.6H^2O$, crystallises in monoclinic prisms, isomorphous with magnesio-potassic sulphate. (G. Werther, Bull. Soc. Chim. 1865, i. 60.)

SELENIUM, OXYCHLORIDE OF. $SeCl^2O = SeCl^4.SeO^2$. *Selenacichlorid.* (R. Weber, Pogg. Ann. cviii. 615.)—Produced by distilling tetrachloride of selenium over selenious oxide gently heated in a sealed tube: also in the decomposition of the tetrachloride by a small quantity of water, and is therefore always present in the liquid resulting from the deliquescence of the tetrachloride, in damp air. It is a slightly yellowish liquid, having a specific gravity of 2·44, boiling at about 220°, fuming in damp air, and easily decomposed by water into hydrochloric and selenious acids.

SELENIUM, SULPHIDES OF. Two of these compounds are known, analogous in composition to selenious oxide and the unknown selenic oxide. The disulphide or selenious sulphide, SeS^2, is produced by fusing 1 at. selenium with 2 at. sulphur; also by the action of sulphydric acid on a solution of selenious acid.* The latter method yields it as a bright yellow precipitate, becoming darker when dry. It softens at 100°, melts at a somewhat higher temperature, and when more strongly heated, boils, distils over, and solidifies on cooling to an orange-yellow mass resembling orpiment. Alkalis dissolve the sulphur from it easily and completely, together with a small quantity of selenium. Alkaline sulphydrates dissolve it completely. (Berzelius.)

The trisulphide or selenic sulphide, SeS^3, is produced by fusing 1 at. selenium with 3 at. sulphur. It is a brick-red, fusible, volatile solid, soluble without residue in alkaline hydrates and sulphydrates. (Berzelius.)

SEMECARPUS. The almonds of *Semecarpus Anacardium*, L. (*Anacardium orientale*), an East Indian plant, contain a small quantity of sweet oil; the pericarp contains 32 per cent. of a a vesicating oil of specific gravity 0·991, easily soluble in ether, blackening on exposure to the air. (J. Lepire, J. Pharm. [3] xl. 16.)

SEMEN CINÆ. Syn. with WORMSEED.

SEMEN COCCOGNIDII. Mezereum-seeds (iii. 1010).

SEMIBENZIDAM. This name was given by Zinin to a compound produced by the action of sulphide of ammonium on dinitrobenzene; probably impure α-phenylene-diamine (iv. 480).

SEMINAPHTHALIDAM, SEMINAPHTHALIDINE. See the next article.

SEMINAPHTHYLAMINE. $C^{10}H^8N^2$ = AMIDONAPHTHYLAMINE, $C^{10}H^8(NH^2)N$ or NAPHTHYLENE-DIAMINE $\left.\begin{matrix}(C^{10}H^6)''\\H^4\end{matrix}\right\}N^2$; also called *Seminaphthalidine, Seminaphthalidam*, and *Azonaphthylamine*. (Zinin, Ann. Ch. Pharm. lii. 362; lxxxv. 329.)—A base produced by the action of sulphydrate of ammonium on dinitronaphthalene (iv. 15). To prepare it, dinitronaphthalene is dissolved in alcohol saturated with ammonia, and the crimson solution is saturated with sulphydric acid, then boiled, whereupon it deposits a large quantity of sulphur; afterwards, mixed with water, boiled again, and filtered quickly at the boiling heat. On cooling it deposits a large quantity of naphthylene-diamine in thin, shining, copper-coloured needles, which may be rendered colourless by alternate crystallisation from alcohol and water.†

Naphthylene-diamine crystallises from alcohol in long shining needles, slightly soluble in water, very soluble in alcohol and ether; forming brownish-yellow solutions, which quickly become darker-coloured and turbid on exposure to the air. In the dry state it may easily be kept unaltered. It melts at 160°, and when heated above 200°, boils and distils, with partial decomposition and carbonisation. It dissolves in strong sulphuric acid, forming a dark-violet solution, which remains unchanged for months if left to itself; but, on addition of water, is immediately transformed into a reddish-white crystalline mass. The alcoholic solution of the base is decolorised by aqueous acids, forming crystalline magmas, whence it is precipitated by ammonia without alteration.

Salts of Naphthylene-diamine.—This base is diacid, uniting with 2 at. of a monatomic and 1 at. of a diatomic acid. The *hydrochlorate*, $C^{10}H^{10}N^2.2HCl$, is prepared by dropping rather strong hydrochloric acid into a cold concentrated solution of naphthylene-diamine in a vessel externally cooled. A magma of shining scales is thus obtained, which must be washed with alcohol. The salt cannot be sublimed. Its aqueous solution becomes coloured on exposure to the air. The *chloromercurate* crystallises in broad very soluble laminæ.—The *chloroplatinate*, $C^{10}H^{10}N^2.2HCl.Pt^{iv}Cl^4$, is a yellow-brown sparingly soluble powder.

The *sulphate*, $C^{10}H^{10}N^2.H^2SO^4$, is obtained by treating an alcoholic solution of the base with dilute sulphuric acid, as a white powder, slightly soluble in water and in alcohol, whence it crystallises in colourless scales.—The *phosphate* forms shining scales, more stable than the sulphate, slightly soluble in water and in alcohol, and crystallising therefrom without alteration.

---

* According to H. Rose, however, the precipitate thus formed is only a mixture of selenium and sulphur.

† The red colour of the first crop of crystals arises from a foreign substance much more soluble in alcohol than naphthylene-diamine itself. This coloured body crystallises from water in very slender lustreless needles, which, when heated in a tube, melt to a red liquid, and then distil with partial decomposition.

The *oxalate* is a white crystalline powder, slightly soluble in water, still less soluble in alcohol and in ether. A solution prepared at the boiling heat deposits it on cooling, in shining scales.—The *tartrate* crystallises in radiate groups of slender needles, moderately soluble in water and in alcohol, less soluble in ether. It decomposes in solution, but is more permanent in the dry state.

SEMI-OPAL. A variety of opal, translucent at the edges only (iv. 204).

SENARMONTITE. The monometric variety of antimonious oxide, Sb^2O^3 (i. 323), occurring at Sensa, in the province of Constantine, Algeria, and at Perneck near Malackza in Hungary, in regular unmodified octahedrons, and in masses with granular structure. Hardness = 2 to 2·5. Specific gravity = 5·22 to 5·3. It has a greyish or yellowish colour, and resinous lustre inclining to subadamantine; transparent to translucent.

SENECA OIL. American petroleum, so called because it was collected and sold by the Seneca Indians.

SENEGAL GUM. See GUM (ii. 954).

SENEGIN or **SENEGUIN.** See SAPONIN (p. 193).

SENNA. A purgative drug consisting of the leaves of *Cassia acutifolia*, a shrub indigenous in Egypt, Nubia, Arabia, and India, and *Cassia obovata*, indigenous in Egypt, Tripoli, and Syria. It has been examined by several chemists, chiefly with the view of extracting the active principle, but the results are by no means accordant. Lassaigne and Feneulle (J. Pharm. x. 58) attribute the purgative action to a bitter uncrystallisable substance, soluble in water and alcohol, insoluble in ether, which they denominate cathartin (i. 817). Bley and Diesel (Arch. Pharm. [2] lv. 257), obtained from senna-leaves a similar substance, together with a yellow resin, chrysoretin (i. 960), soluble in ether, and resembling chrysophanic acid, probably a mixture of that acid with other substances. According to Martius (*Monographie der Sennesblätter*, Leipzig, 1857), senna contains chrysophanic acid (i. 258) together with two brown substances, similar to or identical with the aporetin and phæoretin of rhubarb; also margarin; he regards the chrysophanic acid as the active principle. Sawicki, on the other hand (*Dissertatio inauguralis*, Dorpati, 1857), doubts the correctness of this view, inasmuch as the purgative principle of senna is extracted by water much more easily than by alcohol, whereas chrysophanic acid is nearly insoluble in water, but dissolves in alcohol, by which indeed it is extracted from rhubarb. Wiggers endeavours to explain this contradiction by supposing that the chrysophanic acid in senna is for the most part combined with bases, and in that state insoluble in alcohol, whereas in rhubarb it exists chiefly in the free state.

Martius found in senna-leaves from *Cassia acutifolia* from 9 to 12 per cent. of ash. The composition of the ash in 100 pts. is, according to Martius (*a* and *b*) and Schreiber (*c*), as follows:—

	K^2O	Na^2O	MgO	CaO	$Fe'''PO^4$	P^2O^5	SiO^2	Cl	SO^3	CO^2	Sand and charcoal.
Alexandrian (*a*)	16·58	1·08	7·46	35·92	0·32	. .	2·00	0·35	2·95	24·75	6·97
East (*b*)	11·20	8·50	6·10	36·28	5·70	. .	4·06	0·70	3·52	21·10	3·69
Indian (*c*)	13·47	1·24	0·85	35·36	1·50	3·82	14·49	3·81	1·45	23·57	

SEPEERINE, or **SEPIRINE.** Syn. with SIPEERINE.

SEPIA. A dark-brown pigment prepared from a black juice, which is secreted by certain glands of the cuttle-fish (*Sepia officinalis*, *Sepia Loligo*, &c.), and ejected by the animal to darken the water when it is pursued. One part of the juice is capable of making 1000 parts of water nearly opaque. The juice, when dried, yields a black mass, which, according to Prout, consists of 78 per cent. black pigment or melanin, 10·40 calcium-carbonate, 7·00 magnesium-carbonate, 2·16 alkaline sulphates and chlorides, and 0·84 mucus. The black pigment may be isolated by boiling the black mass successively with water, hydrochloric acid, and dilute solution of ammonium-carbonate. It is a black, inodorous, and tasteless substance, quite insoluble in water, alcohol, and ether, but, remaining suspended in water for a very long time, its deposition may, however, be accelerated by addition of acids or sal-ammoniac. It dissolves in warm caustic potash solution, forming a dark-brown solution, from which it is precipitated by sulphuric and hydrochloric acid, but not by nitric acid. It dissolves also in ammonia, but not in alkaline carbonates.

The pigment is prepared by saturating the dried native sepia with a little caustic lye, then adding more lye, boiling the liquid for half an hour, filtering, precipitating with an acid, washing the precipitate, and drying it at a gentle heat. It is of a dark-brown colour and fine grain.

Os sepiæ, *Meerschaum*, or *White Fish-bone*, is the calcareous shield or shell on the back of the cuttle-fish. It consists of two layers: the upper thin, but very compact, while the lower is thicker but porous. The upper layer contains, according to John, 80 per cent. calcium-carbonate with traces of phosphate, 9 gelatinous substance, insoluble in water and in cold lime-water, 4 water, and traces of magnesia. The lower layer contains 85 calcium-carbonate, with traces of potash, 4 gelatinous matter, and 4 water, with traces of magnesia. Forchhammer found in *Os sepiæ* 0·10 per cent. magnesium-carbonate.

Os sepiæ is used as tooth-powder, for polishing, and for modelling for fine gold articles; it was formerly used as an internal remedy in cases of goître. (Handw. d. Chem. vii. 839.)

SEPIOLITE. Syn. with Meerschaum (iii. 864).

SEPIRINE. Syn. with Sipeerine.

SEPTARIA. Calcareous concretions intersected by veins of calcspar, which, when calcined and ground, form an excellent hydraulic cement.

SERBIAN. Syn. with Miloschin.

SERICIC ACID. Syn. with Myristic acid.

SERICIN (from *Serica*, silk). A name proposed by Schlossberger (Ann. Ch. Pharm. cx. 245) for the fibroïn of silk and of gossamer-threads (ii. 644), which, according to him, are identical, but different from the organic matter of sponges, for which he retains the name fibroïn.

The name sericin was formerly also applied to myristin, the glyceride of myristic acid (iii. 1072), on account of its silky aspect.

SERICITE. A mineral occurring in a schist of the Taunus range in Western Germany. It has a greenish or yellowish-white colour, silky lustre; hardness = 1; specific gravity = 2·897. Foliated in one direction, the plates being undulated. Exfoliates strongly before the blowpipe, and melts on the edges with a bright light, forming a greyish enamel. Decomposed slowly by hydrochloric acid. Contains, according to List (Ann. Ch. Pharm. lxxxi. 193), 1·22 per cent. fluorine, 0·31 phosphoric anhydride, 1·59 titanic anhydride, 50·00 silica, 23·65 alumina, 8·07 ferrous oxide, 0·93 magnesia, 0·63 lime, 9·11 potash, 1·75 soda, and 3·11 water. It is distinguished from potash-mica by its small amount of alumina. List regards it as identical with Damourite (ii. 303).

SERICOLITE. *Satin spar. Atlasspath.* A mineral from Alston Moor, in Cumberland, formerly regarded as a fibrous arragonite, but belonging, according to G. Rose's latest investigations, not to arragonite, but to calcspar. (Handw. d. Chem. vii. 841.)

SEROLIN. This name was given by Boudet (J. Pharm. xix. 291), to a fat which he obtained by treating dried blood-serum with ether or boiling absolute alcohol, and evaporating the solution. According to Boudet, it is quite destitute of crystalline structure; according to Verdeil and Marcet (J. Pharm. [3], xx. 89), it crystallises from boiling alcohol in nacreous laminæ. When once separated from blood-serum, it no longer dissolves in that liquid. According to Gobley (*ibid.* xxi. 241), the so-called serolin is not a pure substance, but a mixture of several fats of different melting points.

SEROUS FLUID. The serous cavities of the body (viz., peritoneal, pleural, pericardial, &c.) contain a small quantity of fluid, called serous fluid, from its general resemblance to the serum of blood. A similar fluid, found in blisters, in cuticular vesicles, and in the interstices of connective tissue, is more generally called 'lymph.' Under certain morbid conditions, the quantity of serous fluid in various parts becomes very much increased, giving rise to the various forms of dropsy.

There is reason to believe that in health, and during life, serous fluid, whether from peritoneum, pericardium, pleura, or vagina testis, possesses, like blood, the property of coagulating at the ordinary temperature when removed from the body; in other words, that it contains both the elements necessary for the formation of fibrin. When, however, serous fluid is not removed from the body until several hours after death, the power of spontaneous coagulation has either become very much lessened or entirely disappeared. When the quantity has been abnormally increased, as in dropsies, the spontaneous coagulation is often absent. In most of these cases, if not in all, coagulation (formation of fibrin) can be brought about by the addition of blood, or of a solution of globulin (fibrinoplastin), showing that one element of fibrin (fibrinogen) still remains. These fibrinary elements may be separated by saturating the fluid with sulphate of magnesia and filtering, in which process they are retained on the filter, and may be readily dissolved in water; or by diluting the fluid with 5 or 10 times its bulk of water, and either passing carbonic anhydride through it, or cautiously adding a few drops of dilute acetic acid, collecting the precipitate, and dissolving it in a dilute solution of a neutral alkaline salt, or by the aid of a few drops of an extremely dilute solution of caustic alkali. Serous fluid, when freed by filtration from fibrin (if it has been formed), epithelial scales, &c., is clear, slightly fluorescent, of a yellow or golden colour, and distinctly alkaline, with a specific gravity varying from 1·005 to 1·030. It contains, besides the fibrinary elements, albumin, fats, cholesterin (protagon?) sugar (or an unfermentable substance reducing cupric salts), urea, uric acid, and frequently xanthine. According to Naunyn (Arch. Anat. Phys. 1865, p. 166), creatine, creatinine, and hippuric acid are never found in it. The inorganic salts are nearly the same as those of blood-serum. In serous fluid which had become purulent, Naunyn found leucine, tyrosine (guanine), and xanthine, but no urea or uric acid. In 1000 cc. of peritoneal fluid (ascites), Planer found 95·2 cc. free, and 48·8 cc. combined, carbonic anhydride, 21·0 cc. nitrogen, and 0·14 cc. oxygen (measured at 0° and 76 mm.). The following table shows the composition of serous fluid from various sources:—

	Hydrocele. (W. Müller.)	Hydrocele. (W. Müller.)	Pleura. (C. Schmidt.)	Pleura. Morbus Brightii. (F. Hoppe.)	Pericardium. Gorup-Besanez.	Peritoneum ascites. (Vogel.)
Specific gravity	1·021	1·022				
Water	940·155	934·079	936·0	957·59	955·13	946.0
Solids	59·845	65·921	64·0	42·41	44·87	54·0
Albumin	43·855	51·758	53·4	27·82	25·49	33·0
Fat and extractives	7·748	4·942	3·0		12·69	13·0
Salts	8·242	9·221	7·4		6·69	8·0

	Peritoneum. Cirrhosis. (Hoppe.)	Peritoneum. Morbus Brightii. (Hoppe.)	Peritoneum. Cirrhosis. (Redtenbacher.)	Œdema of Feet. Morbus Brightii. (Hoppe.)	Aqueous Humour of Calf. (Lohmeyer.)	Tears. (Lerch.)
Specific gravity	1·094		1·018			
Water	984·59	963·68	947·17	982·17	986·870	982·0
Solids	15·50	32·32	52·83	17·83	13·130	18·0
Albumin	6·17	16·11	42·05	3·64	1·223	5·0
Fat and extractives	1·25	5·27	3·02	5·19	4·210	
Salts	8·08	10·94	7·76	9·00	7·697	13·2 (NaCl 13·0)

Hoppe (Schmidt, A. Archi. Anat. Phys. 1861, p. 713) estimated, by means of the polarization apparatus, the percentage of albumin in 38 cases to be as follows:—Hydrocele: mean of 17 cases 5·6; pericardium: mean of 11 cases 2·0, case of general dropsy 0·7, case of typhus 4·0; peritoneum: mean of 5 cases 1·3, case of general dropsy 0·2; pleura: hydrothorax 1·6, pleurisy 4·2.—*Aqueous humour*, which may be considered as a serous fluid, contains globulin (fibrinoplastin) and urea. The *tears* contain mucus in addition to albumin, and are remarkable for their large amount of chloride of sodium.

M. F.

SERPENTARIN, or *Aristolochin*. The bitter principle of the root of *Aristolochia serpentaria*.

SERPENTINE. *Ophite*, *Ophiolite*: including *Picrolite*, *Marmolite*, *Metaxite*, *Williamsite*, *Bowenite*, *Chrysotil*, *Sparkling Asbestos*, *Baltimorite*, *Antigorite*.—A mineral, consisting essentially of hydrated magnesium-silicate, the magnesium being replaced, to a variable but never very considerable amount, by iron (ferrosum).

Serpentine usually occurs massive, sometimes forming entire mountain masses, also granulous, impalpable, fibrous, or foliated; sometimes in crystals, apparently trimetric; but these are not true crystals of serpentine, but pseudomorphs after chrysolite. From variations in the proportions of its constituents, and its mode of occurrence, and from admixture with other minerals, it exhibits numerous varieties, some of which have been regarded as distinct species: *e.g.* Picrolite, Williamsite, Bowenite, Antigorite, Baltimorite, &c.

Serpentine has usually a leek-green or blackish-green colour, sometimes nearly white, becoming yellowish-grey on exposure; it is often spotted or veined, as in verd antique marble, which consists of serpentine veined with calcic carbonate. Chrome-iron is also frequently disseminated through serpentine, giving it a mottled appearance like the skin of a snake, whence its name. Streak white, slightly shining. Lustre resinous or greasy, but of low intensity: the fibrous variety, chrysotil, has a silky lustre. Translucent to opaque. Hardness = 3 – 4. Specific gravity = 2·507 – 2·591. Fracture conchoïdal or splintery. Sectile. Thin fibres flexible.

Serpentine heated in a glass tube gives off water and often blackens. Before the blowpipe it mostly burns white, and melts with difficulty on the sharpest edges. When pulverised it dissolves in hydrochloric, and more readily in sulphuric acid.

Some serpentines contain alumina, others are free from it. In the following analyses the two classes are distinguished, and in each class the analyses are arranged according to increasing amount of iron:—

I. Serpentines not containing Alumina:—*a.* Serpentine from Gulsjö in Wermland, Sweden (Mosander)*.—*b. Bowenite,* from Smithfield, Rhode Island: green; fine-grained; specific gravity = 2·594 — 2·787 (Smith and Brush).—*c.* Serpentine from Sala, in Sweden (Lychnell).—*d. Williamsite,* from Westchester, Chester County, Pennsylvania: green, laminated; specific gravity = 2·29 — 2·64; accompanied by common serpentine and chrome-iron (Smith and Brush).—*e. Chrysotil,* from Newhaven, Connecticut: specific gravity = 2·49 (Brush).—*f. Picrolite,* from Reichenstein, in Silesia: greenish-grey (List).—*g. Marmolite,* from Blandford, Massachusetts (Shepard).—*h.* Serpentine, from Windish Mattrey, Kaiserthal, in the Tyrol: conchoïdal; specific gravity = 2·59; (Gilm).—*i.* Serpentine, from Kynance Bay, in Cornwall (Houghton):

	a.	*b.*	*c.*	*d.*	*e.*	*f.*	*g.*	*h.*	*i.*
Carbonic anhydride	0·89	. .	1·03						
Silica . . .	42·34	42·29	42·16	42·10	44·05	44·61	40·08	43·07	38·29
Magnesia . .	44·20	42·30	42·26	41·50	39·24	39·75	41·40	38·05	34·24
Ferrous oxide .	. .	1·21	2·03	2·43	2·53	2·63	2·70	5·71	13·50
Nickel oxide .	. .	. .	. .	0·45

	99·81	98·76	99·81	99·18	99·31	99·56	99·85	99·74	98·12

II. Serpentines containing Alumina:—*a. Chrysotil* in compact serpentine, from Abbotsville, New Jersey: yellowish-white (Reakirt).—*b. Marmolite* from New Jersey (Garrett).—*c. Williamsite* from Westchester (Hermann).—*d. Chrysotil* (sparkling asbestos) from Reichenstein in Silesia (v. Kobell).—*e.* Noble serpentine from Fahlun (Lychnell).—*f.* Serpentine from the Serpentine Peak, Ate Chonire, between Breona and Chombaira in the Valais: massive; blackish-green (Schweizer).—*g. Antigorite* from the Antigoria Valley near Domo d'Osola (Brush).—*h. Radiated Picrolite* from the Taberg, Sweden (Lychnell).—*i.* So-called *asbestos* from the compact serpentine of Zöblitz in Saxony: specific gravity = 2·60 — 2·65 (C. Schmidt).—*k. Baltimorite* from Bare Hills, Maryland (Thomson):

	a.	*b.*	*c.*	*d.*	*e.*	*f.*	*g.*	*h.*	*i.*	*k.*
Carbonic anhydride . .	. .	. .	. .	. .	3·42	. .	. .	1·73		
Silica	42·62	42·32	44·50	43·50	41·95	44·22	41·58	40·98	43·70	40·95
Alumina	0·38	0·66	0·75	0·40	0·37	1·36	2·60	0·73	2·76	1·50
Magnesia	42·67	42·23	39·71	40·00	40·64	36·41	36·80	33·44	29·96	34·75
Ferrous oxide . . .	0·27	1·28	1·39	2·08	2·22	4·90	7·22	8·94	10·03	10·05
Nickel-oxide . . .	. .	. .	0·90							
Soda	. .	. .	. .	. .	. .	. .	. .	. .	1·98	
Water	14·25	13·80	12·75	13·80	11·68	13·11	12·67	12·86	12·27	12·60
	100·19	100·29	100·00	99·78	100·28	100·00	100·87	98·68	100·70	99·85

All these analyses may be approximately represented by the formula $3Mg''O.2SiO^2.2H^2O$, or $Mg''SiO^3.\overset{''}{M}g^2SiO^4.2H^2O$, the magnesium being more or less replaced by iron, and the silica in the serpentines of the second class partly replaced by alumina. The calculated composition of a non-aluminiferous serpentine is, according to this formula, 44·14 per cent. silica, 42·97 magnesia, and 12·89 water.

Serpentine is frequently a result of pseudomorphic changes. Hornblende, augite, chrysolite, garnet, spinel, mica, and many other minerals occur thus altered. Rose has found that some of the supposed crystals of serpentine are partly chrysolite, the change not having been complete.

Precious or noble serpentines come from Fahlun and Gulsjö in Sweden, the Isle of Man, the neighbourhood of Portsey in Aberdeenshire, Corsica, Saxony, and Siberia, and many localities in the United States of America. Serpentine occurs in crystals at Lake Auschkal, in Miask, Borsovka, &c. Common serpentine occurs at Lizard's Point in Cornwall, and many other places.

---

* For references, see *Rammelsberg's Mineralchemie*, p. 531.

Serpentine admits of a high polish, may be turned in a lathe, and is used for making vases, boxes, and various ornamental articles; it may also be made available as a source of magnesia. (Dana, ii. 284.)

SERPENTINE-ASBESTOS. *Chrysotil.* (See the last article.)

SERPENTINE-DOLOMITE. Mixtures of serpentine and dolomite. For these and similar mixtures of serpentine with calcspar, magnesite, &c., T. S. Hunt (J. pr. Chem. lxxiv. 150) proposes the name ophiolite, distinguishing them as calcitic, dolomitic, magnetitic, ophiolitic, &c.

SERPENTINITE, from Reichenstein in Silesia, appears to be a soft, somewhat steatitic alteration of serpentine.

SERRATULA TINCTORIA. *Sawwort.* A composite plant of common occurrence, formerly cultivated for its yellow dye, which, however, is now seldom used, as it is inferior to weld.

SERUM OF BLOOD. See Blood (i. 608).

SERUM OF MILK. *Whey.* The opalescent liquid containing milk-sugar and various salts, which separates when milk is curdled by the action of acids, rennet, &c.

SESAME-OIL. A fatty oil obtained from the seeds of *Sesamum orientale*, a plant indigenous in India, and cultivated in other warm countries. According to Lefort, it has the composition $C^{16}H^{18}O^2$, and forms with bromine and chlorine the substitution-products $C^{16}H^{17}BrO^2$ and $C^{16}H^{17}ClO^2$. It is a non-drying oil, of yellowish colour, inodorous, and having a slight taste of hemp. Specific gravity = 0·9230 at 15°, diminishing, with rise of temperature, by 0·00075 for each degree centigrade. At $-5°$ it solidifies to the consistence of palm-oil. It is used for burning in lamps, for soap-making, and for adulterating olive-oil; in India as an article of food.

SESLERIA CŒRULEA. *Blue Moor Grass.*—This grass, growing on the mountains of England and Scotland, contains, according to C. Sprengel (J. f. techn. Chem. x. 51) in 100 pts.: 55 pts. water, 10·1 matter soluble in water, 19·0 soluble in dilute potash, 0·8 wax and resin, 14·9 (?) iron. 100 pts. of the dried plant yield 5·67 pts. ash (Sprengel), 4·6 pts. (Hruschauer, Ann. Ch. Pharm. lix. 204). The ash contains in 100 pts., after deduction of carbonic anhydride:

K^2	Na^2O	CaO	MgO	Al^2O^3	Fe^2O^3	Mn^2O^3	SO^3	P^2O^5	SiO^2	$NaCl$	
14·8	4·3	22·6	trace	2·5	1·2	0·6	5·5	3·7	44·8	trace	(Sprengel)
9·2	8·8	17·2	6·4	. .	5·9	. .	5·9	15·5	27·3	3·8	(Hruschauer.)

SESQUI. Prefix, denoting one and a half: *e.g.* Fe^2O^3 or $FeO^{1\frac{1}{2}}$, sesquioxide of iron.

SEVERITE. An argillaceous mineral from Saint-Sevêre in France, where it occurs in masses below tertiary gypsum. It contains, according to Pelletier, 50 per cent. silica, 22 alumina, and 26 water, and appears to be related to halloysite and lenzin. But it is very difficult to determine whether a mineral of this character is a distinct species or a mixture. Another mineral from Saint-Sevêre, exactly resembling severite in physical characters, was found by v. Hauer to contain 44·42 per cent. silica 36·00 alumina, 18·4 water, and 0·65 lime. (Handw. d. Chem. vii. 844.)

SEXANGULITE. Breithaupt's name for sulphide of lead, occurring at Berncastel in hexagonal forms, as a pseudomorph after pyromorphite. (Jahresb. 1862, p. 709; 1863, p. 796.)

SEYBERTITE. Syn. with Clintonite (i. 1026).

SHEA-BUTTER. A vegetable fat obtained in West Africa from the nuts of *Bassia Parkii.* The nuts are shelled, and the kernels, which consist almost wholly of fat, are boiled with water and pressed. Shea-butter is greenish-white, solid at common temperatures, softens at 35°, melts at 43°; dissolves for the most part in boiling alcohol, and crystallises on cooling; also in ether, and crystallises therefrom. By saponification and decomposition of the soap, it yields an acid which separates in pearly scales, melts at 61·1°, and forms a silver-salt containing 54·71 per cent. carbon, 8·98 hydrogen, 27·83 silver, and 8·48 oxygen (Thomson and Wood, Phil. Mag. [3], xxxiv. 350). According to Oudemanns (J. pr. Chem. lxxxix. 205), it yields 29·7 per cent. oleic acid, 70·3 stearic acid (melting at 69°), but no palmitic acid or any other acid of the series $C^nH^{2n}O^2$, of lower atomic weight. Similar results have been obtained by Ruff. (*Gmelin's Handbook*, xvi. 334.)

SHELLAC or **SHELL-LAC.** Lac purified by melting and straining (iii. 451). Seed-lac or grain-lac contains, according to John, two resins soluble in alcohol, and an insoluble resin (laccin), besides colouring matter, a bitter principle, and impurities. Shellac contains two resins and a wax, but no laccin. It is of yellowish-brown, brown, or black colour, translucent, hard, with a shining conchoïdal fracture, and has, according to Brisson, a specific gravity of 1·139. It dissolves easily in hydrochloric acid, acetic acid, potash, soda, and borax, but not in ammonia (Hatchett); with moderate facility in wood-spirit, and is precipitated therefrom by water. It is perfectly soluble in amylic alcohol and valerianic aldehyde, moderately soluble in valerianic acid, slightly in amylic valerate (Trautwein). It dissolves partially in cold creosote (Reichenbach), but slightly in boiling rock-oil (Sunssure) and in benzene, though benzene mixes with its solution in methylic or ethylic alcohol (Mansfield); in 1⅓ pts. of acetone, forming a thick oily varnish. (Wiederhold.)

The bleaching of shellac on the large scale is effected by chlorine or its compounds, but the best material for the purpose is bone-charcoal (Elsner), especially bone-black, purified by means of hydrochloric acid, and not subsequently dried (Kraut). A perfectly white shellac, having a silky lustre, and completely soluble in alcohol, is obtained by the following process: 25 pts. of shellac are dissolved in 600 pts. of water containing 10 pts. of soda; and the solution is mixed with dilute hypochlorite of sodium (prepared from 30 pts. chloride of lime), and then with hydrochloric acid, as long as the precipitate redissolves. It is then exposed to the sun for a day or two, filtered, mixed with sulphite of sodium, and precipitated by hydrochloric acid. (*Gmelin's Handbook*, xvii. 420.)

SHEPARDITE. This name is given by W. Haidinger to the small brown striated prisms, consisting essentially of a sulphide of chromium, occurring in the meteorite of Bishopsville in South Carolina (iii. 981). Shepard, who examined this mineral, called it *Schreibersite*; but this name belongs to the phosphide of iron and nickel occurring in meteoric iron.

SIBERITE. Syn. with Rubellite or Red Tourmalin. (See TOURMALIN.)

SICCATIVES. Varnishes added to oil-paints to make them dry quickly. They are prepared by boiling linseed-oil with metallic oxides, or salts. Formerly litharge, minium, umber, and gypsum were employed for the purpose, but more recently the oxides and salts of manganese have come into use; they produce rapidly drying siccatives, and when added to zinc-white, do not introduce any substance that can be blackened by sulphuretted hydrogen. A mixture of equal parts of manganous sulphate and acetate with an equal quantity of zinc-sulphate and 97 pts. zinc-white added in the proportion of one-half to one per cent. to the zinc-oxide with which the oil-colour is to be prepared, is said to effect the drying of the paint in 12 hours. A similar mixture is the *siccative zumatique de Barruel*, which, according to Bolley (Dingl. pol. J. cxli. 398), is made by mixing from 5 to 6 pts. of borous manganate with 95 pts. of zinc-white, and adding to zinc-white colours in the proportion of 2½ per cent. (Handw. d. Chem. vii. 846.)

SIDA CARPINIFOLIA. The leaves and flowers of this plant are used medicinally in Brazil for the same purposes as mallow.

SIDERITE. A name applied to native ferrous carbonate or spathic iron-ore, to pharmacosiderite or cube-ore (ferric arsenate, ii. 171), and to a blue variety of quartz from Golling, near Salzburg.

SIDEROCHALCITE. Syn. with Abichite, one of the forms of native cupric arsenate.

SIDEROCONITE. A variety of calcspar, coloured yellow or brown by ferric hydrate.

SIDERODOTE. Breithaupt's name for a calcareous iron-spar from Radstadt in Salzburg: specific gravity = 3·41.

SIDEROFERRITE. This name is given by Bahr (J. pr. Chem. liv. 194) to native iron found in a petrified tree on a floating island in the Ralanger Lake in Smaland, Sweden. The tree is converted into ferrous hydrate (bog iron-ore), and the iron forms small grains, probably resulting from the reduction of an iron-salt. The iron is porous, and has a specific gravity of 6·248 to 6·497, increased by hammering to 6·626.

SIDEROGRAPHITE. A native iron from North America, containing a somewhat considerable quantity of carbon. (Torrey, *Glocker's Grundiss d. Min.*, p. 342.)

SIDEROMELANE. A mineral from the palagonite-tufa of Iceland, resembling obsidian in colour, lustre, and fracture: specific gravity = 2·531. It differs from true palagonite (iv. 324) in not being decomposible by hydrochloric acid. Contains 45·10 per cent. silica, 13·73 alumina, 18·52 ferric oxide, 8·10 lime, 3·21 magnesia, 2·33 soda, 0·95 potash, 0·35 water, and 6·52 residue (= 98·81). The oxygen-ratio in the protoxides, sesquioxides, and silica is 1 : 3 : 6, the same as in labradorite. (Sartorius v. Waltershausen, *Vulkanische Gesteine*, p. 179.)

SIDEROPHARMACOLITE. Syn. with ABICHITE.

SIDEROPLESITE. Breithaupt's name for a variety of mesitin-spar $(Mg ; Fe)''CO^3$, found at Pöhl in the Saxon Voigtland, containing 2 at. $Fe''CO^3$ to 1 at. $Mg''CO^3$. Angle, R : R = 107° 6′; specific gravity = 3·616 to 3·660 (Breithaupt, Sill. Am. J. [2] xxvi. 348). It is also found at Traversalla, in Piedmont, and at Böhmsdorf, near Schleiz. An allied mineral from Mitterberg in the Tyrol was found by Köhn to contain 4 at. $Fe''CO^3$ to 1 at. $Mg''CO^3$. (Jahresb. 1858, p. 733.)

SIDEROSBOLE. A name applied by Breithaupt to a variety of bole, having a higher specific gravity (= 3·24) than ordinary bole, which he attributes to the presence of a larger proportion of iron.

SIDEROSCHISOLITE. A ferroso-ferrous silicate, occurring at Conghonas do Campo in Brazil, in hexagonal crystals, closely resembling cronstedtite in colour and other physical characters, and in its behaviour before the blowpipe. The analysis of a very small specimen by Wernekink (Pogg. Ann. i. 387), gave 16·3 per cent. silica, 75·5 ferroso-ferric oxide, 4·1 alumina, and 7·3 water (= 103·2).

SIDEROSE. A name of native ferrous carbonate.

SIDEROSILICITE. A mineral forming, together with trinacrite, a brown mass on the tufa of Tonnara, at Cape Passaro, the southernmost point of Sicily. It has not been isolated, but, by calculation from the composition of the mixture, it appears to contain 34·04 per cent. silica, 7·48 alumina, 48·54 ferric oxide, and 10·13 water. (Waltershausen, *Vulk, Gesteine*, p. 234.)

SIDEROTANTALITE. See TANTALITE.

SIDEROTYPE. A method of producing sun-pictures by means of ammonio-ferric citrate. Paper impregnated with this salt is exposed to light in the camera, and the picture is developed with a neutral solution of gold or, better, of silver. (Herschel, Phil. Mag. [3] xxi. 225.)

SIBERITE. Red tourmalin.

SIEGENITE. Syn. with NICKEL-LINNÆITE (iv. 44).

SIENITE. Syn. with SYENITE.

SILEX. The old name of SILICA.

SILICA. SiO^2. *Oxide of Silicium, Silicic Oxide, Silicic Anhydride, Anhydrous Silicic Acid* (*Silice, Acide silicique. Kieselerde, Kieselsäure*).—This compound occurs abundantly, and pure or nearly pure, in quartz, flint, chalcedony, hornstone, jasper, opal, &c.; crystalline in quartz and its varieties; amorphous in opal (iv. 204; v. 1). It is the chief constituent of all sandstones, and enters largely into the composition of felspar and a great number of other minerals.

Silica is produced artificially:

1. By burning silicium in the air or in oxygen gas.
2. By the action of water on gaseous fluoride of silicium:

$$SiF^4 + 2H^2O = SiO^2 + 4HF.$$

The silica is thereby precipitated as a gelatinous hydrate, which, when dried and ignited, leaves pure anhydrous silica in the form of an extremely fine white powder.

3. By the decomposition of alkaline silicates.—Pure pulverulent silica may be prepared by fusing ground flint with about three times its weight of an alkaline carbonate, and decomposing the resulting compound with hydrochloric acid. A good mode of operating is to fuse a mixture of the carbonates of potassium and sodium in equivalent proportions at a red heat, and add ground flint or quartz to the melted mass by small quantities at a time, each addition causing a brisk effervescence, due to the escape of carbonic anhydride. The mixture is then heated strongly for some minutes, and, after cooling, treated with dilute hydrochloric acid, which decomposes it completely. On evaporating the liquid, the silica is separated as a gelatinous hydrate, which, on continuing the heat, is ultimately converted into a white earthy powder, consisting of anhydrous silica. It must then be digested with oil of vitriol, to remove any traces of

titanic oxide that may be present, freed from the strong acid by decantation, and lastly washed, dried, and ignited: it is then quite pure.

Silica may likewise be obtained nearly pure by heating quartz or flint to redness and quenching it in water; it is thus rendered friable, and may easily be reduced to a fine powder.

Properties.—The physical characters of natural silica, both crystalline and amorphous, have been described under Opal and Quartz. The crystalline variety has the higher specific gravity, ranging from 2·5 to 2·8, that of amorphous silica being between 1·9 and 2·3. Quartz is also very hard, being capable of scratching glass; the hardness of opal is somewhat less.

Silica, whether natural or artificial, crystallised or amorphous, requires a very high temperature to fuse it. In the flame of the oxyhydrogen blowpipe, or of a spirit-lamp fed with oxygen gas, it melts to a transparent glass, which may be drawn out into long threads. It is not volatile when heated alone, but it is said to volatilise when very strongly heated in a current of steam (*Gmelin's Handbook*, iii. 355), and has been found in the throats of iron-smelting furnaces, in concretionary nodules having a radio-fibrous structure (Scheerer; H. Rose, Jahresb. 1859, p. 147). Before the blowpipe silica decomposes carbonate of sodium with effervescence, and melts to a glass which is perfectly transparent, provided the silica is pure. In microcosmic salt it is almost insoluble.

Silica is decomposed by potassium at a red heat, yielding silicide and silicate of potassium; by carbon, in presence of iron, copper, or silver, at a white heat, into carbonic oxide and silicide of iron, copper, or silver; by hydrofluoric acid into water and fluoride of silicon.

Native silica, whether crystalline or amorphous, is insoluble in water and in all acids except hydrofluoric acid; so likewise is finely divided artificial silica after ignition; and even in the gelatinous state, as separated by acids from alkaline silicates, it is almost insoluble in water and in acids. The gelatinous hydrate obtained in the decomposition of silicic fluoride by water, dissolves, however, in a considerable quantity of water (Berzelius). In alkalis silica dissolves with greater facility. Freshly precipitated unignited silica dissolves in aqueous caustic potash or soda at ordinary temperatures, and even after strong ignition it dissolves slowly but completely in a cold, and rapidly in a boiling solution of caustic alkali. The different kinds of opal which, like precipitated silica, are amorphous, behave in the same manner with alkalis. Hyalite dissolves more slowly than the other varieties in cold aqueous alkalis. Quartz, even in a state of minute division, is perfectly insoluble in a cold solution, and dissolves but slowly in a boiling solution, of caustic alkali; but under pressure it dissolves more easily, forming a solution of an alkaline silicate.

Finely divided amorphous silica and gelatinous silica dissolve also to a slight extent in alkaline carbonates, which are only partially decomposed thereby, and deposit the silica again on cooling in the form of an opalescent jelly, containing a small quantity of the alkali. It appears to be owing to the solubility of silica in alkaline carbonates, that almost all spring and river waters contain minute quantities of silica in solution. When the action of the alkaline liquid is aided by a high temperature, as in the Geysers of Iceland, very large quantities of silica are dissolved; and as the liquid cools, the silica is deposited on the sides of the basin, or as petrifications on bodies contained therein.

Hydrates of Silica.—Silica is precipitated from solutions of alkaline silicates by acids, in the form of a gelatinous hydrate, which, as already observed, is nearly insoluble in water and in acids. If, however, a dilute solution of an alkaline silicate be poured into a considerable excess of hydrochloric acid, the whole of the silica is retained in solution, but may be precipitated by gradually neutralising the acid with an alkali.

From the solution of alkaline silicate in excess of hydrochloric acid, Graham (Phil. Trans. 1861, p. 204) obtains a pure solution of hydrate of silica by subjecting the liquid to dialysis in a hoop-dialyser of parchment-paper (iii. 716). If a stratum of liquid $\frac{4}{10}$ of an inch in depth be subjected for four or five days to dialysis, changing the water in the outer vessel at intervals of 24 hours, the hydrochloric acid and the soluble chlorides diffuse so completely into the water, that the liquid in the dialyser no longer gives a precipitate with nitrate of silver.

A solution may be thus obtained, containing 5 per cent. of silica, and by boiling it down in a flask, it may be concentrated till the quantity of silica reaches 14 per cent.; in open vessels it is apt to gelatinise on the edge, and the whole then solidifies. The solution is tasteless, limpid, and colourless, with a feeble acid reaction, rather greater than that of carbonic acid; 100 pts. of silica require 1·85 pts. of potash (K^2O) to neutralise their acid reaction upon litmus. The solution is not easily preserved for many days, as it becomes converted into a solid transparent jelly, which shrinks and gives up water even in closed vessels. The coagulation is retarded by hydrochloric acid, and by small quantities of caustic potash or soda. Sulphuric, nitric, and acetic acids are without action on the solution, but it is slowly coagulated by a few bubbles of carbonic acid. Its coagulation is also effected in a few minutes by the addition of $\frac{1}{1000}$ part of any alkaline or earthy carbonate in solution, but not by caustic ammonia, or by its salts, either neutral or acid. Alcohol, sugar, gum, and caramel are without action on it, but solutions of gelatin, soluble alumina, and soluble ferric oxide (iii. 717) immediately cause a gelatinous precipitate: when solution of silica is gradually added to solution of gelatin in excess, the precipitate formed consists of 100 pts. silica and 92 pts. gelatin.

The solution, evaporated at 15·5° in a vacuum, leaves the silica in the form of a transparent glassy, very lustrous hydrate, containing, after two days' exposure over oil of vitriol, 21·99 per cent. water, which agrees nearly with the formula $H^2O.SiO^2$ or H^2SiO^3.

Other hydrates of silica have also been obtained, but it is difficult to fix their composition exactly, as silica easily loses a portion of its water, even at low temperatures, and is moreover very hygroscopic. Ebelmen (Ann. Ch. Phys. [3] xvi. 129), by the action of moist air upon silicic ether, obtained a transparent glassy hydrate, containing $3H^2O\ 2SiO^2$. Doveri (*ibid.* xxi. 40), by drying ordinary gelatinous silica in vacuo over oil of vitriol at ordinary temperatures, obtained a hydrate, which had the composition $2H^2O.3SiO^2$, and gave off half its water at 100°. Fuchs (Ann. Ch. Pharm. lxxxii. 119), by drying gelatinous silica (prepared by passing gaseous fluoride of silicium into water) over oil of vitriol for 30 days, obtained the hydrate $H^2O.3SiO^2$, containing 9·1 to 9·6 per cent. water; and by drying it at 100° for 18 days he obtained another hydrate containing 6·6 to 6·7 per cent. water, agreeing with the formula $H^2O.4SiO^2$.

A very white and light hydrate of silica occurs abundantly in certain beds situated at the base of the chalk-formation, between the upper greensand and the gault. The proportion of hydrated silica in these deposits varies greatly, ranging from 5 to as much as 72 per cent., and being most abundant in the upper portion of the deposit.

SILICATES, ALCOHOLIC. See SILICIC ETHERS.

SILICATES, METALLIC. These salts occur abundantly as natural minerals, constituting in fact the greater part of the earth's crust. Many silicates may also be produced artificially, by fusing silica with metallic oxides, or with carbonates, sulphates, and other salts containing volatile acids. Some of the products thus obtained are exactly similar, in crystalline form and other characters, to natural minerals of the same composition. Some silicates, as those of potassium and sodium, are exclusively artificial products. (On the artificial formation of silicates, see Lefort, J. Pharm. [3], xxxix. 110; Jahresb. 1861, p. 205. H. Deville, Compt. rend. liv. 324; Jahresb. 1862, p. 138. B. v. Ammon, Jahresb. 1862, p. 138).

The silicates exhibit great diversity of composition. Those which occur as natural minerals contain proportions of metallic oxide and silica, included between the following limits:

α. For silicates containing only monatomic and diatomic metals $\left.\begin{matrix}4M^2O\\ \text{or } 4M''O\end{matrix}\right\}SiO^2$ and $\left.\begin{matrix}M^2O\\ \text{or } M''O\end{matrix}\right\}2SiO^2$.

β. For silicates containing triatomic metals: $2R^2O^3.SiO^2$, and $R^2O^3.6SiO^2$.

Some of the artificial silicates contain larger proportions of acid; thus by fusing silica with the carbonates of potassium and sodium in the proper proportions, tetrasilicates, $K^2O.4SiO^2$ and $Na^2O.4SiO^2$, are produced; potash is also said to form an octosilicate, $K^2O.8SiO^2$.

The following table exhibits the composition of the several groups of natural silicates, together with the ratios of the quantities of oxygen contained in the base and acid (SiO^2) in each case. The symbol M in the table denotes a monatomic metal: the substitution of equivalent quantities of diatomic and triatomic metals is easily made, the formula in the latter case sometimes requiring to be multiplied by three:—

Composition of Natural Silicates.

Name of Group.*	Oxygen-ratio $M^2O : SiO^2$	Formula.†	Examples.
Hexbasic	$1 : \frac{1}{3}$	$6M^2O.SiO^2 = M^{12}SiO^8$	Collyrite $2Al^2O^3.SiO^2 = \overset{\prime\prime\prime}{\bar{Al}}{}^4SiO^8$
Tetrabasic: tetartosilicates	$1 : \frac{1}{2}$	$4M^2O.SiO^2 = M^8SiO^6$	Staurolite (St. Gothard) $(\frac{5}{8}Al^{\prime\prime\prime}.\frac{1}{8}Fe^{\prime\prime\prime})^8Si^3O^6$
$\frac{2}{7}$-silicates	$1 : \frac{4}{7}$	$7M^2O.2SiO^2 = M^{14}Si^2O^{11}$	Margarite $\left.\begin{matrix}Ca^{\prime\prime}; Mg^{\prime\prime}; K^2; Na^2\\(Al^{\prime\prime\prime}; Fe^{\prime\prime\prime})^4\end{matrix}\right\} Si^2O^{11} + aq.$
$\frac{3}{10}$-silicates	$1 : \frac{3}{5}$	$10M^2O.3SiO^2 = M^{20}Si^3O^{16}$	Thuringite $(\overset{\prime\prime}{Fe}{}^4\overset{\prime\prime\prime}{\bar{Al}}{}^4)Si^3O^{16}$
Tribasic: tritosilicates	$1 : \frac{2}{3}$	$3M^2O.SiO^2 = M^6SiO^5$	Cyanite; Andalusite $\overset{\prime\prime\prime}{\bar{Al}}{}^2SiO^5$
$\frac{3}{8}$-silicates	$1 : \frac{3}{4}$	$8M^2O.3SiO^2 = M^{16}Si^3O^{14}$	Chondrodite $\overset{\prime\prime}{Mg}{}^8Si^3O^{14}$
$\frac{2}{5}$-silicates	$1 : \frac{4}{5}$	$5M^2O.2SiO^2 = M^{10}Si^2O^9$	Euclase $(\overset{\prime\prime}{Gl}{}^2\overset{\prime\prime\prime}{\bar{Al}}{}^2)Si^2O^9 + aq.$
Dibasic: hemisilicates, or Orthosilicates	$1 : 1$	$2M^2O.SiO^2 = M^4SiO^4$	Fayalite $\overset{\prime\prime}{Fe}{}^2SiO^4$ Olivine $(Mg^{\prime\prime}Fe^{\prime\prime})SiO^4$ Garnet $(\overset{\prime\prime}{Ca}{}^3\overset{\prime\prime\prime}{\bar{Al}}{}^2)Si^3O^{12}$
$\frac{9}{16}$-silicates	$1 : 1\frac{1}{8}$	$16M^2O.9SiO^2 = M^{32}Si^9O^{34}$	Nepheline $(Na^8\overset{\prime\prime\prime}{\bar{Al}}{}^8)Si^9O^{34}$
$\frac{3}{5}$-silicates	$1 : 1\frac{1}{5}$	$5M^2O.3SiO = M^{10}Si^3O^{11}$	Prehnite $(\overset{\prime\prime}{Ca}{}^2\overset{\prime\prime\prime}{\bar{Al}}{}^2)Si^3O^{11}$
$\frac{5}{8}$-silicates	$1 : 1\frac{1}{4}$	$8M^2O.5SiO^2 = M^{16}Si^5O^{18}$	Barsowite $(\overset{\prime\prime}{Ca}{}^2\overset{\prime\prime\prime}{\bar{Al}}{}^4)Si^5O^{18}$ Dichroïte $\left.\begin{matrix}\overset{\prime\prime}{Mg}{}^2\\(Al^{\prime\prime\prime}; Fe^{\prime\prime\prime})^4\end{matrix}\right\} Si^5O^{18}$
$\frac{2}{3}$-silicates	$1 : 1\frac{1}{3}$	$3M^2O.2SiO^2 = M^6Si^2O^7$	Serpentine $\overset{\prime\prime}{Mg}{}^3Si^2O^7 + 2$ aq. Degeroïte $\overset{\prime\prime}{Fe}{}^2Si^2O^7$
$\frac{3}{4}$-silicates	$1 : 1\frac{1}{2}$	$4M^2O.3SiO^2 = M^8Si^3O^{10}$	Scolecite $(Ca^{\prime\prime}\overset{\prime\prime\prime}{\bar{Al}}{}^2)Si^3O^{10}$
Monosilicates, or Metasilicates	$1 : 2$	$M^2O^3.SiO^2 = M^2SiO^3$	Wollastonite $Ca^{\prime\prime}SiO^3$ Diopside $(Ca; Mg)^{\prime\prime}SiO^3$
$\frac{9}{8}$-silicates	$1 : 2\frac{1}{4}$	$8M^2O.9SiO^2 = M^{16}Si^9O^{26}$	Oligoclase $\left.\begin{matrix}(Ca^{\prime\prime}; Mg^{\prime\prime}; K^2; Na^2)^2\\\overset{\prime\prime\prime}{\bar{Al}}{}^4\end{matrix}\right\} Si^9O^{26}$
$\frac{5}{4}$-silicates	$1 : 2\frac{1}{2}$	$4M^2O.5SiO^2 = M^8Si^5O^{14}$	Talc $\overset{\prime\prime}{Mg}{}^4Si^5O^{14} + \frac{4}{3}$ aq.
$\frac{6}{5}$-silicates	$1 : 2\frac{2}{5}$	$5M^2O.6SiO^2 = M^{10}Si^6O^{17}$	Pectolite $(Na^2\overset{\prime\prime}{Ca}{}^4)Si^6O^{17}$
Sesquisilicates	$1 : 3$	$2M^2O.3SiO^2 = M^4Si^3O^8$	Orthoclase $(KAl^{\prime\prime\prime})Si^3O^8$ Stilbite $(Ca^{\prime\prime}\overset{\prime\prime\prime}{\bar{Al}}{}^2)Si^6O^{16} + 5$ aq.
Disilicates, or Bisilicates	$1 : 4$	$M^2O.2SiO^2 = M^2Si^2O^5$	Okenite $Ca^{\prime\prime}Si^2O^5 + 2$ aq. Beaumontite $(Ca^{\prime\prime}\overset{\prime\prime\prime}{\bar{Al}}{}^2)Si^8O^{20} + 6$ aq. Petalite $[(Li; Na)^6\overset{\prime\prime\prime}{\bar{Al}}{}^8]Si^{30}O^{75}$

---

* Silicates are sometimes distinguished by names which express directly the oxygen-ratio in the base and acid, the ratio 1 : 1 giving *Singulosilicates*, 1 : 2 *Disilicates*, 1 : 3 *Trisilicates*, 1 : 4 *Quadrosilicates*, &c.

† To convert the formulæ in this table into the older formulæ in which silica is regarded as a trioxide, $\mathfrak{S}iO^3$, multiply the entire formula by 3, correct the silica term by the equation $1SiO^2 = \frac{2}{3}\mathfrak{S}iO^3$, and reduce the whole to its lowest terms: *e.g.*—$2M^2O.SiO^2 = 3M^2O.\mathfrak{S}iO^3$; $M^2O.SiO^2 = 3M^2O.2\mathfrak{S}iO^3$; $2M^2O.3SiO^2 = M^2O.\mathfrak{S}iO^3$. Conversely, to change formulæ containing $\mathfrak{S}iO^3$ into those containing SiO^2, divide by 3, and correct for $1\mathfrak{S}iO^3 = \frac{3}{2}SiO^2$.

The dibasic silicates in which the oxygen-ratio is 1 : 1, are regarded as normal or orthosilicates, and from these the mono- or metasilicates may be derived by abstraction of 1 at M^2O. These two groups, together with the sesquisilicates (2 : 3), include the most numerous and important of the natural silicates. Many of the ordinary varieties of glass may be approximately represented by mixtures of silicates of potassium, sodium, calcium, &c. belonging to the group of disilicates.

Hydrated silicates may be referred to one or other of the preceding groups, according as more or less of their water is regarded as basic: thus dioptase may be formulated either as a hemisilicate, $Cu''H^2SiO^4$, or as a hydrated monosilicate, $Cu''SiO^3.H^2O$. In like manner okenite, represented in the above table as a hydrated disilicate, $Ca''Si^2O^5.H^2O$, may also be formulated as a monosilicate, $(Ca''H^2)Si^2O^6$.

Most silicates are fusible, and their fusibility is increased by mixture with each other: those which contain readily fusible oxides melt at the lowest temperatures, and in general the most easily fusible silicates are those which contain the largest proportion of base.

All silicates are insoluble in water, excepting the silicates of the alkali-metals, which dissolve with greater facility in proportion as they contain a larger quantity of base.

Some silicates are entirely decomposed when pulverised and treated with hydrochloric or nitric acid, the bases being dissolved and the silica being sometimes separated in a pulverulent or gelatinous form, sometimes dissolved either wholly or in part, the solution then yielding a jelly on evaporation. Sulphuric acid diluted with a small quantity of water, likewise decomposes the greater number of silicates when reduced to powder. Some silicates, on the contrary, resist the action of all acids except the hydrofluoric. In general silicates are more easily decomposed by acids; the stronger the bases contained in them, the less the silica predominates, and the larger the proportion of water present: on this account many silicates containing water—zeolites for example—lose their solubility in hydrochloric acid after ignition. All silicates without exception become soluble in dilute hydrochloric or nitric acid: after fusion with from 3 to 5 times their weight of hydrate or carbonate of potassium or sodium, or with carbonate of barium, strontium, or calcium, or with oxide of lead; they become completely disintegrated, and the solution yields on evaporation, first a jelly and then a dry residue, of which the part which is insoluble in hot hydrochloric acid exhibits the characters of silica. Andalusite, cyanite, staurolite, and zircon, require a full white heat to disintegrate them perfectly with an alkaline carbonate, and are more readily acted on by hydrate of potassium. From the native silicates, whether simple or double, which contain potash, soda, or lithia, the alkali may be separated by igniting them with lime, and treating the ignited mass with water. With many, however, as in the case of nepheline, leucite, natrolite, analcime, and chabasite, it is sufficient even to ignite them by themselves, and afterwards boil them in a finely divided state, with milk of lime, or to digest them with it for a longer time in the cold. Clays treated in this manner likewise give up to water the small proportion of potash or soda which they contain; and if they happen to be rich in carbonate of calcium, they merely require to be digested in water after ignition. Volcanic rocks, such as phonolitic lava, give up the potash or soda they contain by digestion with milk of lime, even without previous ignition.

Silicates heated with *fluor-spar* and *oil of vitriol* in a platinum vessel, evolve gaseous fluoride of silicon, which, when the vessel is covered with moistened felt, deposits upon it white flakes of hydrate of silica.—The same gas is evolved, with effervescence, when a silicate in the state of powder is immersed in a strong solution of hydrofluoric acid. *Microcosmic salt* in the blowpipe-flame withdraws the base from the silicates, and sets the silicic acid free. The product is a translucent, blistered mass. When a small quantity only of the microcosmic salt is used, the mass diffuses itself through the silicious crust; when the quantity of flux is larger, the silica floats in the fused bead. When only a small quantity of silica is present, the glass is clear while fused, but becomes turbid on cooling; with still less silica however it remains transparent (Berzelius).—Silicates heated with *carbonate of sodium* before the blowpipe, expel the carbonic acid with effervescence. The silicates of the alkali-metals and of most of the heavy metals yield a transparent glass; those of the earth-metals yield sometimes a clear and sometimes a turbid glass, according to the proportions of silica and of base. If the silica contains at least twice as much oxygen as the earthy base, the latter is dissolved in the glass by the agency of the silica, and the glass remains clear. If the compound contains less silica, it yields a clear glass with a comparatively small proportion of sodic carbonate; but with a larger proportion, it forms a turbid glass, and with a still larger quantity an infusible slag; for the greater the amount of soda, the greater also is the quantity of the earthy base which is separated by its action. (Berzelius.)

Quantitative Analysis of Silicates. Estimation of Silica.

For the analysis of silicates which are completely decomposed by acids, it is sufficient to boil the finely pulverised mineral with strong hydrochloric acid as long as anything continues to dissolve, then evaporate to dryness, and boil the residue with water containing hydrochloric acid: this will dissolve everything excepting the silica, which may then be washed, dried, ignited, and weighed. The liquid filtered from the silica contains the bases of the mineral, which may be separated by the usual methods.

To ensure the complete separation of the silica, it must be perfectly dried before boiling it with the acidulated water. Now to ensure this complete dryness, it is necessary to heat the silica somewhat above the temperature of the water-bath, the desiccation being completed over a sand-bath or a lamp. In doing this it sometimes happens that too much heat is applied, and in that case a portion of the bases, especially alumina and ferric oxide, may also be rendered insoluble in the dilute acid. To obviate this source of error, the dried residue must be moistened all over with strong hydrochloric acid, then left to stand for half an hour, and afterwards boiled with water. Everything will then dissolve excepting the silica.

Silicates which, like felspar, resist the action of hydrochloric acid, are decomposed by fusion with an *alkaline carbonate*. The mineral, very finely powdered, is mixed in a platinum crucible with three or four times its weight of dry carbonate of sodium; or better with a mixture of the carbonates of potassium and sodium in equivalent proportions, which fuses more readily; the platinum crucible is heated to bright redness for about twenty minutes in a gas furnace (ii. 784, 789), or placed within an earthen crucible half filled with carbonate of magnesium, and heated in an ordinary coke furnace; the fused mass, when cold, is removed from the crucible by digestion in dilute hydrochloric acid with the aid of heat; the whole is evaporated to dryness; the silica separated; and the bases are determined as above.

Some native silicates, as zircon, cyanite, cymophane, &c., are decomposed with difficulty by fusion with alkaline carbonates, requiring a very strong heat continued for a long time. In these cases the decomposition may be facilitated by the addition of a fragment of potassic or sodic hydrate, which however, to avoid injuring the crucible, must be introduced into a cavity made in the middle of the mixture of silicate and carbonate, after it has been heated for a short time, not sufficiently to melt it, and solidly pressed down into the crucible.

By these processes, not only the silica, but all the bases of a silicate may be determined, excepting the alkalis. To determine these, the mineral, reduced to an almost impalpable powder, is very intimately mixed with five times its weight of pure *carbonate of calcium*, and the mixture exposed in a platinum crucible, protected as above, to the strongest heat of an air-furnace or a blast gas-furnace (ii. 785) for about half an hour. The mass, which is not fused, but sintered together, is then digested in dilute hydrochloric acid; the silica separated as before; the greater part of the lime and likewise the bases of the silicate precipitated by carbonate of ammonium and free ammonia; the filtrate evaporated to dryness, and the ammoniacal salts expelled by ignition; the residue redissolved in water; the remainder of the lime precipitated by oxalate of ammonium; and the ammoniacal salts again expelled by evaporation and ignition. The residue then contains nothing but the chlorides of the alkali-metals and magnesium, if that substance was contained in the mineral. *Carbonate of barium* may also be used instead of carbonate of calcium, and the excess of barium removed by sulphuric acid.

Another method of obtaining the alkalis in a silicate, is to decompose it with *hydrofluoric acid* aided by a gentle heat. The acid must be added by small portions to the finely pulverised mineral contained in a platinum dish, till the action ceases and the whole is reduced to a pasty mass. This mass is then heated with strong sulphuric acid, which expels fluoride of silicon and hydrofluoric acid; the residue is heated to low redness to expel the excess of sulphuric acid; the dry mass, when cold, is moistened with strong hydrochloric acid, and, after standing for about half an hour, digested with water. The whole then dissolves, provided the decomposition by the hydrofluoric acid has been complete. The solution contains the alkalis and the other bases in the state of sulphates.

Fluoride of ammonium may also be used instead of hydrofluoric acid: it acts more energetically, and decomposes certain silicates which offer considerable resistance to the action of hydrofluoric acid. The finely pulverised mineral is mixed in a platinum dish with seven times its weight of the ammonium-fluoride, and made up into a paste with a small quantity of water. The mixture is gently heated for some time in order to dry it completely, then to dull redness till it no longer gives off any vapour. The dry mass is treated with sulphuric acid, the excess of that acid expelled by evaporation, and the residue digested with water. The whole then dissolves if the decomposition has been complete; in the contrary case a residue is left, which must be again treated with fluoride of ammonium. Nearly all silicates yield to this treatment; zircon, however, is not completely decomposed by it, and must be treated with carbonate and hydrate of sodium as above described. (H. Rose, *Traité de Chimie analytique*, ii. 867.)

Estimation of Water and other volatile substances in Silicates.—The water in most hydrated silicates is easily estimated by heating the pulverised mineral to redness in a platinum crucible, the whole of the water being then driven off without any further alteration of the silicate. Some silicates, however, euclase and idocrase for example, retain their water with great force, parting with it only at very high temperatures. In such cases it is best to expose the mineral to an intense heat in a current of pure and dry air. Idocrase gives up its water only when heated nearly to its melting-point, and at the same time evolves a small quantity of carbonic acid, sufficient to produce a considerable cloud in baryta-water, but not large enough for quantitative estimation. Some silicates contain small quantities of organic matter as well as water, and when strongly heated in a current of hydrogen, give off water containing empyreumatic products and ammonia: this is especially the case with pitchstone. The quantity of carbon may be determined by ignition with oxide of copper, as in organic analysis, and the amount of hydrogen at the same time, if the mineral does not also contain water ready formed; but if water is also present, and is given off only at the same temperature as the organic matter, the determination becomes very difficult. The emerald contains water and likewise a small quantity of organic matter, to which its colour is due.

In some silicates there are other constituents to be estimated besides water, silica, and metallic bases. Thus datholite and botryolite contain boric acid; tourmaline contains boric acid and fluorine; sodalite and ittnerite contain chlorine; cancrinite contains carbonic acid; haüyne and ultramarine contain chlorine and sulphur; many silicates contain fluorine and phosphoric acid; titanic acid also is of frequent occurrence in silicates.

1. *Boric acid.*—The methods of analysing borosilicates have been already given under Boron (i. 631).

2. *Chlorine.*—Most silicates containing chlorine are easily decomposed by acids. To analyse them they are treated with cold nitric acid of specific gravity 1·2, which either dissolves them completely or separates a portion of the silica in the gelatinous form; in the latter case more water must be added, and the liquid left at rest till the separated silica has settled down. The clear solution is then treated with nitrate of silver, the precipitated chloride of silver is left to settle down in a cool place, then collected on a filter, and treated in the usual way (i. 904). The excess of silver is precipitated by hydrochloric acid, the filtrate evaporated to dryness to separate the silica, and the analysis completed in the same way as for other silicates. Pyrosmalite, which contains chlorine, is not easily decomposed by acids: its decomposition may however be effected by digesting it for several days with dilute nitric acid, at a moderate heat, the flask being corked to prevent escape of chlorine; or, better perhaps, by fusion with an alkaline carbonate. (H. Rose.)

3. *Fluorine.*—A great number of silicates contain fluorine, though often only in small quantity. Such silicates which, for the most part, are not decomposed, or only incompletely decomposed by acids, are analysed by fusing them with four times their weight of alkaline carbonate, and boiling the fused mass with water. The whole of the fluorine then dissolves in the form of alkaline fluoride, together with a certain portion of the silica and alumina in the mineral. The insoluble matter is collected on a filter and washed, first with pure water, then with water containing carbonate of ammonium. To separate the silica dissolved in the alkaline filtrate, the liquid is mixed with an alkaline solution of zinc-carbonate, which is added as long as a precipitate continues to form; then evaporated to dryness, and the dried mass treated with water, which leaves the whole of the silica undissolved, together with oxide of zinc. The insoluble residue is then to be treated with nitric acid, the silica separated by evaporation to dryness, &c., and weighed. The liquid filtered from the silicate of zinc contains the whole of the fluorine, as fluoride of sodium. The fluorine is precipitated from it by chloride of calcium, and estimated as fluoride of calcium (ii. 674).—The insoluble residue left on treating the original fused mass with water, contains the greater part of the silica, together with the bases. It is treated with hydrochloric acid, the silica separated, and the bases determined in the usual way, the silica thus obtained being of course added to the quantity precipitated by the zinc-solution. (H. Rose, *Traité de Chimie analytique*, ii. 890.)

4. *Phosphoric acid.*—When silicates containing phosphates are decomposed either by acids, or fusion with alkaline carbonates and subsequent treatment with hydrochloric acid, the whole of the phosphoric acid is found in the acid liquor, and may be separated from the bases and estimated by the methods already given (iv. 546).

When phosphoric acid and fluorine occur together in a silicate which is easily decomposible by acids, and contains no bases except the alkalis, the mineral is decomposed by nitric acid, the liquid is saturated with ammonia, without previous separation of the silica, an ammoniacal solution of zinc-carbonate is added, and the whole is evaporated to dryness over the water-bath. The dried mass is then treated with water, which dissolves the alkaline fluoride and nitrate, leaving a residue of phosphate and silicate of zinc, together with excess of zinc-oxide. The fluorine, silica, and phosphoric acid are then determined as above described.

If, on the other hand, the silicate contains alkaline earths, and especially lime, then, whether it is decomposible by acids or not, it must first be fused with four times its weight of a mixture of potassic and sodic carbonates. The fused mass is treated with water, and after complete disintegration, the liquor is filtered. The filtrate contains the whole of the fluorine and part of the phosphoric acid and silica in the form of alkaline salts, while the residue is composed of alkaline silicate, together with calcic silicate and phosphate, calcic phosphate never being completely decomposed by fusion with alkaline carbonate. The filtrate is treated with an ammoniacal solution of zinc-carbonate, and evaporated to dryness, and the residue is treated with water, which dissolves all the alkaline fluoride, leaving the silica and phosphoric acid as zinc-salts. The remainder of the analysis is the same as above.

5. *Sulphur and Sulphuric acid.*—Silicates containing sulphates are decomposed by hydrochloric acid, or by fusion with alkaline carbonate; and from the acid solution obtained, in the former case directly, in the latter by treating the fused mass with hydrochloric acid, the sulphuric acid is precipitated by chloride of barium.

When sulphur is present in a silicate in combination with a metal, it may be oxidised to sulphuric acid by the action of fuming nitric acid, or of hydrochloric acid and chlorate of potassium, or by fusion with a mixture of alkaline carbonate and nitrate. When the sulphur is present, partly as sulphate, partly as sulphide, the quantity existing in the latter form may sometimes be determined by heating the pulverised mineral with hydrochloric acid, passing the sulphydric acid thereby evolved into a solution of copper, collecting the precipitated sulphide of copper, and treating it as described under COPPER (ii. 57). The liquid remaining in the flask is then filtered to separate the silica, and the sulphur originally existing in the mineral as sulphuric acid is determined by precipitation with a barium-salt.

6. *Tantalic and Niobic acids.*—In silicates containing these acids (which, however, are of very rare occurrence), the quantity of silicon may be estimated by treating the compound with hydrofluoric acid, then adding sulphuric acid, and heating till the whole excess of the latter is expelled. The quantity of silica may then be estimated by loss. This method however is not very exact, because small quantities of tantalum and niobium are liable to be also driven off as fluorides. A better method is to fuse the mineral in a silver crucible with three times its weight of sodium-hydrate, and treat the fused mass with water, which dissolves all the silicon as sodic silicate, leaving tantalate or niobate of sodium undissolved. (H. Rose.)

7. *Titanic acid.*—The best method of treating silico-titanates is to heat them with fluoride of ammonium, and afterwards with sulphuric acid, in the manner already described (p. 245). The whole of the silicon is then expelled as gaseous fluoride, and a residue is obtained completely soluble in water, containing the bases as sulphates, together with the titanic acid, which must be separated and estimated by processes to be described hereafter (H. Rose). See TITANIUM.

Silicates containing only Monatomic and Diatomic Metals: Silicates of Protoxides.

Silicates of the Alkali-metals.—*Silicate of Ammonium* is not known in the solid state. Aqueous ammonia dissolves a large quantity of freshly precipitated silica. Carbonate of ammonia dissolves it but sparingly.

The silicates of potassium and sodium resemble each other so closely that it will be convenient to describe them together. They contain various proportions of acid and base, and are all more or less soluble in water, those which contain the largest proportions of alkali dissolving the most easily.

The alkaline silicates are prepared either by fusing silica with the hydrates, carbonates, nitrates, or other salts of the alkali-metals containing volatile acids, or by boiling flint, sand, &c., with strong solutions of the caustic alkalis under pressure. When 1 part of silica is fused with 2¼ pts. carbonate of potassium, or with 1¾ pt. anhydrous carbonate of sodium, a transparent glass is produced consisting of an alkaline monosilicate, $K^2O.SiO^2$, or $Na^2O.SiO^2$. These salts deliquesce in the air and dissolve readily in water, forming an alkaline solution called *liquor silicum.* When a strong solution of this monosilicate is treated with hydrochloric or nitric acid, the greater part of the silica is precipitated in gelatinous flocks, a certain quantity however always remaining dissolved: but if the solution of the silicate be largely diluted, and a quantity of hydrochloric acid added sufficient to give it a strong acid reaction, no precipitate is formed, but the whole of the silica remains dissolved.

Alkaline silicates containing a larger proportion of silica, but still with a sufficient quantity of alkali to make them completely soluble in water, are denominated "water-glass." These salts are prepared on the manufacturing scale, and applied to several purposes in the arts.

Fuchs of Munich, who first proposed them for economical use, adopts the following processes:—

1. To prepare potash water-glass, a mixture of 15 pts. pulverised quartz or sand, 10 pts. of well purified pearlash, and 1 pt. of powdered charcoal, is ignited for five or six hours at a temperature equal to that required to melt common glass. The proportions of silica and alkali used are about sufficient to form a tetrasilicate, $K^2O.4SiO^2$, allowing for impurities in the pearlash. The use of the charcoal is to facilitate the decomposition of the alkaline carbonate, and decompose any sulphuric acid that may be present. The fused mass is then left to cool, pulverised, and boiled with 5 times its weight of water in an iron pot for three or four hours, the water being renewed as it evaporates. After the whole is dissolved, the boiling is continued, so as to concentrate the solution to a specific gravity of 1·24 to 1·26. In this state it is sufficiently liquid to be used in many operations, but in some cases it requires to be diluted and in others to be evaporated to a syrupy consistence. If it contains any sulphide of potassium (arising from decomposition of the sulphate by the charcoal), a small quantity of oxide of copper or litharge must be added to convert it into hydrate, a certain excess of which renders the water-glass better adapted for many purposes. If, however, a perfectly saturated silicate is required, the saturation may be ensured by boiling the liquid with recently precipitated silica. The solution, purified as just described, is left to cool and clarify, the vessel being well closed to prevent access of air. The clear liquid is then decanted from the deposit (which makes a good manure), and stored in carboys; or it may be evaporated to a jelly and packed in tinned iron vessels.

Water-glass may be obtained in the solid state by mixing the concentrated solution with about one-fourth of its volume of rectified spirit; a gelatinous precipitate is thereby formed, which contracts strongly in a few days, and is deposited in a solid mass; and if the supernatant liquid (containing alkaline carbonates, chlorides, and sulphides) be decanted, and the deposit slightly washed and squeezed, the water-glass is obtained in the solid state, and consisting, according to Fuchs, of potassic tetrasilicate, $K^2O.4SiO^2$, perfectly soluble in water. According to Forchhammer, however, the alcohol, even in the act of precipitation, and still more during the subsequent washing, withdraws a portion of the alkali, until the residue consists of octosilicate, $K^2O.8SiO^2$, which is not completely soluble in water. According to Frémy (Jahresb. 1856, p. 353), the salt precipitated from a solution of potassic silicate by alcohol, has the composition $2K^2O.9SiO^2.aq.$; and the sodic silicate obtained in like manner is $2Na^2O.9SiO^2.20aq.$; according to Lefort (*ibid.* 1861, p. 205), both the salts thus precipitated have the composition $2M^2O.9SiO^2.aq.$

2. Soda water-glass is prepared in a similar manner, the proportions being 45lbs. of quartz, 23lbs. anhydrous carbonate of sodium, and 3lbs. of charcoal: this gives a product having nearly the composition $2Na^2O.5SiO^2$: it fuses more readily than the potash-glass. According to Buchner, soda water-glass may be prepared more economically by means of sodic sulphate, in the proportion of 100 pts. quartz, 60 pts. anhydrous sodic sulphate, and 15 to 20 pts. charcoal-dust.

By dissolving the product obtained by either of these processes in boiling water, and saturating it with recently precipitated silica, it may be converted into the tetrasilicate $Na^2O.4SiO^2$. Rectified spirit does not precipitate this compound so completely as the potash-glass, but merely converts it into a gelatinous mass: in solutions not completely saturated with silica, or slightly diluted, it forms a precipitate.

3. Double water-glass.—Potash and soda water-glass are miscible in all proportions. Normal double water-glass, containing equivalent quantities of potash and soda, may be obtained by fusing together 100 pts. of quartz and 121 pts. of sodio-potassic tartrate (Rochelle salt); or more cheaply by fusing a mixture of potassic and sodic nitrates in equivalent proportions with the corresponding quantity of quartz, or 100 pts. quartz, 28 pearlash, 22 anhydrous carbonate of sodium, and 6 powdered charcoal. This mixture fuses more readily than any of the preceding. A solution of double water-glass suitable for all practical applications, may likewise be prepared by mixing 3 measures of concentrated potash water-glass with 2 measures of concentrated soda water-glass.

Soluble silicates may also be obtained by boiling silica with solutions of caustic alkalis under pressure. The following process, patented in 1844 by Mr. Ransome of Ipswich, is essentially the same as that adopted by Kuhlmann of Lille:—100 lbs. of crystallised sodic carbonate, or 50 lbs. of pearlash, are dissolved in about 50 gallons of water, and the solution, after being rendered caustic by means of lime, is reduced to the bulk of 20 or 25 gallons by heat. This caustic ley is then introduced together with 100 lbs. of finely broken flints or other convenient silicious substance, into an iron boiler or digester, and the mixture is heated with frequent agitation for ten or twelve hours up to a pressure of about 60 lbs. to the square inch. When the mixture is sufficiently incorporated, it may be passed through a sieve to separate any undissolved matter.

The soluble silicates prepared by different manufacturers differ considerably in composition, seldom exhibiting that of a tetrasilicate. Of the following samples—*a* is soda water-glass from the manufactory of Seibel at Liesing; *b*, soda water-glass from Munich; *c*, potash water-glass from Kuhlmann's factory at Lille:—

	a.	*b.*	*c.*
Water . .	65·829	38·66	0·689
Silica . . .	22·258	44·64	63·000
Soda . . .	11·178	16·25	
Potash . .	. .	. .	34·400

a has, approximately, the composition of a disilicate; *b* that of a $\frac{5}{2}$-silicate; *c* that of a trisilicate.

Solid or fused water-glass, when pure, has the appearance of ordinary glass, and dissolves slowly, but completely, in boiling water; it becomes insoluble only when the proportion of silica is considerably increased. A concentrated solution, containing 28 per cent. of the alkaline silicate, is syrupy, somewhat turbid, and has a density of about 1·25. After evaporation at a high temperature, it becomes very tenacious, and may be drawn out into threads like melted glass. The solution is decomposed by *acids*, even by *carbonic acid*, the silica being separated in the gelatinous form. On exposure to the air, it becomes covered with a tough skin, which disappears when thrust beneath the liquid. During evaporating to dryness, it must be kept constantly boiling, to prevent access of carbonic acid. *Alkaline carbonates* and *chlorides*, especially sal-ammoniac, precipitate silica from the solution. *Baryta, strontia, lime, alumina*, and *oxide of lead* decompose it, removing the whole of the silica and a portion of the alkali in the form of a double silicate. Nearly all the soluble salts of the earth-metals and heavy metals likewise produce precipitates consisting of double silicates. *Phosphate of aluminium*, and *carbonate, phosphate*, and *sulphate of lead* triturated with a solution of water-glass, yield a tenacious mass, which acquires a stony hardness on exposure to the air. *Phosphate of calcium* is not decomposed by it.

Uses of Alkaline Silicates.—1. *As cements, and for hardening and preserving stone.*—The soluble silicates may be applied in various ways for imparting solidity to loose structures. This effect is due sometimes to a chemical action between the soluble silicate and the porous material, resulting in the formation of an insoluble silicate or double silicate—sometimes to the gradual decomposition of the alkaline silicate, resulting in great measure from the action of atmospheric carbonic acid, and the consequent deposition, between the particles of the porous material, of a mass of solid silica which binds them firmly together. Ransome, in 1845, patented a process for the application of a soluble silicate for combining small coal into blocks, and for preserving wood from fire and decay.

The action of soluble silicates on calcium-compounds is of particular importance. Water-glass sets rapidly when mixed with slaked lime, and slowly dries up to a hard mass, consisting of a double silicate of calcium and the alkali-metal, on which water has no action. A piece of chalk immersed in a solution of alkaline silicate, absorbs it, and on drying becomes nearly as hard as marble. Pulverised chalk or marble is also converted by water-glass into a hard compact mass; magnesian limestone is rendered still harder. This effect is due either to a combination of the alkaline silicate with the calcic carbonate, resulting in the formation of a compound similar to cancrinite (i. 734), or to a double decomposition resulting in the formation of calcic silicate, which then unites with the undecomposed portion of the carbonate; perhaps both these actions take place together. The silification of limestones is greatly facilitated by heating them with the silicious solution under pressure. Sulphate of calcium is acted upon by soluble silicates in the same manner as carbonate, but the resulting mass is less compact, in consequence, chiefly, of the greater rapidity of the action; a more dilute solution must therefore be used, so as to render the action slower.

These reactions of the soluble silicates have been successfully applied by Ransome, Kuhlmann, and others, to the production of artificial stone for building and ornamental purposes, and to the preservation of the stone of buildings actually constructed. To prepare artificial stone, a concentrated solution of water-glass is mixed with sand, broken flints, pieces of marble, &c., sometimes with addition of cream of lime; the whole being subjected to pressure in moulds, and afterwards dried in an oven. By this means stone of great hardness is obtained, and in some cases is capable of receiving a fine polish.

For hardening building stones, and protecting them from the action of acid vapours, Kuhlmann employs a solution of silicate of potassium. Silicate of sodium produces the same effect, but is said to give rise, after a while, to unsightly efflorescences. The solution is applied with a brush, or sprinkled on the walls of the building by means of large syringes with rose nozzles. The alkaline silicate being gradually decomposed by the action of the carbonic acid in the air, a coating of silica is deposited on the stone, which protects it from further atmospheric action. This process is said to have been successfully applied at the Louvre and the cathedral of Notre Dame in Paris, and to several buildings in other towns of France. In the moist climate of England, however, the application of alkaline silicates in this manner is attended with very uncertain results, the liquid coating being liable to be removed from the surface by rain, or even by the ordinary humidity of the air, before it has time to absorb sufficient carbonic acid to precipitate the silica in an insoluble form. This inconvenience may be obviated, and a much more compact silicious coating obtained, by washing the surface of the building first with a solution of alkaline silicate, and then with a solution of chloride of calcium, whereby an insoluble silicate of calcium is formed, possessing strongly cohesive properties and perfectly indestructible by atmospheric influences. This process was patented by Mr. Ransome in 1856, and is said to have been applied with good effect to many public buildings.

2. Another very important application of the alkaline silicates is to the art of *Mural Painting*. In ordinary fresco-painting, as is well known, the picture must be executed as soon as the coat of stucco is laid upon the walls, and finished before the stucco is dry; moreover, it cannot be afterwards retouched. Now by working on a surface of plaster prepared with a solution of water-glass, it is found that this inconvenience is completely obviated—that the painter can work at his leisure, and retouch the work as often as is found desirable. The first experiments on this subject were made by Fuchs, who designates this kind of mural painting by the name stereochromy.

Two methods of silicious painting have been proposed: one by Fuchs, in which the colours, ground up with water, are laid upon a prepared surface and afterwards fixed with a silicious solution; the other by Kuhlmann, in which the colours are ground up with the alkaline silicate. In Fuchs' method the wall is first coated with a layer of ordinary lime-mortar containing a rather large proportion of sand of medium fineness; and on this, when dry, is laid a second coating of lime-mortar prepared with rain or distilled water, and well-washed sand of greater fineness than that used for the first coating. This when dry is impregnated with a solution of double water-glass clarified with *liquor silicum* (p. 247), and diluted with an equal bulk of water. This solution is applied twice, allowing time for the first washing to dry.

In his latest essay on the subject, however, Fuchs recommends the preparation of the upper layer with water-glass cement—that is to say, water-glass intimately mixed with pounded marble or dolomite, or quartz-sand mixed with a little dry slaked lime—the water-glass being used in such quantity as to give the mass the consistence of ordinary mortar. The surface having been prepared, the painting is executed upon it with mineral colours ground up with pure water; and when it is finished, the colours are fixed by washing or sprinkling the surface with "fixing water-glass," consisting of a mixture of 4 or 5 measures of concentrated water-glass saturated with silica, and 1 measure of concentrated *liquor silicum* (monosilicate of sodium), the mixed liquid being diluted with half its bulk of water. Paintings thus executed are found to possess great durability and power of resisting destructive influences. Plates of earthenware, tiles, and lithographic stone impregnated with water-glass may also be used as grounds for silicious painting.

In Kuhlmann's method, the colours are ground up with the silicious solution, and consequently do not require so much preparation of the painting ground, or so much care in fixing. In painting upon stone, stucco, glass, &c., the colours, ground with water and kept in a pasty state, are immediately mixed with a silicious solution of 15° to 20° Bm., and applied exactly as in oil or distemper painting, except when the stone is very porous, in which case it is best to silicify the stone before applying the colours, to prevent too rapid desiccation. For glass and earthenware the silicious solution must be more concentrated. The silicious colours may also be used for painting on wood, provided it is not impregnated with resin.*

3. The alkaline silicates are also used to mix with soap, forming "silicated soaps,"

---

* For a more detailed account of the preceding applications of soluble silicates, see a paper by Fuchs in *Kastner's Archives of Natural Philosophy*, v. 385—412; *Journal of the Society of Arts*, vii. 521—532; also a pamphlet by Kuhlmann, entitled *Silicatisation, ou applications des Silicates solubles au durcissement des pierres poreuses*, &c. Paris 1858; also Richardson and Watt's *Chemical Technology*, Part iv., pp. 69—104; v. pp. 348, 582.

which possess powerful detergent properties, and are extensively manufactured for the cleansing of woollens, &c. (See SOAP.)

4. A solution of silicate of sodium, as nearly neutral as possible, and having a specific gravity of 1·53, is now very generally used as a substitute for cowdung in preparing mordanted calico for dyeing.

The silicates of potassium and sodium unite with the silicates of calcium, lead, and other metals, forming the several varieties of glass. These double silicates are more fusible than either of their component simple silicates, and require a smaller quantity of silica to render them capable of resisting the action of water and acids. The ordinary varieties of glass contain 2, 3, or sometimes 4 atoms of silica in proportion to 1 atom of base; common bottle-glass, prepared with impure materials, also contains alumina and oxide of iron. Bohemian glass-tubing consists of potassio-calcic trisilicate, $\left\{\begin{matrix}2(K^2O.3SiO^2)\\3(Ca''O.3SiO^2)\end{matrix}\right.$; window-glass of sodio-calcic disilicate, $\left\{\begin{matrix}Na^2O.2SiO^2\\Ca''O.2SiO^2\end{matrix}\right.$; flint-glass of potassio-plumbic disilicate, $\left\{\begin{matrix}2(K^2O.2SiO^2)\\3(Pb''O.2SiO^2)\end{matrix}\right.$, &c. (See GLASS, ii. 840.)

The alkaline silicates do not occur alone as natural minerals; neither do they enter frequently into the composition of silicates containing only protoxides without alumina or ferric oxide: in fact, there are only two such minerals into which the alkali-metals can be said to enter in definite proportions—viz., apophyllite, which is a potassio-calcic silicate, and pectolite, which is a sodio-calcic silicate (iv. 362). Some varieties of augite and hornblende contain indeed small quantities of alkali, but its presence appears to be due to alteration, resulting from the action of alkaline waters. On the other hand, double silicates containing sesquioxides (alumina and ferric oxide) and alkalis are of frequent occurrence, and constitute important mineral species, the felspars and micas for example.

Silicates of Barium. One part of silica heated to whiteness forms, with 3 parts of baryta, a pale-green solid mass, soluble in acids (Vauquelin). Lefort (Jahresb. 1861, p. 206), by precipitating a dilute neutral solution of a barium-salt with a dilute solution of the salt $2Na^2O.9SiO^2$ (p. 248), obtained a trisilicate of barium, $Ba''O.3SiO^2.3H^2O$; v. Ammon (*ibid.* 1862, p. 140), by precipitation with sodic monosilicate, obtained the salt $Ba''O.SiO.^2$

Silicates of Calcium. The compounds $2Ca''O.SiO^2$, $2Ca''O.3SiO^2$, $Ca''O.2SiO^2$, and $Ca''O.3SiO^2$, are produced by exposing mixtures of quartz and marble, in the proper proportions, to the full heat of a smith's forge: the first does not fuse, but merely bakes together; the other three are more fusible. A silicate of calcium is precipitated on mixing a solution of any calcium-salt with silicate of potassium or sodium (p. 249). Lefort obtained by precipitation, as above, the salt $2Ca''O.9SiO^2.3H^2O$; v. Ammon obtained the monosilicate $Ca''O.SiO^2$.

Silicate of calcium forms the essential constituent of hydraulic mortars which harden under water. This kind of mortar is produced by mixing pure lime slaked to a paste with water and silica or silicious materials in such a state that the silica can unite with the lime in the wet way. A mixture of lime with pounded quartz or fine sand does not harden under water. Such a mixture, in fact, constitutes ordinary mortar, which hardens only on exposure to the air, partly by drying, partly from absorption of carbonic acid. But if pounded opal or precipitated silica be substituted for the quartz, combination takes place, and the mixture hardens under water. More complete hardening is, however, obtained by mixing lime with certain silicious minerals, called *natural cements*—viz., the pozzolana of Naples and other volcanic districts (iv. 724), the tufa-stone (called *trass* in the pulverised state) found abundantly in valleys in the North of Ireland, among the schistose formations on the banks of the Rhine, and at Monheim in Bavaria,—also pumice, basalt-tuff, and slate-clay. All these substances consist mainly of hydrated silicates of aluminium with a large proportion of silica and smaller quantities of lime, magnesia, oxide of iron, and alkalis. Tufa-stone contains 57·0 per cent. silica, 16·0 clay, 2·6 lime, 1·0 magnesia, 7·0 potash, 1·0 soda, 5 oxides of iron and titanium, and 9·6 water. When any of these materials are mixed with lime and water, silicate and aluminate of calcium are formed—sometimes also silicates of magnesium and iron, which assume a stony hardness. *Marl*, which is a mixture of clay with carbonate of calcium, forms a natural hydraulic limestone. It is best adapted for the purpose when it contains 1 pt. of clay to 3 pts. of calcic carbonate. When such a mixture is ignited, silicate and aluminate of calcium are formed, and the pulverised product hardens readily under water. If the clay is in much smaller proportion than the above, a cement must be added after burning and slaking the lime; if, on the other hand, the marl contains too much clay, pure slaked lime must be added. The silicious nodules, or septaria, found in the Isle of Sheppey and elsewhere on the English coast, which consist of silicious clay intersected by veins of calcspar, also yield when calcined a hydraulic mortar, known as *Roman* *cement.* Artificial mixtures of chalk or lime with clay or pulverised flint, yield similar products when burnt in a kiln. (See *Gmelin's Handbook*, iii. 390; and *Ure's Dictionary of Arts*, &c. iii. 200.)

Natural Silicates of Calcium.—a. Monosilicate or *Metasilicate*, $Ca''SiO^3 = Ca''O.SiO^2$, Wollastonite, or Tabular Spar, occurs in monoclinic crystals (of specific gravity = 2·78—2·9, and hardness = 4·5—5) in the Bannat, at Pargas in Finland, Konigsberg in Norway, on the Castle Rock, Edinburgh, in basalt, and in lava at Capo di Bove, near Rome.

β. Sesquisilicate, $2Ca''O.3SiO^2.\frac{8}{3}H^2O$. This is essentially the composition of gyrolite or gurolite (ii. 963).

Disilicate, $Ca''Si^2O^5.2H^2O = Ca''O.2SiO^2.2H^2O$. Okenite (iv. 191).

Silico-borate of Calcium, $Ca''Si^2O^5.Ca''B^2O^4$, occurs with 1 at. water as datholite (ii. 305), and with 2 at. water as botryolite (i. 651).

Silico-titanate of Calcium, $Ca''Si^3O^7.2Ca''TiO^3$, occurs as sphene (*q. v.*)

Silicate of Cerium, $2Ce''O.SiO^2$. Cerite (i. 831) has this composition, the cerium being partly replaced by lanthanum, didymium, calcium, and iron.

Silicate of Cobalt. The aqueous solution of potassic or sodic disilicate forms a beautiful blue precipitate with cobalt-salts (Fuchs). The solution of the tetrasilicate forms no precipitate.

Silicates of Copper. *a. Monosilicate.*—Two cupric minerals are known having the composition of cupric monosilicate with different proportions of water—viz., dioptase, $Cu''SiO^3.H^2O$ (already described, ii. 335), and chrysocolla, $Cu''SiO^3.2H^2O$. The latter occurs, accompanying other copper ores, in Cornwall, Hungary, and other localities, in botryoïdal or massive forms, also encrusting and disseminated. Hardness = 2 – 3. Specific gravity = 2—2·238. It has a mountain-green or bluish-green colour, passing into sky-blue, with vitreous or earthy lustre, and is translucent in various degrees, or opaque. Fracture conchoïdal. Rather sectile; translucent varieties brittle.

Analyses of Chrysocolla.—a. From Stromsheien in Satersdälen, Norway (Scheerer, Pogg. Ann. lxv. 289).—*b.* From Lake Superior (*Rammelsberg's Mineralchemie*, p. 351):

	SiO^2.	CuO.	Fe^2O^3.	CaO.	MgO.	H^2O.		
a.	35·14	43·07	1·09	. .	. .	20·36	=	99·66
b.	32·55	42·32	1·63	1·76	1·06	20·68	=	100

The formula $CuO\ SiO^2.2H^2O$ requires 34·83 silica, 44·82 cupric oxide, and 20·35 water.

Plattner's *Kupferblau*, from the Herrensegen mine in Baden, containing 45·5 per cent. cupric oxide, also belongs to this place.—A more highly hydrated cupric monosilicate, containing $Cu''SiO^3.4H^2O$ (according to Nordenskiold, 31·45 per. cent. SiO^2, 37·31 CuO, 0·40 FeO, and 31·18 water), occurs at Nischne-Tagilsk in Siberia: it gives off about three-fourths of its water at 100°.

The chrysocollas of Siegen and of Canaveilles near Prades in the Pyrenees, also the blue copper from the Turjinian mines in the Ural, are mixtures of cupric silicate and carbonate.—*Copper pitchblende*, a brown scoriaceous mineral from the same mines, is a mixture of chrysocolla and brown hæmatite; a similar mineral, from Zomelahuacan in Mexico, has the composition of a hydrated cupric disilicate, $CuO.2SiO^2.4H^2O$, mixed with brown hæmatite.

β. Sesquisilicate, $2Cu''O.3SiO^2.6H^2O$?—This appears to be the composition of a mineral from Somerville, New Jersey, analysed by Berthier, and from Chili, analysed by Kittredge:

	SiO^2.	CuO.	FeO.	CaO.	MgO.	H^2O.		
New Jersey	35·4	35·1	. .	. .	. .	28·5	=	99·0
Chili	40·09	27·97	4·94	1·49	0·78	24·73	=	100

The formula requires 40·89 SiO^2, 35·08 CuO, and 24·03 water.

Among cupric silicates must also be enumerated demidoffite, a mineral occurring as a thin blue coating on malachite at Nischne-Tagilsk, and containing, according to Nordenskiold, 10·22 per cent. P^2O^5, 31·35 SiO^2, 33·14 CuO, 3·15 MgO, 0·5 Al^2O^3, and 23·03 water. (*Rammelsberg's Mineralchemie*, p. 533.)

Silicate of Didymium. See Cerite (i. 831).

Ferrous Silicates.—*a.* $\overset{''}{Fe}{}^2SiO^4 = 2Fe''O.SiO^2$.—This is the composition of Fayalite or iron-chrysolite (ii. 617); also, approximately, that of some of the refinery-slags obtained in the conversion of cast into malleable iron (iii. 351), and in the refining of coarse copper. (*Gmelin's Handbook*, v. 278.)

β. Monosilicate, $Fe''SiO^3 = Fe''O.SiO^2$.—Grunerite, an asbestiform mineral from Collobrières, has this composition.—A black augite from Arendal, specific gravity = 3·467, is a calcio-ferrous monosilicate, containing, according to Wolff (J. pr. Chem. xxxiv. 236), 47·78 per cent. SiO^2, 23·95 CaO, and 27·01 FeO, agreeing nearly with the formula $\left.\begin{matrix}\frac{1}{2}Ca''O\\ \frac{1}{2}Fe''O\end{matrix}\right\}SiO^2$.

γ. *Tetrasilicate?* A solution of ferrous chloride in less than 2,500 pts. of water gives a greyish-green precipitate with tetrasilicate of sodium. (Walker.)

Silicates of Lanthanum. See Cerite (i. 381).

Silicates of Lead. Silica melts with lead-oxide to a yellow glass. Silicate of lead is also precipitated on adding ammonia to silicofluoride of lead.—A *borosilicate of lead* is obtained by fusing 112 pts. lead-oxide with 16 pts. silica and 24 boric anhydride, as a yellow glass, which melts less easily than borate of lead, but more easily than flint-glass, and is strongly tarnished by immersion in sulphydric acid gas. (Faraday.)

Silicate of Glucinum. $\overset{\prime\prime}{G}{}^2SiO^4 = 2G''O.SiO^2$. Phenacite (iv. 387).

Silicates of Magnesium. α. $8Mg''O.3SiO^2$.—Chondrodite (i. 930) is represented by this formula, the oxygen being, however, partly replaced by fluorine, and the magnesia in most cases partly by ferrous oxide.

β. $Mg^2SiO^4 = 2Mg''O.SiO^2$.—This is the composition of chrysolite and olivin (iv. 201), the magnesium being always more or less replaced by iron. Forsterite, from Monte Somma, exhibits the nearest approach to a pure magnesic orthosilicate, containing only 2·33 ferrous oxide. In the other varieties of olivin, the ferrous oxide varies from 3 to about 20 per cent.—Monticellite, a rare mineral occurring on Somma in yellow-grey crystals, of specific gravity 3·119, contains, according to Rammelsberg (*Mineralchemie*, p. 442), 37·89 per cent. silica, 34·92 lime, 22·04 magnesia, and 5·61 ferrous oxide, agreeing with the formula $\overset{\prime\prime}{Ca}{}^2SiO^4.\left.\begin{matrix}\frac{7}{8}Mg''\\ \frac{1}{8}Fe''\end{matrix}\right\}^2SiO^4$. Batrachite, a massive mineral, of specific gravity 3·033, from the Rizoniberg in the Southern Tyrol, appears to have the same composition.

γ. $3Mg''O.2SiO^2.2aq. = \overset{\prime\prime}{Mg}{}^2SiO^4.Mg''SiO^3.2aq.$—This is the composition of serpentine (p. 236), the magnesia being replaced by ferrous oxide to the extent of 0 to 13·5 per cent. Pure magnesian serpentine is found at Gullsjö, in Wermeland, Sweden. Small quantities of soda, manganous oxide, and nickel-oxide are also occasionally present, and in many varieties the silica is replaced to a small amount by alumina.—Vorhauserite from Monzoni, in the Tyrol, is a serpentine containing 3 at. water.—Thermophyllite from Hopoovaara in Finland appears, from Arppe's analysis, to have the composition $2(3MgO.2SiO^2).3aq.$; but other analyses give different results. (See Thermophyllite.)

δ. $4Mg''O.3SiO^2 = \overset{\prime\prime}{Mg}{}^2SiO^4.2Mg''SiO^3$.—This formula with 6 at. water represents the composition of gymnite or deweylite (ii. 312). Hydrophite or Jenkinsite (iii. 212) is the same with 4 at. water, and $\frac{2}{5}$ of the magnesium replaced by iron. Thermophyllite, according to Northcote (J. pr. Chem. lxxvi. 253), is also a $\frac{3}{4}$-silicate of magnesium with 2 at. water.

ε. $Mg''O.SiO^2 = Mg''SiO^3$.—This formula, with the magnesia more or less replaced by ferrous oxide, manganous oxide, and lime, and the silica sometimes by alumina, represents the composition of the several varieties of augite and hornblende (i. 475; iii. 167). These two mineral species differ in crystalline form: they are both monoclinic, but differ in their angles:

	a : *b* : *c*.	Angle *b* : *c*.	Angle ∞P : ∞P.
Augite	0·9136 : 1 : 0·5399	74° 1′	92° 54
Hornblende	1·837 : 1 : 0·5401	75° 10′	55° 30′

The replacement of silica by alumina takes place more frequently and to a greater extent in hornblende than in augite; many aluminiferous hornblendes also contain ferric oxide, being, according to Rammelsberg, mixtures of the isomorphous compounds $M''O.SiO^2$, $Fe^2O^3.3SiO^2$, and $3M''O.2Al^2O^3$ (iii. 170).

The following are hydrated monosilicates of magnesium:—

Aphrodite, $4Mg''SiO^3.3H^2O$.
Picrophyll, $3(\frac{8}{9}Mg.\frac{1}{9}Fe)''SiO^3.2H^2O$
Picrosmin, $2Mg''SiO^3.H^2O$.
Monradite, $4(\frac{6}{7}Mg.\frac{1}{7}Fe)''SiO^3.H^2O$.

Aphrodite contains, according to Berlin's analysis, 51·56 per cent. SiO^2, 0·17 Al^2O^3, 33·90 MgO, 1·55 MnO, 0·57 MnO, and 11·83 water. The analyses of the other three minerals have been given in their alphabetical places.

ζ. $6MgO.7SiO^2$.—This appears to be the composition of an anhydrous talc found in the valley of Chamounix.—Spadaite, a reddish massive mineral, from Capo di

Bove, containing 56·00 SiO^2, 0·66 Al^2O^3, 30·67 MgO, 0·66 FeO, and 11·34 water, may be approximately represented by the same formula with 5 at. water, or by $5Mg''O.6SiO^2 + 4aq$. (*Rammelsberg's Mineralchemie*, p. 520.)

η. $4Mg''O.5SiO^2 = 4Mg''SiO^3.SiO^2$.—This, with $\frac{3}{4}$ at. water, is the composition of talc, a small portion of the magnesia being replaced by ferrous oxide.

θ. $2Mg''O.3SiO^2 = 2Mg''SiO^3.SiO^2$.—This, with 2 at. and 4 at. water, is the composition of meerschaum. The same formula with 12 at. water, and $\frac{2}{7}$ of the magnesia replaced by ferrous oxide, gives the composition of chlorophæite.

Silicates of Manganese. α. $2Mn''O.SiO^2 = \overset{''}{Mn}{}^2SiO^4$.—Tephroite, from Sparta, New Jersey, has this composition, with a small portion of the manganese replaced by iron.—Knebelite, from Ilmenau and from Dannemora in Sweden, consists of $(Mn''.Fe'')^2SiO^4$.—Troostite, from Sterling, New Jersey, is an orthosilicate, containing manganese and zinc, with small quantities of iron and magnesium.

β. $Mn''O.SiO^2 = Mn''SiO^3$.—Rhodonite is a manganous augite, containing also calcium, iron, and magnesium (p. 107).—Fowlerite and Jeffersonite are similar in composition, but also contain zinc.

Silicates of Mercury. Tetrasilicate of sodium gives a white precipitate with mercurous nitrate. It does not precipitate mercuric chloride, but the mixed solution yields very small dark crystals on evaporation, or even without evaporation if it is concentrated. (*Gmelin's Handbook*, v. 110.)

Silicates of Molybdenum. Molybdous and molybdic silicofluoride yield with ammonia, dark-brown flocks, from which the ammoniacal solution gradually removes the oxide of molybdenum, leaving pure silica. (Berzelius.)

Silicates of Nickel. See PIMELITE (iv. 647). Nickel-gymnite is a hydrated silicate of nickel and magnesium, containing $\left.\begin{matrix}\frac{1}{2}Ni''O\\ \frac{1}{2}Mg''O\end{matrix}\right\}^4.3SiO^2.6aq$.

Silicates of Potassium and Sodium (pp. 247-251).—Monosilicate of sodium may be obtained in well-defined monoclinic prisms containing $Na^2SiO^3.8H^2O$, by digesting ignited silica with an equivalent quantity of crude soda-ley, evaporating out of contact with air, till small crystals of sodic carbonate separate, cooling the remaining syrup to −22°, stirring with a glass rod till it solidifies to a crystalline pulp, redissolving in water, and leaving the solution to stand. The solution of this salt yields, with barium and calcium-salts, precipitates containing $Ba''SiO^3$ and $Ca''SiO^3$ respectively, and with magnesium-salts, a precipitate containing $3Mg''SiO^3.5H^2O$. (v. Ammon.)

Silicate of Strontium. One part of silica fuses, with an equal weight of strontia, partly to an amber-coloured glass, and partly to a black and white enamel (Kirwan). With 3 parts of strontia it forms a solid, grey, sonorous mass, which is nearly tasteless, and dissolves but sparingly in water, though readily in aqueous acids (Vauquelin). Carbonate of strontium, digested in solution of silica, is converted into dense hydrated silicate of strontium. (Kuhlmann.)

Silicate of Thorinum, $3\overset{''}{Th}{}^2SiO^4.4H^2O$. Thorite (*q.v.*).

Silicate of Yttrium. Gadolinite is an orthosilicate of yttrium, cerium, and iron $(Y'';Ce'';Fe'')^2SiO^4$.

Silicate of Zinc. The orthosilicate, $\overset{''}{Zn}{}^2SiO^4$, occurs anhydrous as willemite, hydrated as silicious calamine or zinc-glance, $\overset{''}{Zn}{}^2SiO^4.H^2O$ (i. 714). Troostite from Sterling, New Jersey, is an orthosilicate of zinc, manganese, magnesium, iron, and calcium. Fowlerite and jeffersonite are augitic minerals containing small quantities of zinc.

Silicates containing Triatomic Metals: Silicates of Sesquioxides.

Silicates of Aluminium. α. $2Al^2O^3.SiO^2$.—This, with 9 at. water, is the composition of collyrite (i. 1084), from Schemnitz in Hungary (Klaproth, *Beiträge*, i. 257), and from Esquerra in Spain (Berthier, Ann. Ch. Phys. [2] xxxii. 332):

	Calculation.		*Schemnitz.*	*Esquerra.*
SiO^2	60	13·85	14	15·0
$2Al^2O^3$	151	45·94	45	44·5
$9H^2O$	162	40·21	42	40·5
$2Al^2O^3.SiO^2.9aq.$	373	100·00	101	100·0

A mineral called collyrite, from Weissenfels in Saxony, has the composition $Al^2O^3.SiO^2.5aq.$ like the allophanes; another, occurring in alum-slate, contains

$8Al^2O^3.9SiO^2.54aq.$, like some varieties of staurolite (*infra*).—Schrötterite or opaline allophane, from Freienstein in Styria—having a density of 1·985 to 2·015, greenish-white colour, vitreous lustre, and conchoïdal fracture—contains, according to Schrötter (J. pr. Chem. xi. 380), 11·94 SiO^2, 46·29 Al^2O^3, 2·80 Fe^2O^3, 1·16 CaO, 0·25 CuO, 0·63 SO^3, and 35·85 water, agreeing approximately with the formula $5Al^2O^3.2SiO^2.20aq.$, which is more basic than that of collyrite; but the mineral is probably a mixture containing hydrate of aluminium.

β. $4Al^2O^3.3SiO^2$.—This formula, with the alumina partly replaced by ferric oxide, represents the composition of some varieties of staurolite from the St. Gothard, a mineral which crystallises in trimetric prisms, having the axes $a : b : c = 1 : 2·1123 : 1·4478$, and the angle $\infty P : \infty P = 129° 20'$. Observed combination $\infty P . \infty\breve{P}\infty . . \infty\bar{P}\infty . oP$. Cleavage parallel to $\infty\breve{P}\infty$, distinct but interrupted; parallel to ∞P, in traces. The crystals are thick and often cruciform, translucent or opaque, with brown colour, subvitreous lustre inclining to resinous, and conchoïdal fracture. Hardness = 7—7·5. Specific gravity = 3·5—3·75.

Analyses.—*a*. Red (Klaproth, *Beitr.* v. 80).—*b*. Dark-red: specific gravity = 3·737—3·741 (Lohmeyer, s. Jacobson).—*c*. (Rosales, *ibid.*)—*d*. Marignac (Ann. Ch. Phys. [3] xiv. 9).—*e*, *f*, *g*, *h*. Jacobson (Pogg. Ann. lxii. 419; lxviii. 414):

	Calculation.		Analyses.							
			a.	*b*.	*c*.	*d*.	*e*	*f*.	*g*.	*h*.
$3SiO^2$	180·00	28·15	27 00	27·02	27·25	28·47	29·13	29·72	30·31	30·91
$\frac{10}{3}Al^2O^3$	343·33	54·02	52 25	49·96	56·39	53·34	52·01	54·72	46 80	48·68
$\frac{2}{3}Fe^2O^3$	106·67	16·83	18·50	20 07	19·37	17·41	17·58	15·60	18·08	15·37

Magnesia	. .	. .	. .	. .	2·57	0·72	1·28	1·85	2·16	1·33
$\left.\begin{matrix}\frac{5}{6}Al^2O^3\\ \frac{1}{6}Fe^2O^3\end{matrix}\right\} .3SiO^2$	630·00	100·00	98·0	97·33	105·58	100·25	100·00	101·98	97·48	97·48

Dillnite (ii. 331) is a hydrated $\frac{3}{4}$-silicate of aluminium, $4Al^2O^3.3SiO^2.9aq.$, containing small quantities of lime and magnesia, but no ferric oxide.

γ. $10Al^2O^3.9SiO^2$. Staurolite from Airolo on the St. Gothard: specific gravity = 3·66—3·73.

	Calculation.		Jacobson.	
$9SiO^2$	540·00	33·06	33·45	32·99
$\frac{25}{3}Al^2O^3$	858·33	51·04	47.23	47·92
$\frac{5}{3}Fe^2O^3$	171·67	15·90	16·51	16·65
Magnesia	. . .	. .	1·99	1·66
$\left.\begin{matrix}\frac{5}{6}Al^2O^3\\ \frac{1}{6}Fe^2O^3\end{matrix}\right\}^{10} .9SiO^2$	1570·00	100·00	99·18	99·22

δ. $Al^2O^3.SiO^2$.—Under this formula are included andalusite (i. 291), cyanite or kyanite (iii. 449), sillimanite, and a few other minerals, apparently produced by alteration of these. Topaz (*q. v.*) consists of the same silicate in isomorphous mixture with aluminic silicofluoride. Allophane is the same silicate with 5 or 6 at. water.

Analyses.—1. Andalusite.—*a*. Brazil (Damour).—*b*. Robschütz, near Meissen in Saxony: reddish, harder than quartz: specific gravity = 3·11 (Pfingsten).[*]—*c*. Bräunsdorf, near Freiberg: reddish: specific gravity = 3·07 (Pfingsten).—*d*. Lisens in the Tyrol; specific gravity = 3·401. (Roth.)

2. Cyanite.—*e*. St. Gothard (Rosales).—*f*. The Sau Alp in Carinthia (Köhler).—*g*. Elfdal in Wermland: specific gravity = 3·8 (Igelström):

	Calculation.		Andalusite.				Cyanite.		
			a.	*b*.	*c*.	*d*.	*e*.	*f*.	*g*.
SiO^2	60	37 5	37·03	36·84	37·37	36·74	36 67	37·92	40·02
Al^2O^3	103	62·5	61·45	55·82	59·88	59·65	63·11	61·60	58·46

In andalusite from Lisens, Bunsen found 40·17 per cent. silica and 58·62 alumina; A. Erdmann, 39·99 silica and 58·60 alumina, agreeing more nearly with $8Al^2O^3.9SiO^2$, which requires 40·3 silica and 59·7 alumina.

3. Sillimanite.—*h*—*m*. Saybrook, Chester County, Connecticut: *h*, Thomson; *i*, Bowen; *j*, Hayes; *k*, B. Silliman; *l*, Staaf; *m*, Connel; *n*, Fairfield, New York. (Norton.)

---

[*] For references, see *Rammelsberg's Mineralchemie*, pp. 558, 560, 562.

4. Talc-lithomarge; *o.* Rochlitz in Saxony (Korsten).—*p.* Zeidover, near Temesvar in Hungary (Kussin):

	Sillimanite.							Talc-lithomarge.	
	h.	*i.*	*j.*	*k.*	*l.*	*m.*	*n.*	*o.*	*p.*

	99·70	99·72	99·31	100·06	98·98	96·69	102·73	99·57	99·73

Monrolite from Monroe, New York, exhibits the same characters and nearly the same composition as cyanite, but gives off from 1 to 2·5 per cent. water when heated; specific gravity = 3·04—3·09. Wörthite, a mineral occurring near St. Petersburg in white translucent fragments, infusible before the blowpipe, has also nearly the same composition. Both minerals doubtless result from the alteration of cyanite.

Bucholzite from Faltigl in the Tyrol and Chester County, Pennsylvania, Fibrolite from the Carnatic and from Delaware, and Xenolite, found near St. Petersburg, are fibrous minerals, which appear also to have been produced by the alteration of cyanite, sillimanite, or andalusite, but they are probably sometimes also mixed with quartz. The older analyses by Thomson, Brandes, and others, give for these minerals from 40·05 to 47·44 per cent. silica, and 58·88 to 50·0 alumina, agreeing approximately with the formula $2Al^2O^3.3SiO^2$, but the more recent analyses by B. Silliman (Sill. Am. J. [2] viii. 10), give 35·13—36·31 silica, and 64·93—62·42 alumina, which is the same as that of cyanite, &c. Xenolite forms prisms of 91°, which seems to show that it has been formed from andalusite.

Chiastolite or Hollow spar (i. 868) is an andalusite varying greatly in hardness and composition, and usually enclosing masses of rock, found in Spain, at Bona in Algeria, at Lancaster in Massachusetts, and in Bretagne.

5. Allophane.—*a.* Friesdorf, near Bonn (Bunsen).—*b.* New Charlton, near Woolwich (Northcote).—*c.* Bleiberg in the Eifel (Bergemann).—*d.* Gersbach, in the Black Forest (Walchner).—*e.* Richmond, Massachusetts (B. Silliman).—*f.* New Charlton (Woolwich).—*g.* Goldhausen, near Corbach, Waldeck: light-coloured. —*h.* The same, dark-coloured: specific gravity = 2·02 (Schnabel).—*i.* Schneeberg (Ficinus):

	a.	*b.*	*c.*	*d.*	*e.*	*f.*	*g.*	*h.*	*i.*
Carbonic anhydride	. .	2·73	1·24	. .	. .	2·44	. .	. .	1·2

	100·00	99·71	98·89	97·95	99·49	99·98	99·19	99·87	100·3

This table shows that the name allophane has been applied to substances differing greatly in constitution. The analyses *a*, *b*, *c* may be represented approximately by the formula $Al^2O^3.SiO^2.6aq.$ (22·14 SiO^2, 38·01 Al^2O^3, 39·85 H^2O); *d*, *e*, *f* by $Al^2O^3.SiO^2.5aq.$ (24·34 SiO^2, 40·35 Al^2O^3, 35·31 H^2O). Both varieties are often mixed with calcic carbonate and cupric silicate; in the latter case they have a blue colour. The more highly cupriferous allophanes, *g*, *h*, *i*, are mixtures of hydrated aluminic silicate and cupric silicate.

Chrome-ochre, Miloschin, and Wolchonskoïte, are chromiferous clays of very variable composition. The first contains from 46 to 64 per cent. silica, 22·5 to 30·5 alumina, 4 to 10·5 chromic oxide, and 6·25 to 12·5 water; the second, from Rudniak in Servia, 27·5 per cent. silica, 45 01 alumina, 3·61 chromic oxide, and 22·30 water; the third, from Kreis Ochansk, in the government of Perm, Russia, 27 to 37 per cent. silica, about 6·5 alumina, 18 to 34 chromic oxide, 7 to 10 ferric oxide, 21·84 water, with small quantities of lime, magnesia, and manganous oxide.

Collyrite, from Weissenfels, containing, according to Kersten, 23·3 per cent. silica, 42·8 alumina, and 34·7 water, is also represented most nearly by the formula $Al^2O^3.SiO^2.5aq.$

ε. $8Al^2O^3.9SiO^2$.—Staurolite, from Polewskoi, in the Ural, contains, according to Jacobson, 38·33—38·68 per cent. SiO^2, 45·97—47·43 Al^2O^3, 14·60—15·06 Fe^2O^3, and 2·44—2·47 magnesia, agreeing nearly with the formula $\left.\begin{matrix}\frac{5}{6}Al^2O^3\\ \frac{1}{6}Fe^2O^3\end{matrix}\right\}^8.9SiO^2$. (Compare p. 255.)

---

* Magnesia.

† Quartz and Gypsum.

Collyrite, occurring in alum-slate, contains, according to **Anthon** (Berz. Jahresb. xxiii. 280), 24·2 per cent. SiO^2, 34·5 Al^2O^3, and 41·3 water, agreeing approximately with the formula $8Al^2O^3.9SiO^2.54aq$.

ζ. $5Al^2O^3.6SiO^2$.—**Staurolite**, from Bretagne (specific gravity = 3·527—3·529), contains, according to Jacobson, 39·19—40·35 per cent. SiO^2, 44·87—44·22 Al^2O^3, 15·09—15·77 Fe^2O^3, 0·17—0·10 Mn^2O^3, and, in one specimen, 0·32 magnesia, which may be represented by the formula—$\left.\begin{matrix}\frac{5}{6}Al^2O^3\\ \frac{1}{6}Fe^2O^3\end{matrix}\right\}^5.6SiO^2$.

η. $2Al^2O^3.3SiO^2$.—This, with various quantities of water, represents approximately the composition of **porcelain clay**, from Gutenberg, near Halle (**Bley**, J. pr. Chem. v. 313), and of **pholerite** (i. 496), near Fins, Dept. de l'Allier (**Guillemin**, Ann. Min. xi. 489), and from Naxos (**Smith**, ibid. [4], xviii. 299).

Clay from Gutenberg.			Bley.
$3SiO^2$ . .	180	40·91	39·62
$2Al^2O^3$ . .	206	46·82	45·00
$3H^2O$ . .	54	12·27	10·00

$4H^2O$ . .	72	15·72	15·00	13·14
CaO . . .	. .	. .	. .	1·21
$2Al^2O^3.3SiO^2.4aq.$	458	100·00	100·00	99·96

Plinthite, from the county of Antrim, in Ireland, contains, according to **Thomson** (*Outlines*, i. 323), 30·88 per cent. silica, 20·76 alumina, 26·16 ferric oxide, 2·6 lime, and 19·96 water, and may be represented by the formula $2(Al^2O^3;Fe^2O^3).3SiO^2.6aq$.

Carpholite, from the Schlackenwald, in Bohemia (i. 806), has a composition represented by the formula $2(Al^2O^3;Mn^2O^3;Fe^2O^3).3SiO^2.3aq$.

θ. $3Al^2O^3.5SiO^2$.—**Lenzinite**, from La Vilate, in France (iii. 571), and that from Koll, in the Eifel, containing, according to John, 37·5 per cent. silica, 37·5 alumina, and 25·0 water, are approximately represented by the formula $3Al^2O^3.5SiO^2.11aq.$; the same name is, however, applied to a clay containing a much larger proportion of silica.

ι. $Al^2O^3.2SiO^2$.—This, with 2 at. water, represents the composition of nearly all varieties of **kaolin**, or **porcelain-clay**. The numerous analyses of this substance yield on the average about 47 per cent. silica, 40 alumina, and 13 water, the formula $Al^2O^3.2SiO^2.2aq.$ requiring 47·05 silica, 39·21 alumina, and 13·74 water. The following are examples:—

a. Aue near Schneeberg (**Forchhammer**, Pogg. Ann. xxxv. 331).—*b.* Morl near Halle (**Forchhammer**).—*c.* Altenberg in the Erzgebirge: a pseudomorph after prosopite (**Scheerer**, Pogg. Ann. ci. 361).—*d.* St. Yrieux near Limoges (**Forchhammer**).—*e.* St. Yrieux: produced by weathering of beryl (**Damour**, Bull. geolog. [2] vii. 224).—*f.* Cornwall (**Brown**, J. pr. Chem. xliv. 232).—*g.* Rio Janeiro (**Kussin**, Ramm. Mineralch. p. 574).—*h*, *i*. China: *h* from Tonkang, *i* from Sykang (**Ebelmen** and **Salvétat**, Ann. Ch. Phys. [3] xxxi. 257):

	100·28	100·00	99·82	99·83	100·55	99·85	99·65	99·9	100·0

Kaolin is produced by the decomposition of orthoclase, $K^2O.Al^2O^3.6SiO^2$, which under the influence of water containing carbonic acid, or sulphuric acid resulting from the oxidation-pyrites, loses its potash and two-thirds (4 at.) of its silica, and at the same time takes up 2 at. water. Some varieties of kaolin have, however, a different composition: thus that of Gutenberg, as already observed, is nearly $2Al^2O^3.3SiO^2.3aq.$, and that of Passau—which, according to Fuchs, is produced by the decomposition of porcelain-spar—is, according to Forchhammer, $4Al^2O^3.9SiO^2.12aq$. [For analyses of **fire-clays**, see ii. 653.]

Lithomarge (i. 730) is a name applied to a number of aluminous silicates, most of which have nearly the composition of porcelain-clay.

---

* Glucina.

Analyses: *a.* Rochlitz, in Saxony: compact (Klaproth).*—*b.* Buchberg, near Landshut, in Silesia (Zellner).—*c.* Clausthal: white, phosphorescent; specific gravity = 1·59 (Dumenil).—*d.* Rumpelsberg, near Auerbach: from topaz rock; crystalline under the microscope: specific gravity = 2·6 (Clark).—*e.* Schlackenwald, Bohemia: radiate; glows brightly before the blowpipe; not decomposible by hydrochloric acid (Rammelsberg).—*f.* *Tucsite*, from the Tweed (1) Thomson; (2) Richardson:—

	a.	*b.*	*c.*	*d.*	*e.*	*f.*	*g.* (1).	*g.* (2).
Silica . . .	45·25	49·2	43 00	47·33	47·26	43·46	44 30	43·80
Alumina . .	36·50	36·2	40·25	40·23	39·02	41·48	40·40	40·10
Ferric oxide .	2·75	0·5	0·48	. .	. .		. .	0·94
Lime.	. .	. .	0·47	1·44	. .	1·20	0·75	0·64
Magnesia . .	. .	. .	. .		0·89	0·37†	0·50	0·55
Water . . .	14·00	14·0	15·50	12·36	13·55	13·49	13 50	14 21
	98·50	99·9	99·70	101·36	100·72	100·00	99·45	100·21

The following varieties are distinguished by containing a considerable amount of potash:—*h.* Green lithomarge, from St. Zorge in the Harz: specific gravity = 3·086 (Rammelsberg).—*i.* Lithomarge from Schlackenwald (Krieg):—

	SiO^2.	Al^2O^3.	Fe^2O^3.	CaO.	MgO.	K^2O.	Na^2O.	H^2O.		
h.	49·75	29·88	6·61	0·43	1·47	6·35	. .	5·48	=	99·97
i.	52·40	31·94	1·23	. .	1·44	5·41	1·73	5·00	=	99·15

Ferruginous lithomarge from Planitz, near Zwickau in Saxony, contains, according to Schüler, 41·66 per cent. silica, 22·85 alumina, 12·98 ferric oxide, 1·68 manganic oxide, 3·04 lime, 2·55 magnesia, 0·93 potash, and 14·20 water, which may be represented by the formula $(Al^2O^3; Fe^2O^3) 2SiO^2$.

Halloysite (iii. 7) has sometimes the composition of kaolin or lithomarge; some varieties, however, contain a larger quantity of water, agreeing with the formula $Al^2O^3.2SiO^2 4aq$. The latter formula also represents nearly the composition of some kinds of **bole** (i. 618).

κ. $4Al^2O^3.9SiO^2$.—This formula, with 12 at. water, represents porcelain-clay from Passau, containing, according to Forchhammer, 45·14 per cent. silica, 35·00 alumina, 2·70 ferric oxide and lime, and 18·50 water. The same formula, with 18 at. water, and the alumina partly replaced by ferric oxide, gives the composition of most varieties of **bole**.

λ. $Al^2O^3.3SiO^2$.—This formula, with 3 at. water, represents **razoumoffskin**, an argillaceous mineral from Kosemütz in Silesia (p. 78); also **pyrophyllite** (iv. 769), if the small quantity of protoxides be left out of consideration.

μ. $2Al^2O^3.9SiO^2$.—**Cimolite** (i. 964) is represented by this formula, generally with 6 at., but occasionally with 4 at. water. **Anauxite** (i. 288), from Bilin in Bohemia—containing, according to Plattner, 55 per cent. silica, a large quantity of alumina, 11·5 per cent. water, with small quantities of magnesia—is probably a variety of cimolite.

ν. $Al^2O^3.4SiO^2$.—*a.* **Montmorillonite** (iii. 104), from Montmorillon, Dept. Haute-Vienne; *b.* the same, from Strumbuly in Transylvania; *c.* **Halloysite**, from Confolert, Dept. Charente; *d.* **Lenzinite**, from St. Sevin, Dept. Landes; and *e.* **Bole**, from Michac, Dept. Dordogne, are approximately $Al^2O^3.4SiO^2$ + 2 and 3 at. water; but it is very probable that some of them contain free silica:—

	SiO^2.	Al^2O^3.	Fe^2O^3.	CaO.	MgO.	MnO.	K^2O,Na^2O.	H^2O.			
a.	49·40	19·70	0·80	1·50	0·27	. .	1·50	25·67	=	98·84	Salvétat.
b.	50·04	20·16	0·68	1·46	0·23	. .	1·27	26·00	=	99·84	Damour.
c.	52·40	21·80	. .	2·50	4·28	. .	1·34	17·68	=	100	Hengenau.
d.	49·5	18·0	. .	2·1	2·1	. .	. .	28·0	=	99·7	Berthier.
e.	50·0	22·0	. .	. .	. .	. .	. .	26·0	=	98·0	„
f.	50·55	19·15	. .	0·63	. .	4·40	. .	24·05	=	98·78	v. Hauer.

The last gives off 14·03 per cent. water at 100°. (*Rammelsberg's Mineralchemie*, p. 1014.)

ξ. $Al^2O^3.6SiO^2$?—**Malthacite**, from Steindürfel in the Oberlausitz—containing, according to Meissner (J. pr. Chem. x. 510), 50·2 per cent. silica, 10·7 alumina, 3·1 ferric oxide, 0·2 lime, and 35·8 water—may be approximately represented as $Al^2O^3.6SiO^2.16aq.$, but is probably a mixture.

ο. *Aluminic Silicates of indeterminate composition.*—**Dysyntribite**, from Lawrence County, New York (ii. 368); **Nacrite**, from Brunswick, in the State of Maine, and **Talcite**, from Wicklow in Ireland (iv. 1); **Neurolite**, from Stamstead in Lower Canada (iv. 32); **Portite** from the gabbro of Tuscany (iv. 690); **Rhodalite**, from Ireland, containing, according to Richardson, 55 9 per cent. silica, 11 4 ferric oxide, 8·3 alumina, 1·1 lime, 0·6 magnesia, and 22·0 water; Samoite, from the lava of Upolu (v. 187); Scarbroïte, from Scarborough (v. 204); Smectite, from Cilly in Styria, containing, according to Jordan (Pogg. Ann. lxxvii. 591), 51·21 per cent. silica, 12·25 alumina, 2·07 ferric oxide, 1·89 magnesia, 2·13 lime, and 27·89 water; Smelite, from Telkobanya in Hungary, containing, according to Oswald (J. pr. Chem. xxxv. 39), 50 per cent. silica, 32 alumina, 2 ferric oxide, 2·1 soda, and 13 water; and an earthy mineral from Condé, near Houdan, Dept. Seine et Oise, containing, according to Salvétat (Ann. Ch. Phys. [3] xxxi. 102), 44·5 per cent. silica, 32·5 alumina, 1·2 ferric oxide, 1·02 lime, 0·3 magnesia, 0·4 potash and soda, and 21·7 water.

---

* For references, see *Rammelsberg's Mineralchemie*, p. 576.

† Soda.

The following are unctuous clays included under the general denomination of mountain-soaps:—*a*. From Plombières (Berthier, Ann. Min. [3], xi. 479).—*b*. Thüringen (Bucholz, Gehlens N. J. iii. 597).—*c*. Arnstadt, in Thuringia (Ficinus, Schw. J. xxvi. 279).—*d*. Wilhelmshöhe near Cassel (Bechmann, Leonh. Jahrb. 1831, p. 125):—

	P^2O^5.	SiO^2.	Al^2O^3.	Fe^2O^3.	Mn^2O^3.	CaO.	MgO.	H^2O.	Carbon.	Humic acid.	Fossil resin.		
a.	. .	46·8	23·4	. .	. .	. .	2·1	26·6	. .	. .	. .	=	98·9
b.	. .	44·0	26·5	8·0	. .	0·5	. .	20·5	. .	. .	. .	=	99·5
c.	. .	23·3	16·1	10·3	3·1	1·1	3·1	43·0	. .	. .	. .	=	100·
d.	0·55	46·44	17·40	6·22	0·09	0·86	1·25	12·69	6·95	6·46	0·56	=	99·47

Ferric Silicates. There are but few ferric silicates of definite composition. Degeroïte, from Finland (ii. 309), consists mainly of $Fe^2O^3.SiO^2.3aq$.—Anthosiderite, from Minas Geraes, Brazil (i. 309), is $2Fe^2O^3.9SiO^2.2aq$.—Chloropal (i. 921) is a mixture of $Fe^2O^3.3SiO^2.3aq$. with opal.—Pinguite (iv. 650) has nearly the composition $Fe''O.3SiO^2.4(Fe^2O^3.2SiO^2).30aq$.—Nontronite (iii. 134), unghwarite (*q. v.*), and a ferruginous bole from Halsbrücke, near Freiberg, are ferric or ferroso-ferric silicates to which no definite formula can be assigned. The last contains, according to Kersten, 46·40 per cent. silica, 3·01 alumina, 23·50 ferric oxide, and 24·50 water.

Manganic Silicates. The black silicious ores of manganese, which give off chlorine when treated with hydrochloric acid, appear to have been formed by the oxidation of manganous silicates (rhodonite, cummingtonite, bustamite), and are often mixed with the latter, so that their composition is very variable.

Analyses:—*a*, *b*, *c*. Three varieties of a black silicious manganese, from Sweden: specific gravity = 2·74—2·98.—*d*. An accompanying black substance: specific gravity = 3·207 (Bahr, J. pr. Chem. liii. 308):—

	SiO^2.	Mn^2O^3.	Fe^2O^3.	Al^2O^3.	CaO.	MgO.	H^2O.		
a.	36·20	47·91	0·70	1·11	0·60	4·43	9·43	=	100·38
b.	36·11	42·00	11·31	0·90	0·70	0·57	9·43	=	101·02
c.	34·72	42·64	10·45	1·09	0·56	0·35	9·76	=	99·57
d.	23·69	56·21	9·14	0·61	0·50	0·39	9·50	=	100·04

e. Stratopeite, a black amorphous mineral, of specific gravity 2·64, from the Pajsberg mine, near Philipstad in Sweden, containing, according to Igelström (J. pr. Chem. liv. 192, 290), 35·43 per cent. silica, 32·41 manganic oxide, 10·27 ferric oxide, 8·04 magnesia, and 13·75 water, is a decomposition-product of similar character.

f. A black silicious manganese from Klapperud, in Dalarne, Sweden, in which Klaproth found 25 per cent. silica, 55·8 manganous oxide, and 13·0 loss by ignition, was probably a hydrated mixture of manganous silicate, manganous carbonate, and manganic oxide or peroxide; the deficiency in the analysis (6 2 per cent.) was probably carbonic anhydride.

g, *h*, *i*. Marceline or Heterochine, from St. Marcel in Piedmont: *g* by Berzelius (Afhandl. i. Fis. iv. 382); *h* by Ewreinoff (Pogg. Ann. xlix. 204); *i* by Damour (J. pr. Chem. xxviii. 284).—*k*. Dense, hard, silicious manganese from Tinzen in the Grisons (Berthier, Ann. Ch. Phys. [2] li. 79).—*l*. The same by Schweizer (J. pr. Chem. xxiii. 278):—

	SiO^2.	Mn^2O^3.	Fe^2O^3.	Al^2O^3.	CaO.	MgO.	K^2O.	H^2O.		
g.	15·17	75·80	4·14	2·80	. .	. .	. .	. .	=	97·91
h.	10·16	85·87	3·28	. .	0·61	. .	0·44	. .	=	100·36
i.	10·24	76·32	11·49	. .	1·14	0·26	. .	. .	=	99·45
k.	15·3	80·9	1·0	1·0	. .	. .	. .	. .	=	98·2
l.	15·50	77·34	3·70	. .	1·70	. .	. .	1·76	=	100

g, *k*, and *l* are, approximately, $2Mn^2O^3.3SiO^2$, but they may also be mixtures; *h* and *k* are still less definite.

A brown sinter from the mine-waters of Himmelfahrt, near Freiberg, was found by

Kersten to contain 18·98 per cent. silica, 25·01 manganic oxide, 22·90 ferric oxide, and 33·00 water, which may be represented by the formula $\mathrm{(Mn^2O^3;Fe^2O^3).3SiO^2.6aq}$.

Carpholite (p. 257) is a manganic silicate containing alumina and ferric oxide.

Silicates containing Monatomic, Diatomic, and Triatomic Metals: Double Silicates.

These compounds being specially described, and their analyses given in separate articles, it will be sufficient to give in this place a tabular view of the composition of those whose formulæ may be considered as definitely established. In the preceding tables (pp. 260, 261), to avoid the continual repetition of atomicity-marks, a monatomic metal is denoted by M, a diatomic metal by $\bar{\mathrm{M}}$, and a triatomic metal by R.

Compounds or Mixtures of Silicates with other Salts.

1. With *Aluminates.*—It has already been mentioned (p. 253), that certain varieties of augite and hornblende may be regarded as mixtures of silicates and aluminates of magnesia, &c. A similar composition is also assigned to the following minerals, the alumina being more or less replaced by ferric oxide:

Clintonite, $\mathrm{(2\bar{M}O.3SiO^2)\,.\,2(3\bar{M}O\,.\,2Al^2O^3)}$.
Xanthophyllite, $\mathrm{(\bar{M}O.3SiO^2)\,.\,3(3\bar{M}O.2Al^2O^3)\,.\,3aq}$.
Disterrite or Brandisite $\mathrm{(2\bar{M}O.3SiO^2)\,.\,4(\bar{M}O.Al^2O^3)\,.\,2aq}$.

The minerals of the **chlorite** group may be represented either as double silicates of magnesia (ferrous oxide) and alumina, or as compounds of silicates and aluminates: thus—

Chlorite, $\mathrm{6\bar{M}O.Al^2O^3.3SiO^2.4aq.} = \mathrm{2(3\bar{M}O.SiO^2)\,.\,(Al^2O^3.SiO^2)\,.\,4aq}$.
$= \mathrm{(4\bar{M}O.3SiO^2)\,.\,(2MO.Al^2O^3)\,.\,4aq}$.
Ripidolite, $\mathrm{4\bar{M}O.Al^2O^3.2SiO^2.3aq.} = \mathrm{(4\bar{M}O.SiO^2)\,.\,(Al^2O^3.SiO^2)\,.\,3aq}$.
$= \mathrm{4(\bar{M}O.SiO^2)\,.\,(3MO.Al^2O^3)\,.\,3aq}$.

2. With *Borates.*—The native calcic borosilicates have already been mentioned, viz.:—

Datholite, $\mathrm{CaB^2O^4.CaSiO^3.aq}$.
Botryolite, $\mathrm{CaB^2O^4.CaSiO^3.2aq}$.

Tourmalines are double silicates, containing both proto- and sesquioxides, most of which may be included in the general formula,

$$\mathrm{2(M^2;\bar{M})O.SiO^2\,.\,}n\mathrm{(R;B)^2O^3.SiO^2},$$

the boron being supposed to replace a portion of the triatomic metal R.

Axinite is a borosilicate containing

$$\mathrm{3[2CaO.SiO^2]\,.\,2[(R;B)^2O^3.3SiO^2]}.$$

3. With *Carbonates.*—**Cancrinite** consists of $\mathrm{(CaO.CO^2).3[Na^2O.Al^2O^3.2SiO^2]}$, or $\mathrm{CaCO^3.3(Na^2SiO^3.Al^2SiO^5)}$.

4. With *Chlorides.*—**Sodalite** consists of a sodio-aluminic silicate combined with chloride of sodium, and may be represented by the formula $\mathrm{NaCl.}n\mathrm{(Na^4SiO^4.Al^4Si^3O^{12})}$. **Porcelain-spar** contains, according to Schafhäutl, a small quantity of potassic chloride.

5. With *Fluorides.*—**Lepidolite** consists of 6 or 12 at. of a silicate of aluminium and alkali-metals, including lithium, with 1 at. of a fluoride; or the fluorine may be regarded as replacing a portion of the oxygen in the silica. (For the formula, see iii. 1011). A similar replacement of oxygen by fluorine takes place to a small extent in many other silicates.

6. With *Sulphates.*—This division includes **haüyne**, **nosean**, **ittnerite**, and **ultramarine**. The composition of the first three is as follows:—

Haüyne, $\mathrm{(M^2;\bar{M})SO^4} + n\mathrm{[(M^2;\bar{M})SiO^3.Al^2SiO^5]}$.
Nosean, $\mathrm{NaCl} + \mathrm{3(Na^2SiO^3.Al^2SiO^5)}$
$+ \mathrm{10[Na^2SO^4.3(Na^2SiO^3.Al^2SiO^5)]}$.
Ittnerite, $\mathrm{NaCl} + \mathrm{3[Na^2SiO^3.Al^2SiO^5).6aq}$.
$+ \mathrm{3[(Ca;Na^2)SO^4.3[(Ca;Na^2)SiO^3.Al^2SiO^5].6aq}$.

Nosean is a compound of 1 at. sodalite and 10 at. of a soda-haüyne; ittnerite of 1 at. hydrated sodalite and 3 at. of a hydrated haüyne. Lapis-lazuli, or ultramarine, is a mixture of variable composition.

7. With *Titanates.*—The following minerals of this class are known:—

Titanite, $\mathrm{Ca''^2}\left\{\begin{matrix}\mathrm{SiO^3}\\ \mathrm{TiO^3}\end{matrix}\right. = \mathrm{Ca''SiO^3.Ca''TiO^3}$.

Yttrotitanite, $\mathrm{\bar{M}^3R^8O^{15}.15\bar{M}(Si;Ti)^2O^5}$; $\mathrm{[\bar{M} = Ca, Y;\ R = Al, Fe]}$.

Schorlamite, $9Ca''\begin{cases}\tfrac{3}{5}SiO^3\\ \tfrac{2}{5}TiO^3\end{cases} + \overset{'''}{Fe^2}\begin{cases}\tfrac{3}{5}Si^3O^9\\ \tfrac{2}{5}Ti^3O^9\end{cases}$.
Tschewkinite, $Fe''(Si;Ti)^{iv}O^3 . 3(Ca;La;Di;Ca)''.(Si;Ti)^{iv}O^3$.
Enceladite, $6(Mg;Fe;Ca)^7(Si;Ti)O^4 . Al^4(Si;Ti)^9O^{12}.6aq$.

Mosandrite is a hydrated silicotitanate, containing cerium, lanthanum, didymium, iron, calcium, magnesium, potassium, and sodium; but its exact composition has not been determined.

8. With *Tungstates.*—There are no native minerals consisting of silicates and tungstates; but Marignac has lately obtained a series of such compounds artificially. (See TUNGSTATES.)

9. With *Zirconates.*—**Eudialyte**, from Greenland, consists of $(Na^2;Ca'';Fe'')(Si;Zr)^{iv}O^3$; Norwegian eudialyte contains the same elements, but in somewhat different proportions.

Catapleiite, from the syenite of Lamö, near Brevig in Norway, consists of $(Na^2;Ca'';Fe'')(Si^{iv};Zr^{iv})^4O^9.2aq.$ or $(Na^2;Ca;Fe'')(Si;Zr)^{iv}O^3.3(Si;Zr)^{iv}O^2.2aq$.

Oerstedite is a hydrated silico-zirconio-titanate of calcium, magnesium, and iron, the formula of which has not been exactly determined.

10. With *Zirconates* and *Niobates.*—**Wöhlerite**, from the Langesundfjord, near Brevig in Norway, probably consists of $(Ca'';Na^2)(Si;Zr.Nb)^{iv}O^3$. In the same neighbourhood is found a red-brown mineral of similar character, but containing no zirconium, probably formed by alteration of the wöhlerite.

SILICIC ETHERS. (Ebelmen, Ann. Ch. Phys. [3] xvi. 144.—Friedel and Crafts, Ann. Ch. Phys. [4] ix. 5.)—Silicates of alcohol-radicles produced by the action of alcohols on silicic chloride.

Amylsilicic Ethers. *Tetramylic Silicate*, $(C^5H^{11})^4SiO^4 = 2(C^5H^{11})^2O.SiO^2$.—Prepared like the corresponding ethyl-compound, the product, which passes over between 320° and 340°, being collected apart and rectified. It is a colourless limpid liquid, having a faint odour, somewhat like that of amylic alcohol. Specific gravity = 0·868 at 20°. Boiling-point between 322° and 325°. Vapour-density: obs. = 15·2; calc. = 13·03. It burns with a long white flame, depositing impalpable silica. It dissolves freely in ethylic alcohol, ethylic ether, and amylic alcohol, is insoluble in water, and is decomposed thereby much less quickly than the ethylic silicates. Alcoholic ammonia also decomposes it with difficulty. (Ebelmen.)

Ethylsilicic Ethers. *Tetrethylic Silicate*, $(C^2H^5)^4SiO^4 = 2(C^2H^5)^2O.SiO^2$.—When a small quantity of absolute alcohol is poured upon silicic chloride, a brisk action takes place, accompanied by copious evolution of hydrochloric acid, and a considerable depression of temperature; and on distilling the resulting transparent and colourless liquid, more hydrochloric acid is evolved, then towards 90° a strongly acid product, after which the temperature quickly rises to 160°, at which point tetrethylic silicate passes over, and must be collected in a separate receiver.

Tetrethylic silicate is a colourless liquid, having a rather pleasant ethereal odour, and a strong peppery taste. Specific gravity = 0·933 at 20° (Ebelmen); 0·9676 (Friedel and Crafts). It boils without alteration between 165° and 166°. Vapour-density: obs. = 7·32; calc. = 7·207. It is combustible and burns with a dazzling flame, diffusing a white smoke, consisting of silica in a state of extremely minute division. It is insoluble in water, which however decomposes it gradually, with separation of gelatinous silica. Ammonia and the fixed alkalis dissolve and decompose it with facility. (Ebelmen.)

According to Knop and Wolf (Jahresb. 1861, p. 207), the liquid obtained by saturating absolute alcohol (kept cool) with fluoride of silicon, is a mixture of tetrethylic silicate and silicofluoric acid (p. 270).

Diethylic Silicate, $(C^2H^5)^2SiO^3 = (C^2H^5)^2O.SiO^2$, is produced by the action of silicic chloride on aqueous alcohol:

$$SiCl^4 + 2C^2H^6O + H^2O = (C^2H^5)^2SiO^3 + 4HCl.$$

It is a colourless liquid, having a faint odour, specific gravity = 1·079, and boiling at 350°. Water decomposes it with separation of silica. When it is left in contact with moist air, the silica solidifies to a transparent mass, which contracts more and more, and acquires in two or three months the lustre and vitreous fracture of hyaline quartz, and becomes hard enough to scratch glass. (Ebelmen.)

Diethylic Disilicate, $(C^2H^5)^2Si^2O^5 = (C^2H^5)^2O.2SiO^2$, is formed by distilling the preceding compound with a small quantity of aqueous alcohol. Diethylic silicate then passes over first, and diethylic disilicate remains in the retort. If, however, too much heat is applied, more diethylic silicate is given off, and free silica remains behind. (Ebelmen.)

Diethylic disilicate dissolves in ether, alcohol, and the other silicic ethers.

Hexethylic Disilicate, $(C^2H^5)^6Si^2O^7 = 3(C^2H^5)^2O.2SiO^2$.—Friedel and Crafts were not able to obtain the two ethylic silicates last mentioned; but having prepared a considerable quantity of ethylic silicate with alcohol that was not quite anhydrous, they found that the greater part of the product distilled over towards 240°, but that it was not possible, by distillation under the ordinary atmospheric pressure, to obtain a product of definite boiling-point. By distillation *in vacuo*, however (under a pressure of 3 to 5 mm.) they obtained, after eight fractionations, a product boiling between 125° and 130°, and having the composition of hexethylic disilicate.

This ether is a slightly oily liquid, having a rather fragrant odour like that of normal silicic ether. Specific gravity of 1·0196 at 0°, and 1·0119 at 19°. Vapour-density: obs. = 12·025; calc. = 11·86.

Ethylsilicic Chlorhydrins.—By heating chloride of silicon with tetrethylic silicate in various proportions, Friedel and Crafts have obtained compounds derived from the latter by substitution of 1, 2, and 3 at. chlorine for an equivalent quantity of hydroxyl (HO).

Ethylsilicic monochlorhydrin, $(C^2H^5)^3ClSiO^3$, is produced: 1. By heating 1 at. silicic chloride with 3 at. tetrethylic silicate to 150° for an hour in a closed vessel:

$$SiCl^4 + 3(C^2H^5)^4SiO^4 = 4(C^2H^5)^3ClSiO^3.$$

2. Together with ethylic acetate, by heating 1 at. tetrethylic silicate with 1 at. chloride of acetyl to 170°—180°:

$$(C^2H^5)^4SiO^4 + C^2H^3OCl = (C^2H^5)^3ClSiO^3 + (C^2H^3O)(C^2H^5)O^2.$$

3. By distilling tetrethylic silicate with pentachloride of phosphorus. It is a limpid liquid, of specific gravity 1·0483 at 0°. Boils at 157°. Vapour-density: obs. = 7·05; calc. = 6·81. It does not fume in the air, but is quickly decomposed by the action of moist air and of water, yielding hydrochloric acid and silica. It burns with a green-edged flame, diffusing white fumes of silica.

Ethylsilicic Dichlorhydrin, $(C^2H^5)^2Cl^2SiO^2$.—Produced by heating 1 at. tetrethylic silicate with 1 at. silicic chloride:

$$SiCl^4 + (C^2H^5)^4SiO^4 = 2(C^2H^5)^2Cl^2SiO^2;$$

or 1 at. silicic chloride with 2 at. of the monochlorhydrin:

$$SiCl^4 + 2(C^2H^5)^3ClSiO^3 = 3(C^2H^5)^2Cl^2SiO^2.$$

In either case the materials must be heated together for some time, and the product purified by repeated fractional distillation, great care being taken to prevent access of moisture. It is a liquid resembling the preceding, and having a specific gravity of 1·44 at 0°. Boiling-point 137°. Vapour-density: obs. = 6·76; calc. = 6·545.

Ethylsilicic Trichlorhydrin, $(C^2H^5)Cl^3SiO$.—Prepared by heating the dichlorhydrin, monochlorhydrin, or tetrethylic silicate, for a long time with excess of silicic chloride, and fractionating the product a great number of times with the precautions above indicated. It is a liquid of specific gravity 1·291 at 0°, boiling at 104°. Vapour-density: obs. = 6·378; calc. = 6·216.

Ethylamylic Silicates.—These ethers are produced by distilling ethylsilicic mono-, di-, or tri-chlorhydrin with an equivalent quantity of amylic alcohol: *e. g.*—

$$\underset{\substack{\text{Ethylsilicic}\\ \text{monochlorhydrin.}}}{(C^2H^5)^3ClSiO^3} + \underset{\substack{\text{Amylic}\\ \text{alcohol.}}}{(C^5H^{11})HO} = \underset{\substack{\text{Amyl-triethylic}\\ \text{silicate.}}}{(C^2H^5)^3(C^5H^{11})SiO^4} + HCl.$$

The *monamylic compound*, $(C^2H^5)^3(C^5H^{11})SiO^4$, is a limpid slightly oily liquid, having a faint odour, like that of amyl-compounds in general; boils between 216° and 225°.—The *diamylic compound*, $(C^2H^5)^2(C^5H^{11})^2SiO^4$, has a specific gravity of 0·915 at 0°, and boils between 245° and 250°.—The *triamylic compound*, $(C^2H^5)(C^5H^{11})^3SiO^4$, has a specific gravity of 0·913 at 0°, and boils between 280° and 285°. These mixed ethers, like tetramylic silicate, are less easily decomposed by alcoholic ammonia than tetrethylic silicate. (Friedel and Crafts.)

Triethyl-acetylsilicic Ether, $(C^2H^5)^3(C^2H^3O)SiO^4$. *Ethylic Silico-acetin.*—Produced by heating tetrethylic silicate with acetic anhydride to 180° for fourteen hours, and separated by fractional distillation. It is a limpid slightly oily liquid, with a slightly acetic odour, becoming stronger after exposure for some time to a moist atmosphere. Boils at about 190°. Burns with emission of white clouds of silica.

Methylsilicic Ethers. (Friedel and Crafts, Ann. Ch. Phys. [4] ix. 32.)—*Tetramethylic silicate*, $(CH^3)^4SiO^4$, is prepared, like the corresponding ethyl-compound, by the action of silicic chloride on perfectly pure and anhydrous methylic alcohol (obtained by distilling ordinary methylic alcohol, first over sodium, and then over phosphoric anhydride). It is a colourless limpid liquid, having a fragrant ethereal odour, and a specific gravity of 1·0589 at 0°. Boils at 121°—122°. Vapour-density: obs. = 5·380; calc. = 5·264. It is moderately soluble in water, the solution remaining clear, and not depositing gelatinous silica till after the lapse of several weeks. It burns with emission of white fumes. It is rapidly decomposed by exposure to moist air. Aqueous alcohol converts it into a mixture of methylic polysilicates.

Hexmethylic Disilicate, $(CH^3)^6Si^2O^7 = 3(CH^3)^2O.2SiO^2$, is obtained in the preparation of tetramethylic silicate when the methyl-alcohol used is not quite anhydrous: also by heating the tetramethylic ether with wood-spirit containing the quantity of water required by theory for its production: $2(CH^3)^4SiO^4 + H^2O = (CH^3)^6Si^2O^7 + 2(CH^3)HO$. It resembles the tetramethylic ether, has a specific gravity of 1·1441 at 0°, and boils between 201° and 202·5. Vapour-density: obs. = 9·19; calc. = 8·93.

Methylsilicic Chlorhydrins.—These compounds are precisely analogous to the ethylsilicic chlorhydrins already described, and are obtained in like manner. They are limpid liquids, having an ethereal odour, burning with a green-edged flame, and diffusing white clouds of silica; easily decomposed by moisture; converted by wood-spirit into tetramethylic silicate. Their densities and boiling-points are exhibited in the following table:—

	Boiling-point.	Specific gravity at 0°.	Vapour-density.	
			obs.	calc.
Monochlorhydrin, $(CH^3)^3ClSiO^3$.	114·5°—115·0°	1·1954	5·578	5·42
Dichlorhydrin, $(CH^3)^2Cl^2SiO^2$ . .	98° —103°	1·2595	5·66	5·57
Trichlorhydrin, $(CH^3)Cl^3SiO$ . . .	82° —86°		5·66	5·73

Methyl-ethylsilicic Ethers.—These compounds are produced by the action of ethylic alcohol on the methylsilicic chlorhydrins.

Ethyl-trimethylic Silicate, $(CH^3)^3(C^2H^5)SiO^4$, is obtained, together with a small quantity of the following compound, by treating methylsilicic monochlorhydrin with excess of common alcohol. It boils between 133° and 135°.

Diethyl-dimethylic Silicate, $(CH^3)^2(C^2H^5)^2SiO^4$, is obtained by the action of ethylic alcohol on methylsilicic dichlorhydrin, and by that of methylic alcohol on tetrethylic silicate. It is a liquid of specific gravity 1·004 at 0°, and boiling between 143° and 146°. Vapour-density: obs. = 6·178; calc. = 6·233.

Triethyl-methylic Silicate, $(CH^3)(C^2H^5)^3SiO^4$, is obtained by the action of ethylsilicic monochlorhydrin on methylic alcohol. It has a specific gravity of 0·981 at 0°, and boils between 155° and 157°.

Dimethyl-diamylic Silicate, $(CH^3)^2(C^5H^{11})^2SiO^4$.—Produced by distilling methylsilicic monochlorhydrin with two-thirds of its weight of amylic alcohol. Boils between 225° and 235°. Decomposed by alcoholic potash, but not easily by alcoholic ammonia.

SILICIDES, METALLIC. Silicon unites readily with aluminium, iron, zinc, platinum, and some other metals, but not with sodium, and apparently not with lead or potassium. Towards aluminium and zinc, silicon behaves in the same manner as carbon to cast-iron, dissolving in these metals when melted, and separating in the crystalline form on cooling.

Silicide of Calcium, probably $CaSi^2$, is prepared by intimately mixing 300 grains of graphitoïdal silicon with 3,000 grains of chloride of calcium in a hot mortar, briskly agitating the mixture in a wide-mouthed bottle with 350 grains of sodium cut into small pieces, and introducing the whole into a red-hot crucible, into which a little fused common salt has been previously thrown, and upon this a mass of sodium weighing 350 grains. The whole is then covered with a layer of fused and pulverised chloride of sodium, the cover is put on, and the fire is gradually raised to a temperature sufficient to melt cast-iron, at which it must be maintained for half an hour. On breaking the crucible when cold, the silicide of calcium is found (if the operation has been successful) in a well-fused button, which must be preserved in tightly-closed vessels.

Silicide of calcium has a lead-grey colour, metallic lustre, and scaly crystalline structure with an indistinct indication of hexagonal plates. When exposed to the air, or thrown into water, it slowly crumbles down to a mass of graphite-like plates, with evolution of hydrogen. This disintegration is due to the hydration and oxidation of part of the calcium and silicon, the new products remaining mixed with some unaltered silicide. Fuming nitric acid does not attack silicide of calcium. Hydrochloric, acetic, or dilute sulphuric acid converts it into a compound of silicon, hydrogen, and oxygen, called silicone or chryseone (p. 275).—(Wöhler, Ann. Ch. Pharm. cxxvii. 257.)

Silicide of Cerium, CeSi.—When a mixture of fluoride of potassium and oxide of cerium, fused in a porcelain crucible, is subjected to electrolysis, silicide of cerium is deposited at the negative pole together with potassium; and on washing the deposit with water to remove the latter, the silicide of cerium remains as a brown powder, which is insoluble in acids, and burns with a reddish flame, leaving a yellow powder mixed with black particles. (Ulik, Zeitschr. f. Chem. [2] ii. 60.)

Silicides of Copper.—These compounds possess great hardness, and become harder but less malleable as the proportion of silicon increases. A white copper-silicide, very hard to the file, is formed in the preparation of silicon by passing the vapour of silicic chloride over sodium heated in copper trays. A copper silicide containing 12 pts. silicon to 88 pts. copper is obtained by fusing 3 pts. of potassic silicofluoride, 1 pt. sodium, and 1 pt. copper-turnings, at such a temperature that the melted metal is covered by a very fluid slag. The compound is white, brittle, and more fusible than silver. By fusing this silicide with a larger quantity of copper, a compound may be obtained containing 4·8 per cent. silicon: it has a fine light bronze colour, is as malleable as ordinary bronze, somewhat less hard than iron, and may be wrought like the latter, is very malleable, and may be drawn out into wire having at least as much tenacity as iron wire. (Deville and Caron, Ann. Ch. Pharm. civ. 232; Ann. Ch. Phys. [3] lxvii. 455.)

By precipitating cupric sulphate with siliciuretted hydrogen, a copper-silicide is obtained, as a dark copper-coloured film, translucent with brownish colour when very thin. This compound is easily oxidisable, being quickly converted, by exposure to the air at ordinary temperatures, into lemon-yellow cupric silicate. Dilute nitric acid decomposes it immediately, separating metallic copper; hydrochloric acid dissolves it, with evolution of hydrogen and separation of silicic oxide. With potash-ley it quickly gives off hydrogen, and deposits copper free from silicon; it also gives off hydrogen in contact with ammonia.

Silicide of Iron. See IRON (iii. 334).

Silicide of Magnesium.—The mass obtained by fusing together chloride of magnesium, chloride of sodium, silicofluoride of sodium, and metallic sodium, for the preparation of siliciuretted hydrogen, contains, besides free silicon, two silicides of magnesium, one of which gives off siliciuretted hydrogen when treated with aqueous sal-ammoniac or hydrochloric acid; whereas the other, when treated with hydrochloric acid, yields free hydrogen and hydrated oxide of silicon. (Wöhler).

Silicide of Manganese. See MANGANESE (iii. 816).

Silicide of Platinum.—Platinum unites readily with silicon, forming a very fusible compound: hence, on fusing silicon in a platinum crucible lined with lime, care must be taken to make the lining very dense, as, if the silicon comes in contact with the platinum, the crucible will be perforated.

Silicide of Potassium(?).—According to Berzelius, silicide of potassium is formed in the preparation of silicon by heating potassic silicofluoride with potassium; but, according to Deville, the potassium is merely mixed with the free silicon.

SILICIDES, ORGANIC. (Friedel and Crafts, Bull. Soc. Chim. 1863, p. 468; 1865, i. 358.)—*Silicon-ethyl*, *ethylic silicide*, or *silicic ethide*, $Si(C^2H^5)^4$, and the corresponding *methyl-compound*, $Si(CH^3)^4$, are prepared by heating silicic chloride with zinc-ethyl and zinc-methyl respectively in sealed tubes. They are limpid liquids lighter than water, and burning with a bright flame, emitting white clouds of silica. They are not attacked by potash or by ordinary nitric acid, but are decomposed, the methyl-compound with great difficulty, by heating with fuming nitric acid in sealed tubes. Their boiling-points and vapour-densities are as follows:—

	Boiling-points.	Vapour-density.	
		Obs.	Calc.
$Si(CH^3)^4$	30°— 31°	3·083	3·043
$Si(C^2H^5)^4$	152°—154°	5·13	4·99

SILICIUM. Syn. with SILICON.

SILICO-ALUMINATES.
SILICO-BORATES. } See SILICATES (p. 262).

SILICOFLUORIDES. See SILICON, FLUORIDE OF (p. 270).

SILICON, or SILICIUM. *Atomic weight*, 28; *Symbol*, Si.—This element, though very abundant in nature, is never found in the free state, but always in combination, either with oxygen alone, as silica (p. 240), or with oxygen and metals, forming silicates.

Silicon is obtained in the free state by the action of reducing agents on the chloride or fluoride, and, like boron, assumes the amorphous, graphitoïdal, or crystalline state, according to the mode of separation adopted.

1. *Amorphous Silicon.*—This is the form in which silicon was first isolated by Berzelius (in 1823). It is obtained by heating dry potassic silicofluoride in a glass or iron tube, with eight or nine-tenths of its weight of potassium, or sodic silicofluoride with half its weight of sodium. Fluoride of potassium or sodium is then formed, and silicon is set free:

$$2KF.SiF^4 + 2K^2 = 6KF + Si.$$

The mass when cold is treated with cold water as long as the wash-water exhibits any alkaline reaction, then with boiling water as long as anything is dissolved. Silicon may also be prepared by passing the vapour of silicic chloride over potassium or sodium heated in procelain trays in a glass tube, which it is best to protect by lining it with thin plates of mica.—Amorphous silicon is likewise obtained by electrolysing a fused mixture of silicofluoride and fluoride of potassium; it may be purified from potassium deposited at the same time by washing with sulphuric acid. (Ulik.)

Silicon thus obtained is a dull brown powder, heavier than water, and insoluble therein. It is a non-conductor of electricity; soils the fingers when touched; is not acted upon by nitric or sulphuric acid, but dissolves easily in hydrofluoric acid and in warm aqueous potash. When heated in a non-oxidising atmosphere to a temperature between the melting-points of steel and cast-iron, it fuses; but when heated in air or oxygen-gas, it burns brilliantly, and is converted into silica, which melts from the intense heat, and forms a superficial crust over the unburnt silicon.

2. *Graphitoïdal Silicon.*—When amorphous silicon is strongly heated in a platinum crucible, it shrinks together, becomes much denser and darker in colour, and much less oxidisable (Berzelius). A similar modification of silicon was obtained by Deville in preparing aluminium by the electrolysis of sodio-aluminic chloride (i. 152). The first portions of aluminium thus obtained are contaminated with silicon derived from the charcoal electrodes; and when this alloy of silicon and aluminium is treated with hydrochloric acid, the silicon remains undissolved in the form of shining metallic scales resembling graphite. A more productive method of obtaining this variety of silicon is given by Wöhler (Compt. rend. xlii. 48). It consists in mixing aluminium with between 20 and 40 times its weight of silicofluoride of potassium, and heating the mixture in a Hessian crucible to the melting-point of silver. A metallic button is thus obtained, which, when treated successively with hydrochloric and hydrofluoric acids, yields graphitoïdal silicon, partly in isolated hexagonal tables, the edges of which are often curved. Another mode of preparation is to fuse 1 pt. of aluminium with 5 pts. of glass free from lead, and 10 pts. of powdered cryolite, and treat the mass first with hydrochloric, then with hydrofluoric acid. Graphitoïdal silicon exhibits all the properties ascribed by Berzelius to silicon which has been strongly heated. Its density is 2·49, which is less than that of quartz (from 2·6 to 2·8). It may be heated to whiteness in oxygen-gas without burning or undergoing any alteration in weight; but when heated to redness with *carbonate of potassium*, it decomposes the carbonic acid, with vivid emission of light and formation of silica. With *nitrate* or *chlorate of potassium*, it may be fused at a red heat without alteration, but at a white heat it burns brilliantly; the oxidation is greatly facilitated by the addition of a little carbonate of potassium. It is not attacked by any acid, excepting a mixture of nitric and hydrofluoric acids. A strong solution of *potash* or *soda* dissolves it slowly, with evolution of hydrogen. Heated to commencing redness in dry *chlorine gas*, it burns completely and forms chloride of silicon.

3. *Crystalline or Adamantine Silicon.*—α. When silicon is heated in a platinum crucible lined with lime, to a temperature between the melting-points of steel and cast-iron, it melts to dark steel-grey globules, which frequently show well-marked signs of crystallisation, and sometimes yield the silicon in double six-sided pyramids. (Deville, Ann. Ch. Phys. [3] xlix. 68.)

β. When vapour of silicic chloride is passed over aluminium kept in a state of fusion in an atmosphere of hydrogen, part of the aluminium is converted into chloride, which volatilises, and the silicon thereby separated dissolves in the remaining aluminium, which thus becomes more and more saturated with silicon; and at length a point is obtained at which the excess of silicon separates from the melted aluminium in large beautiful needles, having a dark iron-grey colour, reddish by reflected light, and exhibiting iridescence like that of iron-glance. These crystals appear to be derived from a rhombic octahedron, and often, like the diamond, exhibit curved faces. They are very hard, and capable of scratching or cutting glass (Deville). An easier method of obtaining crystallised silicon is to introduce into a red-hot earthen crucible a mixture of 3 pts. potassic silicofluoride, 1 pt. of sodium in small pieces, and 4 pts. of granulated zinc. The mixture must be kept at a red heat, but below the temperature required to volatilise the zinc, till the slag is completely melted; then left to cool slowly. The mass of zinc thus obtained contains long needles of silicon formed of octahedrons (? rhombic) inserted one into the other. Much of the zinc may be extracted by partial fusion at a low temperature, and the zinc which runs from the pasty mass, in which the silicon is retained, may be employed again in a similar operation. The zinc, which still adheres to the silicon, may be removed by digestion, first in hydrochloric, and afterwards in boiling nitric acid. If a very high temperature be employed in the operation, the whole of the zinc may be expelled, and the silicon obtained in the fused state. Deville and Caron have in this way fused several hundred grammes of silicon under a layer of potassic silicofluoride, at a temperature near the melting-point of cast-iron, and have cast it into large cylindrical bars, without sensible loss by oxidation. These bars exhibited a brilliant surface, which was not altered by exposure to the air (Ann. Ch. Phys. [3] lxiii. 26; lxvii. 441); see also Robbins (*Chem. News*, v. 102).

SILICON, BROMIDE OF. $SiBr^4$.—This compound, discovered by Serullas, is produced by passing bromine-vapour over an intimate mixture of silica and charcoal, heated to redness in a porcelain tube: it is purified by agitation with mercury, and distillation. Colourless liquid, of specific gravity 2·813, and having a pungent odour. It solidifies at 12° to 15° to an opaque, white, slightly nacreous mass; boils at 153·4° (under a pressure of 762 mm.), fumes very strongly in moist air, and in contact with water is immediately resolved into hydrobromic acid and gelatinous silica. Heated with potassium, it decomposes with detonation.

Silicohydric Bromide, $Si^3H^4Br^{10} = 3SiBr^2.4HCl$, is obtained by passing hydrobromic acid gas over ignited crystalline silicon, and passing the evolved vapours through a U-tube, cooled with ice and salt. When purified from free bromine by agitation with mercury, it is a colourless liquid, of specific gravity about 2·5; it fumes strongly in the air, and is instantly decomposed by water, yielding hydrobromic acid, and the corresponding hydrated oxide, $Si^3H^4O^5$, which forms a film on the surface, and for a while protects the remaining bromine-compound from further decomposition. (Wöhler and Buff, Ann. Ch. Pharm. civ. 99.)

SILICON, CHLORIDE OF. $SiCl^4$.—This compound is formed when silicon is heated in chlorine gas; but the best mode of preparing it is to mix finely-powdered silica to a paste with oil and charcoal, heat the mixture in a covered crucible, and ignite the charred mass in a porcelain tube, through which a current of chlorine is passed:

$$SiO^2 + 2Cl^2 + C^2 = 2CO + SiCl^4.$$

The product is received in vessels cooled by a freezing mixture.

Chloride of silicon, or silicic chloride, is a transparent colourless liquid, of specific gravity 1·5237 at 0°. It remains liquid at − 20°, boils at 50° (Serullas). Vapour-density: obs. = 5·939 (Dumas); calc. = 5·8905. The vapour has a suffocating odour, and reddens litmus.

Chloride of silicon is quickly decomposed by *water*, yielding hydrochloric acid and silica, a considerable quantity of which remains dissolved if the water is in large proportion. *Potassium*, heated in the vapour, decomposes it with separation of silicon. Fused potassium dropped upon the liquid chloride causes an explosion.

Silicohydric chloride, $Si^3H^4Cl^{10} = 3SiCl^2.4HCl$, analogous to silicohydric bromide, is prepared in like manner by passing hydrochloric acid gas over crystallised silicon heated to barely visible redness, and condensing the product in a U-tube cooled to 0°. It is a colourless very mobile liquid, of specific gravity 1·65, boiling at about 42°. It fumes strongly when exposed to the air, depositing a white film on surrounding bodies, and emitting a suffocating vapour. It is highly inflammable, and burns with a greenish feebly luminous flame, depositing silica and emitting hydrochloric acid. The vapour mixed with oxygen explodes violently on transmission of an electric spark, depositing silica, and yielding hydrochloric acid and tetrachloride of silicon. It may be boiled over sodium without decomposition—hence it does not appear to contain ready-formed hydrochloric acid; a similar observation applies to the bromide. When passed through a red-hot tube, it is resolved into a mixture of hydrochloric acid and the tetrachloride, whilst half the silicon is deposited in the form of a brown, amorphous, metallic-shining crust. Water decomposes it immediately, with great rise of temperature, forming hydrochloric acid and the corresponding hydrated oxide, called *leucone*: $Si^3H^4Cl^{10} + 5H^2O = Si^3H^4O^5 + 10HCl$. (Wöhler and Buff, Ann. Ch. Pharm. civ. 94.)

SILICON, DETECTION AND ESTIMATION OF. The methods of analysing compounds, in which silicon occurs as silicic acid, have been already detailed (p. 245).

The **chloride, bromide,** and **iodide** of silicon are completely decomposed by water; and on evaporating the liquid to dryness, the whole of the resulting hydrochloric, hydrobromic, or hydriodic acid goes off, and the silica remains, and may be weighed. The quantity of chlorine, &c. may also be directly determined by precipitation with nitrate of silver.

When **fluoride of silicon** is decomposed by water, part of the silica is precipitated, while another portion remains dissolved, as silicofluoric acid: $2HF.SiF^4$. The precipitated silica is separated by filtration after addition of alcohol, and the silicofluoric acid may be completely precipitated from the filtrate by addition of chloride of potassium. The precipitated silicofluoride of potassium is collected on a filter, washed with a mixture of equal volumes of alcohol and water, then dried at 100°, and weighed; and the quantity of silicon (or the corresponding quantity of silica) contained in it is determined by calculation. As the liquid filtered from the precipitated silicofluoride may still contain silica (which in the precipitated state is somewhat soluble in water, p. 241), it must be evaporated to dryness, the residue digested with water, and the silica that remains undissolved, collected and weighed.

Metallic silicofluorides are most easily analysed by heating them with strong sulphuric acid, whereby the whole of the silicon and fluorine are driven off in the form of silicic fluoride and hydrofluoric acid, while the metal remains as sulphate, which may be weighed, after the excess of sulphuric acid has been expelled by heat, aided, if necessary, by addition of carbonate of ammonium; the quantity of metal thence determined, gives the quantity of metallic fluoride in the compound $2MF.SiF^4$ or $M''F^2.SiF^4$.

If it be desired to determine directly the quantity of silicic fluoride, the silicofluoride may be decomposed by boiling it with a slight excess of sodic carbonate, whereby fluoride of sodium is formed, carbonic anhydride is evolved, and the metal of the silicofluoride is precipitated as oxide, mixed with the silica. These may be separated by the usual methods, and the fluorine precipitated by chloride of calcium (ii. 674). The same method must be resorted to if the silicofluoride to be analysed is in solution, or if it is mixed with other salts. (H. **Rose**, *Chimie Analytique*, ii. 888.)

The decomposition of silicofluorides by ignition does not yield very exact results; for although the whole of the fluoride of silicon is ultimately expelled, and the metallic fluoride remains, the weight of the latter can seldom be determined exactly, because the escaping fluoride of silicon being decomposed by the moisture of the air, or by water evolved from the lamp or other source of heat, a deposition of silica takes place on the crucible, and increases its weight. (H. **Rose**.)

Atomic weight of Silicon.—Berzelius regarded silica as a trioxide, SiO^3, and represented the chloride, bromide, &c. by the corresponding formulæ, $SiCl^3$, $SiBr^3$, &c. L. **Gmelin**, in his *Handbook* (iii. 352), adopted for silica the formula SiO^2, on account of the greater simplicity of the formulæ which it yields for the compounds of silicon both natural and artificial. This view, which amounts to regarding silicon as tetratomic, is corroborated by the vapour-densities of the chloride and fluoride of silicon, and by the composition of the silicic ethers (p. 263). The vapour-density of silicic chloride, as determined by Dumas, is 5·939, and that of the fluoride 3·60. Now if these compounds be represented by the tetratomic formulæ $SiCl^4$ and SiF^4 [Si = 28], their vapours will exhibit the normal condensation to 2 volumes, whereas the formulæ $SiCl^3$ and SiF^3 [Si = 21] would represent a condensation to 1½ volume: thus—

$$\text{Chloride, } SiCl^4;\quad \frac{28 + 4\,.\,35\cdot5}{2} \times 0\cdot0693 = 5\cdot8995.$$

$$\text{,,}\quad SiCl^3;\quad \frac{21 + 3\,.\,35\cdot5}{1\cdot5} \times 0\cdot0693 = 5\cdot8905.$$

$$\text{Fluoride, } SiF^4;\quad \frac{28 + 4\,.\,19}{2} \times 0\cdot0693 = 3\cdot604.$$

$$\text{,,}\quad SiF^3;\quad \frac{21 + 3\cdot195}{1\cdot5} \times 0\cdot0693 = 3\cdot604.$$

The older numerical determinations of the atomic weight of silicon by Berzelius, depending on the analyses of certain silicates and of cast-iron containing silicon, did not yield accordant results. By the analysis of silicofluoride of barium (100 pts. of the dry salt, decomposed by sulphuric acid, yielding 82·933 pts. sulphate of barium) Berzelius obtained Si (tetratomic) = 27·54. More exact results are obtained by decomposing chloride of silicon with nitrate of silver. **Pelouze** (Ann. Ch. Pharm. lvi. 202) found that 3·685 pts. of silver dissolved in nitric acid, precipitated the chlorine from 1·454 pts. chloride of silicon; whence Si = 28·48. **Dumas** (*ibid.* cxiii. 31), from the mean of three experiments conducted on the same principle, obtained the number 28·02.

SILICON, FLUORIDE OF. SiF^4.—A gaseous compound, produced whenever hydrofluoric acid comes in contact with silica or any silicious substance, such as glass, and therefore also when a mixture of a fluoride with silica or a silicate is heated with sulphuric acid. The reaction is,

$$4HF + SiO^2 = 2H^2O + SiF^4.$$

To prepare it, powdered fluor-spar, mixed with sand or finely-pounded glass, is gently heated in a flask with strong sulphuric acid, and the gas is collected over mercury in dry glass jars. If the receivers are coated with a film of moisture, they become coated with an opaque deposit of silica, which cannot be removed.

Fluoride of silicon is a colourless gas, having a specific gravity of 3·60, and a highly pungent and suffocating odour, like that of hydrochloric acid. According to J. Davy, it reddens litmus-paper even when perfectly dry. It liquefies under very strong pressure (Faraday), and solidifies at $-140°$ (Natterer). It is not inflammable, but extinguishes a lighted taper. It fumes strongly in the air, and is absorbed in large quantity by water, which at the same time decomposes it into silica and silicofluoric acid:

$$3SiF^4 + 2H^2O = 2H^2SiF^6 + SiO^2.$$

Aqueous *alkalis* and *alkaline earths* either act like water, precipitating only one-third of the silicon as silica, and forming a silicofluoride, $\left.\begin{matrix}M^2\\M''\end{matrix}\right\} SiF^6$, as with potash; or they precipitate the whole of the silica, and form a metallic fluoride, as is the case with soda. Many *metallic oxides* in the anhydrous state absorb gaseous fluoride of silicon, producing heat and sometimes even flame, and apparently forming a mixture of silica and metallic fluoride.—Burnt *lime*, immersed in the gas, becomes red-hot throughout its whole mass.—*Potassium*, at ordinary temperatures, acts but slightly on the gas; but if heated till it melts, it blackens, and burns with a dark-red flame, absorbing a portion of the gas, and yielding a dark-brown brittle mass (Gay-Lussac and Thénard). Sodium acts in a similar manner.

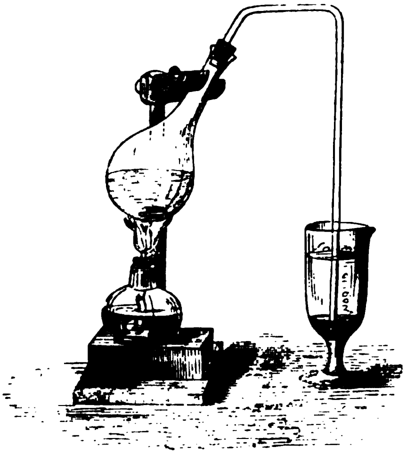
Fluoride of silicon combines with twice its own volume of *ammonia-gas*, forming a volatile crystalline compound, $2NH^3.SiF^4$, which is decomposed by water, yielding silica and a solution of fluoride and silicofluoride of ammonium (J. Davy):

$$2(2NH^3.SiF^4) + 2H^2O = 2NH^4F + (NH^4)^2SiF^6 + SiO^2.$$

Absolute alcohol absorbs fluoride of silicon, forming a liquid called silicofluoric or fluosilicic alcohol, consisting of a mixture of tetrethylic silicate and silicofluoric acid. To obtain a saturated solution, the alcohol must be kept cool. (Knop and Wolf, Chem. Centr. 1861, p. 822; Jahresb. 1861, p. 207.)

Silicofluoric acid, $Si^2H^2F^6 = 2HF.SiF^4$.—An acid produced by the action of water on gaseous fluoride of silicon. To prepare it, the generating flask is fitted with a wide glass tube, dipping under mercury at the bottom of a glass jar, as in *fig.* 743. Water is then poured into the glass, and heat applied to the mixture in the flask. The object of making the end of the tube dip under mercury, is to prevent it from being stopped up by the deposited silica. Each bubble of gas, as it rises through the water, is decomposed, as above explained, into silicofluoric acid and free silica—the former dissolving, while the latter is set free in the solid state, and forms a silicious envelope round the bubble as it rises above the surface of the mercury; ultimately, the liquid sets into a gelatinous mass. When sufficiently saturated, it is separated from the silica by pressure between linen, and finally by filtration through paper.

Fig. 743.



An easier method of obtaining the acid in large quantities is to dissolve silica in dilute hydrofluoric acid.

A saturated solution of silicofluoric acid forms a very sour fuming liquid, which gradually evaporates at 40° in platinum vessels without leaving any residue. It does not attack glass except when evaporated upon it; in that case the fluoride of silicon goes off first, leaving hydrofluoric acid, which corrodes the glass, and ultimately evaporates also as fluoride of silicon.

According to Stolba (J. pr. Chem. xc. 193), the specific gravity of the aqueous acid increases regularly with its strength, as shown by the following numbers:—

Percentage of H^2SiF^6 . .	0·5	1	1·5	2	5	10
Specific gravity at 17·5° . .	1·0040	1·0080	1·0120	1·0161	1·0407	1·0834

Silicofluorides. $2MF.SiF^4$, or $M''F^2.SiF^4$.—These salts are produced:—1. By dissolving a metallic oxide, hydrate or carbonate (or, in the case of iron or zinc, the simple metal) in silicofluoric acid till the liquid is nearly saturated,—when, if the compound is not insoluble, it is separated on evaporating the liquid in a platinum-vessel. If it gelatinises from excess of silica, a small quantity of hydrofluoric acid must be added, and this, on further evaporation, volatilises with the silica in the form of silicic fluoride.—2. By the action of silicic fluoride on metallic fluorides (either dry or in solution), which readily absorb the gas: or on metallic oxides or carbonates slightly moistened with water. In the latter case a portion of the silicon is separated in the form of silica.

Most silicofluorides are easily soluble in water; only those of sodium, lithium, barium, calcium, and yttrium, are sparingly soluble. The solutions frequently yield hydrated crystals. Many of these crystals lose their water by efflorescence on exposure to the air, and all of them undergo this change when heated.

The silicofluorides redden litmus, and for the most part have an acid and bitter taste. By prolonged ignition, they give up the whole of the fluoride of silicon, the metallic fluoride remaining behind in the pure state. If they contain water, the gaseous fluoride of silicon, as it escapes, is accompanied by a white sublimate in the form of minute drops, which on exposure to moist air deposit silica.

The silicofluorides, many of them at least, are resolved by ignition with *potassium* into silicon and fluoride of potassium, whilst the metallic fluoride previously in combination with the fluoride of silicon, either remains unaltered, or gives up its fluorine also to the potassium. The action of *iron* at a red heat is similar to that of potassium (Berzelius). With *oil of vitriol*, the silicofluorides at first evolve gaseous fluoride of silicon with effervescence; then, at a temperature which, in the case of the calcium and barium-compound, exceeds 100°, anhydrous hydrofluoric acid is evolved. *Hydrochloric* and *nitric acids* expel only a part of the hydrofluosilicic acid. The silicofluorides are decomposed by excess of alkali, silica being precipitated, and a metallic fluoride remaining in solution: *e.g.*—

$$2KF.SiF^4 + 4KHO = SiO^2 + 6KF + 2H^2O.$$

Silicofluorides of the Alkali-metals.—The *ammonium-salt*, $(NH^4)^2SiF^6 = 2NH^4F.SiF^4$, is produced by neutralising silicofluoric acid with ammonia, avoiding an excess. The filtered liquid yields the salt by spontaneous evaporation, in large, transparent, shining, four- or six-sided prisms, containing water of crystallisation.

The *lithium-salt*, $2LiF.SiF^4$, crystallises from solution in silicofluoric acid in small transparent grains, which under the microscope present the appearance of six-sided prisms. It has a slightly acid and bitter taste, melts at a red heat, and obstinately retains its fluoride of silicon. Pure water dissolves it very slowly; acidulated water more readily.

The *potassium-salt*, $2KF.SiF^4$, is obtained as a transparent gelatinous precipitate, when silicofluoric acid is added to any salt of potassium; when dry it forms an earthy-looking powder. It is one of the least soluble of the potassium-salts, and consequently silicofluoric acid is often used to precipitate potassium from the solutions of its salts; in this manner chloric acid is sometimes prepared from chlorate of potassium. According to Stolba (J. pr. Chem. xc. 193), it has a specific gravity of 2·6649—2·6655 at 17·5°, and dissolves in 833·1 pts. of water at that temperature, and in 104·8 pts. at the boiling heat. It is insoluble in alcohol. The salt melts at a low red heat, and boils at a higher temperature, slowly evolving gaseous fluoride of silicon. Heated with potassium, it yields silicon and fluoride of potassium.

The *sodium-salt*, $2NaF.SiF^4$, resembles the potassium-salt, and is obtained in like manner. According to Stolba, it has a density of 2·7547 at 17·5°, dissolves in 153·3 pts. water at that temperature, and in 40·66 pts. at its boiling heat (101°). It has a great tendency to form supersaturated solutions, and may be used as a test for potassium-salts when the solutions of the latter are not too dilute. The solutions of the potassic and sodic silicofluorides, when slowly evaporated, deposit the salts in ring-shaped crusts on the side of the vessel (Stolba). The sodium-salt is insoluble in alcohol, whether strong or dilute.

Silicofluorides of the Earth-metals.—The *barium-salt*, $Ba''F^2.SiF^4$, is produced on adding silicofluoric acid to a soluble barium-salt, and is quickly deposited in microscopic crystals, insoluble in excess of the acid. It is decomposed by ignition, fluoride of silicon going off and fluoride of barium remaining.—According to Fresenius (Ann. Ch. Pharm. lix. 117), it dissolves in 3,802 pts. of pure water, and in 733 pts. of water acidulated with hydrochloric acid.—The *strontium-salt* separates from a solution of strontium-carbonate in silicofluoric acid, on evaporation or cooling, in short hydrated rhombic prisms, with dihedral summits resting on the acute lateral edges. It is much more soluble than the barium-salt, so that silicofluoric acid may be used to distinguish barium from strontium in solution.—The *calcium-salt* crystallises in four-sided obliquely truncated prisms, which are decomposed by water, yielding on the one hand an insoluble residue of silicon and fluoride of calcium, and on the other silicofluoric acid, by which the remainder of the silicofluoride is dissolved without decomposition (Berzelius).—The *glucinum-salt* is easily soluble in water, and if the solution contains excess of acid, it remains, after the volatilisation of the latter, in hard white masses resembling porcelain (Berzelius).—The *magnesium-salt*, $Mg''F^2.SiF^4$, is a transparent, yellowish, gummy mass, easily soluble in water (Berzelius).—The *yttrium-salt* is insoluble in pure water, but soluble in water containing hydrochloric acid, and separates on evaporation (Berzelius); decomposed by evaporation (Popp).—The *zirconium-salt* forms white pearly crystals, very soluble in water; the solution becomes turbid on boiling, but the greater part of the salt remains dissolved.

Silicofluorides of Heavy Metals.—*Antimony-salt.* A solution of antimonious oxide in silicofluoric acid crystallises by slow evaporation in prisms, which crumble to powder when dried in the air, and dissolve readily in excess of the acid (Berzelius). The *cadmium-salt* forms long, transparent, efflorescent prisms, very soluble in water. (Berzelius.)

Chromic salt.—A solution of chromic oxide in silicofluoric acid, yields by evaporation a transparent, green, amorphous, deliquescent mass, which, if it contains excess of acid, swells up in the fire like alum, and again deliquesces on exposure to the air. (Berzelius.)

Cobalt-salt, $Co''F^2.SiF^4.7H^2O$.—Pale-red rhombohedrons, easily soluble in water. (Berzelius.)

Copper-salts.—The cuprous salt, $2CuF.SiF^4$, is copper-coloured, resembling cuprous fluoride, and behaves like the latter when exposed in the moist state to the air. When somewhat strongly heated, it melts, and gives off fluoride of silica with ebullitions. (Berzelius.)

Cupric Silicofluoride is obtained by spontaneous evaporation of a solution of cupric oxide in silicofluoric acid, in transparent octahedrons and hexagonal prisms, containing $Cu''F^2.SiF^4.7H^2O$, which effloresce in the air, becoming light-blue and opaque, and giving off 2 at. water, and are easily soluble in water. (Berzelius). Knop and Wolf prepare this salt by adding precipitated cupric oxide in slight excess to fluosilicic alcohol (p. 270), diluted with 3 or 4 times its volume of absolute alcohol. A pale-blue crystalline powder is thereby produced, the filtered aqueous solution of which contains pure cupric silicofluoride, and yields, with potassium and barium-salts, precipitates having the usual composition of the silicofluorides, $M^2F.SiF^4$. But by adding precipitated cupric oxide to fluosilicic alcohol diluted with eight times its volume of water, and heated to 50°—60°, a solution is obtained, which yields by double decomposition, compounds containing silicon and fluorine, but of more complex constitution than the ordinary silicofluorides.—Another series of fluosilicic compounds is obtained by decomposing the solution of cupric silicofluoride, or of the copper-salt last described, with zinc or iron. The zinc or iron-salt thus obtained yields, by double decomposition, the third series of salts just mentioned. (Knop and Wolf, Jahresb. 1861, p. 207.)

Silicofluorides of Iron.—The ferrous salt, $Fe''F^2.SiF^4$, is obtained by spontaneous evaporation of a solution of iron in silicofluoric acid, in pale bluish-green six-sided prisms, very soluble in water.—The ferric salt, $2Fe'''F^3.3SiF^4$, remains on evaporating a solution of ferric hydrate in silicofluoric acid, as a yellowish jelly, which dries up to a transparent gummy mass, completely soluble in water. (Berzelius.)

The *lead-salt*, $Pb''F^2.SiF^4$, dries up to a translucent gum, which tastes like other lead-salts, and redissolves completely in water. (Berzelius.)

The *manganous salt*, $Mn''F^2.SiF^4.7H^2O$, crystallises from a very strong solution in long regular six-sided prisms, or by slower evaporation in shorter prisms and rhombohedrons. It has a very light-red colour, and is easily soluble in water. When distilled, it first gives off its 7 at. water, and then gaseous fluoride of silicon. (Berzelius.)

Silicofluorides of Mercury.—The mercurous salt, $2HgF.SiF^4$, formed by digesting recently precipitated mercurous oxide with silicofluoric acid, separates on evaporation in small crystals, sparingly soluble in water.—The mercuric salt, $Hg''F^2.SiF^4$, obtained by dissolving mercuric oxide in the acid, forms small pale-yellow needles, which when distilled give off first gaseous fluoride of silicon, then mercuric fluoride. They dissolve completely in acidulated water, but are decomposed by pure water, yielding an acid solution and an insoluble basic salt. (Berzelius.)

Silicofluorides of Molybdenum.—A solution of molybdous hydrate in excess of silicofluoric acid dries up when heated to a black neutral compound, which redissolves in the aqueous acid.—A solution of molybdic hydrate in silicofluoric acid acquires a bluish tinge when left to evaporate, and yields a black uncrystallisable mass, from which water dissolves out the blue salt, leaving the neutral compound in the form of a jet-black powder.

The yellowish solution of molybdic trioxide in silicofluoric acid leaves, when evaporated, a lemon-yellow opaque substance, which redissolves for the most part in water. (Berzelius.)

Platinic Silicofluoride.—The yellow solution of platinic hydrate in silicofluoric acid dries up to a yellowish-brown gum, which partly redissolves in water, leaving a brown basic salt. (Berzelius.)

Silver-salt, $2AgF.SiF^4$.—A solution of silver-oxide in silicofluoric acid yields deliquescent granular crystals. Ammonia added to the solution throws down a light-yellow basic salt, which, when treated with excess of ammonia, is converted into silicate of silver. (Berzelius.)

Stannic Silicofluoride, $SnF^4.2SiF^4$, crystallises in long prisms, very soluble in water. (Berzelius.)

Uranous Silicofluoride is obtained as a pale-green gelatinous precipitate on adding silicofluoric acid to uranous chloride. When heated in a tube, it yields water, hydrofluoric acid, and sublimed silica. (Rammelsberg.)

Vanadic Silicofluorides.—The blue solution of vanadic dioxide in silicofluoric acid leaves, when quickly evaporated, a blue substance, which, at a moderate heat, swells up to a pale-blue porous mass. The solution, if left to evaporate spontaneously, turns green, and leaves a syrupy liquid containing crystals.—Vanadic trioxide forms with silicofluoric acid a red solution, which leaves on evaporation an orange-yellow mass, only partially soluble in water. (Berzelius.)

Silicofluoride of Zinc.—A solution of zinc-oxide in silicofluoric acid yields, by evaporation at a high temperature, three- and six-sided transparent colourless prisms, containing $Zn''F^2.SiF^4$, permanent in the air, and very soluble in water. (Berzelius.)

SILICON, HYDRIDE OF. SiH (?). *Silicic Hydride, Hydric Silicide, Siliciuretted Hydrogen.* (Wöhler and Buff, Ann. Ch. Pharm. cii. 128; ciii. 218; civ. 94; cvii. 112; Jahresb. 1857, p. 166; 1858, p. 142.)—Silicon forms with hydrogen a gaseous compound, which is not known in the pure state, but is obtained, mixed with a large quantity of free hydrogen, when a wire or plate of aluminium containing silicon is connected with the positive pole of a voltaic battery (a Bunsen's battery of 8 to 12 cells), and made to decompose a solution of chloride of sodium. The aluminium then dissolves as chloride, a considerable quantity of gas is evolved at its surface, and many of the gas-bubbles, as they escape into the air, take fire spontaneously, burning with a white light, and diffusing a white fume. The formation of the siliciuretted hydrogen appears to be due to a secondary action accompanying the electrolysis of the saline solution. The aluminium forming the positive pole of the battery combines with the chlorine and dissolves; but the quantity of aluminium removed is about one-fourth greater than that which is equivalent to the quantity of chlorine eliminated from the solution. This excess of aluminium is found to be removed in the form of alumina, formed by the combination of the metal with oxygen derived from the water. The equivalent quantity of hydrogen is of course set free, and part of it enters into combination with the silicon contained in the aluminium.

Siliciuretted hydrogen is likewise produced in the decomposition of certain metallic silicides by hydrochloric acid, and by the action of heat on the hydrates of silicon. The best alloy for preparing it is a silicide of magnesium, obtained by intimately mixing 40 pts. of fused chloride of magnesium, 35 pts. dried silicofluoride of sodium, and 10 pts. fused chloride of sodium, stirring the mixture in a warm dry tube with 20 pts. of sodium in small fragments, throwing the whole into a red-hot hessian crucible, which is to be immediately covered, and heating it till the vapours of sodium cease to burn. The greyish-black scoriaceous mass thus produced contains, according to Wöhler, two silicides of magnesium, one of which, when treated with hydrochloric acid or solution of sal-ammoniac, gives off siliciuretted hydrogen, while the other yields with hydrochloric acid nothing but free hydrogen and hydrated oxide of silicon.

To obtain the gas, the coarsely pulverised mass is introduced into a two-necked bottle, one tubulure of which is fitted with a straight funnel-tube reaching to the bottom, while the other is provided with a gas-delivery-tube. The bottle is filled up with de-aërated water, and the delivery-tube is made to dip under water in the pneumatic trough, care being taken that not a bubble of air shall remain either in the bottle or in the tube. Strong hydrochloric acid is then poured in through the funnel-tube, and the gas, which is rapidly evolved, is collected in a glass jar filled with de-aërated water. The froth which passes over with it quickly subsides, so that the pure gas may be transferred into another receiver, and dried, if necessary, over chloride of calcium.

Siliciuretted hydrogen mixed with free hydrogen is a colourless gas, insoluble in pure de-aërated water and in salt water; but over water containing air it is decomposed, forming white clouds of silica, and losing its spontaneous inflammability. If it be passed into the air in single bubbles, each bubble takes fire spontaneously, and with explosion, burning with a white flame and separation of silica, which rises in beautiful rings, often coloured brownish by admixture of amorphous silicon. When set on fire, as it issues from a tube, it burns with a brilliant white flame. On opening a glass jar filled with it in the air, it takes fire, the flame gradually passing down the jar, the inner surface of which becomes coated with brown silicon.

The gas, when heated by itself, is decomposed into amorphous silicon and free hydrogen, and at the same time increases in volume, showing that the hydrogen in the compound is in a condensed state. It has not been analysed quantitatively. A piece of porcelain introduced into the flame becomes coated with brown silicon; and, on passing the gas through a glass tube heated to low redness, the interior becomes coated with a dark-brown opaque mirror. The gas is easily decomposed by chlorine. It is not altered by dilute hydrochloric or sulphuric acids. When shaken up with potash-ley, it is decomposed with increase of volume; soda and ammonia do not appear to act upon it. From a solution of cupric sulphate, siliciuretted hydrogen immediately precipitates silicide of copper (p. 265); from nitrate of silver it throws down grey metallic silver mixed with a black substance, probably silicide of silver; from chloride of palladium it throws down black-grey metallic palladium, free from silicon. It does not precipitate acetate of lead or chloride of platinum.

SILICON, IODIDES OF. The iodide of silicon, corresponding to the tetrachloride, has not been obtained: silicon does not unite directly with iodine.

Iodide of Silicon and Hydrogen, $Si^3H^4I^{10}$, is obtained, like the corresponding chlorine and bromine compounds (pp. 267, 268), by passing hydriodic acid gas over heated crystalline silicon, and collects at the colder end of the condensing-tube as a dark-red brittle mass, which fuses readily, and solidifies in the crystalline form on cooling. At a stronger heat it boils, and distils without decomposition. It fumes strongly in the air, assuming at first a bright vermillion colour, but ultimately becoming snow-white. In water it immediately becomes vermillion-coloured, but is only slowly decomposed. Sulphide of carbon dissolves it in large quantity, forming a blood-red solution, which, when concentrated in a retort, deposits the compound on cooling in dark-red crystals. Caustic soda-solution dissolves it, with evolution of hydrogen. (Wöhler and Buff, Ann. Ch. Pharm. civ. 99.)

SILICON, NITRIDE OF. (Deville and Wöhler, Ann. Ch. Pharm. civ. 256; cx. 248.)—Obtained by the action of ammonia on silicic chloride, and by exposing crystalline silicon to an intense heat in nitrogen gas or atmospheric air. Its composition has not been ascertained. It is a white amorphous mass, infusible and unalterable at the highest temperatures, and not oxidised even by ignition in contact with the air. It is not acted on by any acid except hydrofluoric acid, which dissolves it with formation of silicofluoride of ammonium. When strongly ignited in a stream of aqueous vapour and carbonic anhydride, it is decomposed, yielding carbonate of ammonium; it likewise decomposes slowly in moist air, as indicated by the odour of ammonia which it evolves. Aqueous alkalis do not act upon it, but when fused with hydrate of potassium, it forms silicate of potassium, with evolution of ammonia. When fused with carbonate of potassium, it yields silicate and cyanate of potassium; also cyanide, if the nitride of silicon is in excess. When heated with red oxide of lead, it reduces the lead with incandescence, and forms nitrous anhydride.

SILICON, OXIDES AND HYDRATES OF. The only known anhydrous oxide of silicon is the dioxide or silica, SiO^2, already described (p. 240). There is, however, a compound of silicon, hydrogen, and oxygen, $Si^3H^4O^5$, which may be supposed to contain the protoxide of silicon, SiO, and two others (p. 275), which may be formulated as hydrates of a tetrasilicic oxide—viz., $Si^4H^4O^8 = Si^4O.2H^2O$, and $Si^4H^8O^6 = Si^4O.4H^2O$.

a. Leucone, $Si^3H^4O^5 = 3SiO.2H^2O$. (Wöhler and Buff, Ann. Ch. Pharm. civ.

101.—Wöhler, *ibid.* cxxvii. 257.)—Produced by the action of water on the corresponding chlorine or bromine compound (pp. 267, 268), also by the action of water on chryseone (*infra*) under the influence of light. The best mode of preparing it is to heat crystalline silicon to redness in a stream of chlorine, and pass the resulting vapour of silicohydric chloride into water. It must be washed with ice-cold water, strongly pressed between filtering-paper, and dried over oil of vitriol. As thus obtained, it is a snow-white, bulky, amorphous substance, which floats on water, but sinks in ether; by the action of water on chryseone, it is obtained in laminæ having the form of the latter. It is permanent at ordinary temperatures, and may be heated to 300° without alteration; but when more strongly heated out of contact with air, it gives off hydrogen, sometimes mixed with siliciuretted hydrogen. When heated in the air, or in oxygen gas, it glows with a bright light, and leaves silica coloured brown by amorphous silicon, if the supply of oxygen is limited. It is slightly soluble in water, but the solution gradually decomposes, giving off hydrogen gas. Caustic alkalis, even ammonia, and alkaline carbonates, dissolve it, with rapid evolution of hydrogen and formation of alkaline silicates. When recently prepared, it acts as a powerful reducing agent, separating gold and palladium from the solutions of their chlorides, selenium and tellurium from selenious and tellurous acid, &c. In solution of silver-nitrate it immediately turns light-brown, and, on subsequent addition of ammonia, is converted into black silicate of silver.

β. *Chryseone*, $Si^4H^4O^3$ (?). *Silicone.** (Wöhler, Ann. Ch. Pharm. cxxvii. 257; Jahresb. 1863, p. 205.)—Produced by the action of strong hydrochloric acid on silicide of calcium (p. 265). The finely divided silicide is digested with fuming hydrochloric acid in a cooled vessel and in a dark place for several hours, till hydrogen is no longer evolved; the liquid is diluted with 6 or 8 volumes of water, and filtered; and the washed residue is dried over sulphuric acid in a vacuum, and in the dark. If the hydrochloric acid is not quite concentrated, the product is mixed with the following compound, γ.

Chryseone forms bright orange-coloured laminæ, which are pseudomorphs after the crystalline silicide of calcium. It is insoluble in water, alcohol, tetrachloride of silicon, trichloride of phosphorus, and sulphide of carbon. When heated it becomes transiently darker, and at a higher temperature burns with a slight detonation and with scintillation, leaving silica coloured brown by amorphous silicon. When heated in a close vessel, it gives off hydrogen, likewise leaving silica and silicon. If mixed with the compound γ, it detonates even when heated in a tube, and gives off spontaneously inflammable siliciuretted hydrogen. Heated to 100°, by itself or with water, it slowly gives off hydrogen and becomes paler; heated to 190° with water, in a sealed tube, it is quickly and completely converted into laminar silica, while the tube contains compressed hydrogen gas. In the dark it remains unaltered even when moist, in diffused daylight it becomes continually paler, and in direct sunshine, even under water, it is quickly converted into leucone, with evolution of hydrogen. It is not attacked by chlorine, fuming nitric acid, or strong sulphuric acid, even when heated. With hydrofluoric acid it becomes hot, turns white, and finally dissolves. By alkalis, even by very dilute ammonia, and more slowly by alkaline carbonates, it is converted, with rise of temperature and violent evolution of hydrogen, into silica. In presence of alkali it reduces the salts of several metals. In the solution of a copper or silver-salt it quickly turns black; in chloride of gold, brown; from chloride of palladium, osmic acid, and chloride of gold, on addition of alkali, it throws down black or violet-black powders, probably silicates containing lower oxides of those metals. From a solution of lead-oxide in soda-ley, it instantly precipitates the lead as a grey mass.

The results of the analysis of chryseone correspond partly with the formula $Si^4H^4O^3$, partly with $Si^6H^6O^4$. According to the first formula, its formation from silicide of calcium may be represented by the equation:

$$2CaSi^2 + 4HCl + 3H^2O = Si^4H^4O^3 + 3H^2 + 2CaCl^2.$$

γ. $Si^4H^8O^5$.—This compound, containing $2H^2O$ more than the preceding, is produced by the action of cold dilute hydrochloric acid on silicide of calcium. It forms colourless, transparent, nacreous laminæ, which, after washing and drying in a vacuum, take fire spontaneously in contact with the air, and burn with flame, leaving brown silica.

SILICON, SELENIDE OF. The selenide of silicon, analogous to silica, is not known. A silicohydric selenide, analogous to the oxygen-compound last described, is produced by treating silicide of calcium with a mixture of selenious and hydrochloric acids. It is a cinnabar-coloured substance, which smells of hydric selenide when dry, gives off hydrogen in contact with ammonia, and when heated by itself evolves hydric selenide and selenium, without explosion. (Wöhler.)

---

* *Silicone* is the name originally given to this compound by Wöhler, but it is objectionable in English on account of its similarity to silicon. The name *chryseone*, indicating the colour of the compound, was proposed by Dr. Miller.

SILICON, SULPHIDES OF. The disulphide, SiS^2, is produced by the action of carbonic disulphide on silica at high temperatures, or more easily by passing the vapour of carbonic disulphide over a heated mixture of silica and carbon, prepared by moulding a mixture of silica and lampblack with oil into balls and igniting them. The sulphide of silicon is deposited in the colder parts of the tube, in long, white, silky, flexible, asbestiform needles, which may be volatilised in a stream of gas. In contact with moist air, or when heated in aqueous vapour, it decomposes quickly into sulphydric acid and amorphous anhydrous silica, which remains in the form of the sulphide. In water it dissolves completely, with evolution of sulphydric acid, and the solution, left to evaporate in the air, deposits the silica as a transparent vitreous hydrate resembling opal. Alcohol and ether act upon sulphide of silicon even in the cold, forming sulphuretted organic compounds. It is not decomposed by heating in hydrogen gas. Nitric acid decomposes it, with separation of sulphur, and formation of sulphuric acid and silica. (Frémy, Ann. Ch. Phys. [3] xxxviii. 314.)

Silicohydric sulphide, $Si^4H^8O^3$, analogous to the oxygen-compound γ, is produced by the action of excess of aqueous sulphurous acid, mixed with a little hydrochloric acid, on silicide of calcium, and separates in reddish-brown laminæ, while the liquid, which is brownish at first, suddenly becomes milky from separated sulphur. When dried in a vacuum and freed from sulphur by sulphide of carbon, it forms a light-brown powder with a greenish tinge. It smells persistently of sulphydric acid, burns like gunpowder when heated in the air, and explodes violently when heated in a tube, with incandescence and evolution of sulphydric acid. When cautiously heated it gives off sulphydric acid, and the residue, which is no longer explosive, evolves more sulphydric acid in contact with water. With ammonia it rapidly gives off hydrogen, and is converted into a white mixture of silica and sulphur. (Wöhler.)

SILICON, SULPHOCHLORIDE OF. $Si^2S^4Cl^8$? (Pierre, Ann. Ch. Pharm. lxix. 73.)—Obtained by passing a mixture of silicic chloride vapour and perfectly dry sulphydric acid gas through a red-hot porcelain tube, collecting the product in a cooled U-tube, leaving the liquid to clarify, then distilling it, and collecting apart that which passes over between 90° and 100°. It is a colourless, transparent, mobile liquid, having a pungent odour, boiling at 100°, and distilling without residue. Specific gravity = 1·45. It is decomposed by water, yielding sulphydric and hydrochloric acids, silica, and free sulphur.

SILICON, TELLURIDES OF. A silicohydric telluride, analogous to the sulphur-compound above described, is produced by treating silicide of calcium with a dilute solution of tellurous acid in hydrochloric acid. It is a greyish-black powder, inodorous after drying. When heated it gives off hydrogen and tellurium, without explosion, and leaves a shining black residue, probably telluride of silicon, which when treated with ammonia or soda-ley, gives off hydrogen and forms a purple-red solution of alkaline telluride. (Wöhler.)

SILIQUA DULCIS, the so-called *St. John's-bread*, consists of the pods of *Ceratonia Siliqua* (L.), a tree indigenous in the South of Europe and the Levant. The kernels are enveloped in a sweet marrow-like substance, which has been analysed by Reinsch (Jahrb. pr. Pharm. v. 201) and Mercer (Pharm. J. Trans. 1857, p. 469), with the following results:—

	Reinsch.	Mercer.
Glucose	41·2	47·5
Albumin	20·8	3·2
Mucus	. .	4·7
Gum	10·4	
Pectin	7·2	
Tannin	2·0	
Fibrin	6·2 and starch	21·5
Water	12·0	21·0
Chlorophyll, Oil, Starch, and Ash	2·0	2·0

By fermenting the pods, Mercer obtained a quantity of brandy, amounting to one-fourth of their weight. Redtenbacher found butyric acid in the pods. Reinsch found, in 160 pts. of the kernels, 8 pts. starch, 2 sugar, 1·5 fatty oil, together with albumin, fibrin, wax, colouring matter, woody fibre, and other substances.

SILK. The fibrous substance in which the silkworm (the larva of *Phalæna Bombyx*

Mori) envelopes itself previous to passing into the chrysalis state. These insects possess a glandular apparatus called the *Sericterium*, serving for the secretion of a peculiar juice, which is discharged in fine threads, through two small apertures near the lower lip, and quickly solidifies in contact with the air. The solidified fibre consists of a thread of sericin or fibrin (i. 645; v. 235), coated with a yellowish waxy substance, the removal of which constitutes an important part of the process of silk-dyeing (i. 603; ii. 352.)

Silk may be distinguished from cotton and linen:—1. By its reaction with a concentrated *ammoniacal solution of nickel-oxide*, which dissolves it completely, forming a brownish-yellow solution, not precipitated by alkaline salts, sugar, or gum; acids, however, precipitate the silk completely in colourless flocks. Cotton, linen, and other forms of cellulose, on the contrary, are not altered even by several days' immersion in the nickel solution. Silk likewise dissolves in a concentrated ammoniacal solution of *cupric oxide*, and is but incompletely or not at all precipitated therefrom by alkali-salts, sugar, gum, or acids: cellulose, on the other hand, is completely precipitated from the same solution by these reagents (Schlossberger, Ann. Ch. Pharm. cvii. 21).—2. By immersing the fabric, for a few minutes, in a somewhat dilute solution of *picric acid* and then washing it carefully with water. Silk and other animal fibres are thereby turned yellow, whereas vegetable fibres remain white (Pohl, Wien, Akad. Ber. ix. 386). Strong *nitric acid* also turns animal fibres yellow, and does not produce that effect on vegetable fibres.—3. A solution of *stannic chloride* heated to 130°—150° turns linen and cotton black, but does not alter the colour of silk or wool. This test is of course applicable only to light-coloured fabrics (Maumené, Compt. rend. xxx. 447).—On the silk manufacture, see *Ure's Dictionary of Arts*, &c., iii. 654.

SILLIMANITE. A silicate of aluminium, $Al^2O^3.SiO^2$, identical in composition with cyanite and andalusite, occurring in veins in the gneiss of Saybrook, in Chester County, Connecticut, also at Fairfield, in New York. It forms triclinic crystals, usually indistinct, but cleaving perfectly parallel to the macrodiagonal; occurs also compact or loose, fibrous and columnar massive. It is brown, yellowish-grey, or colourless, with waxy lustre, vitreous on the cleavage-faces. Transparent to translucent on the edges only. Brittle. Hardness = 6—7. Specific gravity = 3·2—3·3. Infusible before the blowpipe. Insoluble in acids (Dana, ii. 265). For analyses see SILICATES (p. 255).

Bucholzite, from Chester County, Pennsylvania, and other localities in the United States, and *Fibrolite*, from the Carnatic, are fibrous varieties of sillimanite, of greyish, whitish, and pale-brown colour, with lustre approaching to adamantine.

SILVER. *Argent; Silber.* *Symbol*, Ag; *Atomic weight*, 108.

This metal is remarkable for its whiteness; hence its Greek name *ἄργυρος* from *ἄργος, white.* It is harder than gold and softer than copper. Its lustre, when polished, is nearly as great as that of steel. Its malleability is inferior only to that of gold among the heavy metals; it may be hammered into extremely thin sheet or *silver-leaf*, which is not more than $\frac{1}{100,000}$ of an inch thick. It is also highly ductile, and may be drawn into very fine wire, 400 feet of which weigh only one grain. By hammering and drawing, however, it readily becomes brittle, and requires to be more frequently annealed in working than gold does.

Silver has great tenacity, a wire two millimetres (0·0787 inch) in diameter being capable of supporting a load of nearly 85 kilogrammes (187 lbs.), that being the breaking weight. (See Baudrimont, Ann. Ch. Phys. [3] xxx. 304.)

The specific gravity of silver is 10·5, after being melted. (G. Rose.) Its density is increased to 10·57 by the coining process. The specific gravity of the finely divided metal, obtained by precipitation, is 10·62.

Silver crystallises in forms belonging to the regular system, generally in cubes, sometimes with faces of the octahedron.

The conductivity of silver for electricity and heat is greater than that of any other metal. (See ELECTRICITY, ii. 466; METALS iii. 936; and *ante*, p. 71). It decreases with the temperature. (See Wiedemann and Franz, Pogg. Ann. lxxxix. 497; Buff, Jahresb. 1847, p. 286; Becquerel, Ann. Ch. Phys. [3] xvii. 242; Langsdorff, Ann. Ch. Pharm. lxxxv. 155; Matthiesen, Pogg. Ann. ciii. 428; Benedict, Wien. Akad. Ber. xxv. 590; Jacobi, Petersb. Acad. Bull. xvii. 321; Arndtsen, Pogg. Ann. civ. 1; Clausius, *ibid*. p. 650). The specific heat of silver is 0·05701 (Regnault); 0·05507 (Dulong and Petit). The latent heat of fusion is 21·07 (Person, Ann. Ch. Phys. [3] xxiv. 265). Silver melts at a white heat; the temperature of fusion has been estimated at 1000° (Pouillet), 999° (Prinsep), and 1034° (Guyton Morveau). The melted metal gives off vapour to some extent at very high temperatures (Lampadius, J. pr. Chem. xvi. 204; Despretz, Comptes rend. lxviii. 362). The metal is volatilised more readily in the presence of arsenical and other vapours than when heated alone.

Silver does not combine with oxygen at the ordinary temperature, or, under ordinary circumstances, when heated in contact with atmospheric air. When the metal is melted upon ignited charcoal under a jet of oxygen, it burns with a conical flame, yellow below, purple at the middle, and blue above, while vapours of silver oxide are produced (Vauquelin). Silver is also oxidised under the influence of the electric spark; and when pulverulent, it is converted into peroxide by ozonised oxygen (Schönbein). When silver is melted in contact with alkaline or earthy silicates, it is oxidised to some extent and dissolved by the melted silicate. This is also the case when the finely divided metal is ignited with cupric oxide, or with arsenic or antimony: in the former case, cuprous oxide is formed; in the latter case, the silver-oxide combines with some arsenic or antimonic acid, and the more minutely the silver is divided the more readily does this oxidation take place. It is probable that silver is also oxidised to some extent in cupellation, and that the loss of silver experienced in that operation is mainly due to oxidation, the silver-oxide being in part volatilised, together with the lead fumes, and in part dissolved by the melted lead-oxide, and absorbed by the cupel.

Silver undergoes no change when heated in contact with melted alkaline nitrates or caustic alkalis, and for this reason silver crucibles are very useful in chemical operations with those substances which react with platinum under similar conditions.

When silver is kept melted for some time, at a high temperature, in contact with atmospheric air, it absorbs oxygen gas, and holds it in solution until just before the metal begins to solidify on cooling. The gas is then suddenly disengaged with effervescence, and particles of the metal are liable to be spirted or projected out of the crucible. The presence of a small amount of copper in the melted metal prevents the absorption of oxygen. Silver is capable of dissolving in this way 22 times its volume of oxygen.

Silver combines readily with *sulphur*, *selenium*, *phosphorus*, and *arsenic*. It decomposes *sulphuretted hydrogen* even at the ordinary temperature, and the surface of the metal becomes covered with a brown or black film of silver-sulphide. The discoloration of silver utensils and ornaments by exposure to the atmosphere generally consists in the formation of such a film of sulphide or, in some instances, of phosphide. Such stains may be removed by moistening the surface with a solution of alkaline cyanide and then washing well with water. When the discoloration is very considerable, it may be removed by immersing the metal in a boiling saturated solution of borax or strong caustic alkali, and placing a plate of zinc in contact with it for some time (Böttger, Dingl. polyt. Journ. cxliii. 464). When heat can be applied to the discoloured metal, the silver-sulphide may be decomposed by heating it to redness. The best mode of preventing such discoloration of silver articles when not in use, is to wrap them in paper coated with white lead.

Chlorine, *bromine*, and *iodine* combine with silver, even at the ordinary temperature. *Hydrochloric acid* in solution has but little action on metallic silver, unless it be heated to the boiling-point with the very finely divided metal; the gas is decomposed by silver at a red heat, silver-chloride being formed. Under similar conditions the vapours or other chlorides are decomposed by metallic silver. *Sodium-chloride* ignited with precipitated silver is decomposed, and the silver almost entirely converted into chloride; but when the metal is in large pieces, the formation of silver-chloride is merely superficial, unless the salt is melted, and, by the consequent solution of the chloride, a fresh surface becomes exposed. Silver kept melted under sodium-chloride, gradually decreases in weight, owing to the formation of silver-chloride, and in two or three hours the loss may amount to 2 or 3 per cent. (G. Rose). If alkaline carbonate be mixed with the sodium-chloride, this reaction is prevented. Aqueous solutions of alkaline chlorides gradually react with silver, producing silver-chloride, which dissolves in the form of a double chloride. Solutions of *cupric chloride* and other chlorides convert silver into chloride.

Dilute *sulphuric acid* does not react with silver, but strong sulphuric acid is decomposed when heated with it, yielding silver-sulphate and sulphurous acid gas. *Nitric acid* reacts with silver, even at the ordinary temperature, dissolving it and yielding silver nitrate and nitric oxide. It is the best solvent of silver.

The saline compounds of silver are mostly colourless, except when the electro-negative constituent they contain is coloured. Both the soluble and insoluble compounds of this metal are blackened by sunlight and decomposed, some silver being reduced. Most silver compounds are decomposed, with reduction of the metal, by the action of heat.

Occurrence.—Silver occurs both in the metallic state, and in combination, chiefly with sulphur, also with chlorine, other metals, &c. Ores of other metals frequently contain silver (Malaguti and Durocher, Compt. rend. xxix. 689; Ann. Min.

[4] xvii. 245). It has also been detected in sea-water. (Ann. Ch. Phys. [3] xxvii. 129.)

Native Silver is sometimes crystallised in cubes, octahedrons, and related forms; sometimes in laminated or filamentous masses, and sometimes very minutely disseminated throughout other minerals. It is very rarely pure, containing either gold, copper, or other metals.

Silver-sulphide occurs as silver-glance, sometimes crystallised, but more frequently massive. It has a dark lead-grey colour, and may be cut with a knife. Its specific gravity is 7·196. It contains 87 per cent. silver. Silver-sulphide also occurs in combination with various other metallic sulphides, constituting a great number of minerals, in which the amount of silver varies from 10 to upwards of 60 per cent.

Silver-chloride occurs as horn-silver, both massive and earthy; sometimes crystallised. It has a pearl-grey colour, sometimes passing into lavender; it is translucent, and very soft. Its specific gravity is 5·552.

Among the other silver-compounds which occur as minerals, the *iodide, bromide, selenide, telluride, antimonide, arsenide*, and *mercuride* are met with less abundantly.

Silver-ores occur almost exclusively in lodes traversing gneiss, mica-schist, grauwacke, clayslate, &c. They consist chiefly of metallic silver, silver-sulphide, and its various compounds (silver-chloride, arsenide, and antimonide), associated with lead and copper ores, blende, pyrites, spathic iron, brown hæmatite, earthy carbonates, heavy spar, quartz, &c.

Besides what may be properly called silver-ores, galena and the different varieties of grey copper-ore (*cuivre gris; fahlerz*), often contain such an amount of silver, that, from the greater value of this metal, they must be regarded as ores of silver as much as, or even more than, lead or copper. Such ores frequently contain, in the ton, from 2 to 10 ounces of silver, sometimes upwards of 100 ounces. Pyritic and earthy minerals also frequently contain a small amount of silver, sufficient to render its extraction profitable.

Preparation.—Pure silver is best obtained by decomposing the chloride, the insolubility of which admits of other metals being easily separated from it by washing with dilute acid and water. One of the most convenient methods is to cover the moist freshly precipitated chloride with dilute sulphuric or hydrochloric acid, and then to place upon it pieces of sheet zinc or iron, leaving the whole at rest until the silver is reduced to the metallic state. With zinc the reaction is represented by the equation:

$$2AgCl + Zn = ZnCl^2 + Ag.$$

When the reduction is complete, the spongy silver should be thoroughly washed with dilute acid and boiling water; then dried, and melted with sufficient alkaline carbonate to cover the surface of the metal, and prevent contact with atmospheric air. The chloride may be mixed with about 70 per cent. of chalk and 4 per cent. of carbon, and gradually heated to a sufficient temperature for melting the reduced metal.

PRODUCTION OF SILVER ON THE LARGE SCALE.

Although silver-compounds are generally decomposible without difficulty by heat, with reduction of the metal, the extraction of this metal from its ores is not by any means so simple a matter as might be expected. This is chiefly owing to the circumstance that argentiferous minerals, and even native silver itself, often occur minutely disseminated throughout a matrix of earthy minerals, or intimately mixed with compounds of other metals.

Very rich silver-ores, containing from 90 to 50 per cent. of silver, may be smelted in crucibles with lead or litharge, and proper fluxes for converting the earthy admixtures into slag. Ores containing 40 per cent. and less may be smelted with granulated lead, litharge, or lead-ores in a small blast-furnace, or in a reverberatory furnace with a concave hearth forming a kind of crucible. Metallic iron is sometimes added when the ore contains sulphides. This method is practised to some extent in California and Nevada.

Rich silver-ores are sometimes smelted by adding them in small successive portions to lead which is undergoing cupellation.

Poor argentiferous ores which do not contain any large amount of other easily reducible metals, are smelted with iron pyrites so as to obtain a matt, consisting chiefly of iron-sulphide with some copper- and lead-sulphides, and containing from 40 to 60 ounces of silver in the ton. Such ores often contain pyrites: if they contain too much they must be partially roasted, and earthy ores require pyrites to be added. The proportion of pyrites should be such that the matt produced may amount to from 30 to 50 per cent. of the ore. The following table gives the composition of several products of this kind:—

Composition of Argentiferous Matts.

Analyst	Plattner.	Conrad.				Fritzsche.
Iron	57·333	54·268	57·781	61·041	56·610	65·620
Lead	8·863	6·828	4·996	3·660	5·489	6·460
Copper. . . .	3·273	5·428	4·416	3·326	5·587	4·000
Zinc	1·381	3·633	2·618	0·667	4·774	3·000
Silver	0·151	0·086	0·086	0·065	0·200	0·117
Nickel	0·515	1·101	1·312	0·524	0·525	
Antimony . . .	0·194	0·274	. .	0·583	0·032	
Arsenic . . .	1·243	0·387	0·240			
Sulphur . . .	26·487	27·042	26·702	27·652	22·489	19·963
Silica	. .	. .	. .	. .	2·666	

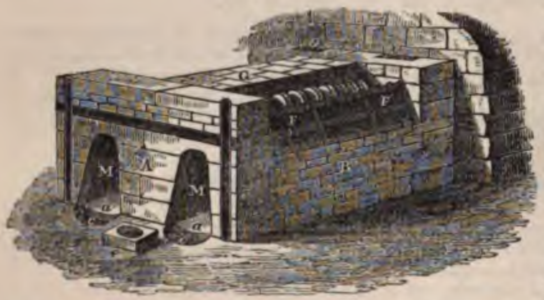
The silver is afterwards extracted from these matts by another operation.

Lead-ores containing silver are smelted in the usual manner (see Lead, iii. 481—526), and the silver is separated from the lead, either by cupellation, or by one of the other methods already described under the head of Lead.

Argentiferous copper-ores are also smelted in the same way as other copper-ores (see Copper, ii. 24—32), and the silver is extracted either from the matt or from the regulus by one of the methods described below.

Separation of Silver from Copper by Eliquation (*liquation; Saigerung*).—This method is based upon the fact that when argentiferous copper is melted with rather more than three times its weight of lead, the silver unites with the lead, and this alloy separates from the copper when the melted metal is gradually cooled. In practice the melted metal is cast into disc-shaped masses, about 2 feet diameter and 3 inches thick, in iron moulds so as to cool it rapidly. A number of these cakes are placed side by side on their edges in the eliquation-hearth (*aire de liquation; Saigerheerd*), *fig.* 744, which has two long cast-iron plates fixed above the open space M, and at a little distance apart. The cakes of metal are laid upon these plates, covered with iron plates (FF) and charcoal, and heated for some time to the melting point of lead. The alloy of lead and silver is thus melted, and gradually flows away through the opening between the plates from the copper, which requires a much higher temperature for melting, and remains behind as a porous mass. The argentiferous lead falls into a gutter (*a*) on the floor of the open space M, and collects in the well *c*. It is afterwards submitted to cupellation to separate the silver.

Fig. 744.



The amount of silver in the copper to be treated by this method must not be less than from 80 to 90 ounces per ton, nor more than 200 ounces per ton. A smaller amount of silver would not repay the cost of the operation, and a larger amount would be only partially separated from the copper. The proportion of lead should not be less than from 30 to 32 lbs. to the ounce of silver.

This method is very imperfect, since the copper always retains from 10 to 20 per cent. of silver, and a number of bye-products are formed containing lead, copper, and silver, which require further treatment.

Extraction of Silver by Amalgamation.

The extraction of silver from its ores and from argentiferous products of other metallurgical operations, is very frequently effected by a method based upon the easy solubility of silver in mercury. This method was invented in Mexico by Bartolomeo de Medina about the year 1557; and being specially suited to that country, by reason of its requiring very little fuel, it soon came into general use, and is now extensively practised, with various modifications and improvements, in all the silver-producing countries of the Western Continent.

The amalgamation of silver-ores differs from the amalgamation of gold-ores, which contain gold in the metallic state, in requiring a preliminary treatment of the ores for the purpose of bringing the silver they contain into such a condition that it can be dissolved by mercury. Silver-ores contain not only metallic silver, but silver-sulphide and other compounds which are not acted upon by mercury. Silver-chloride, however, is decomposed by mercury with formation of mercurous chloride:

$$\mathrm{AgCl + Hg = HgCl + Ag.}$$

Consequently the first step in the operation is to convert all the silver-compounds into chloride.

1. *Mexican method.*—In the treatment of silver-ores by this method, silver-chloride is produced in the wet way by the reaction of cupric and ferric or ferrous salts with silver-sulphide, in the presence of sodium-chloride in excess. The precise nature of the reactions which take place is not well understood. When silver-sulphide is digested with solution of cupric or ferric chloride, no reaction takes place; but when it is mixed with cupric sulphate or ferrous sulphate and sodium-chloride in the moist state, some silver-chloride is formed after a time (Karsten). A solution of cupric chloride with excess of sodium-chloride, digested with silver-sulphide for some days at the ordinary temperature, is gradually decolorised, and the products of the reaction are cupric sulphide with silver-chloride and cuprous chloride, which are partly dissolved by the excess of sodium-chloride. Sulphur is also said to be separated (Boussingault). In this case the reaction is probably as follows:

$$\overset{648}{\mathrm{3Ag^2S}} + \overset{256\,''}{\mathrm{4CuCl^2}} = \overset{648}{\mathrm{6AgCl}} + \overset{128}{\mathrm{2CuCl}} + \overset{128\,''}{\mathrm{2CuS}} + \overset{32}{\mathrm{S}}.$$

The cuprous chloride produced would, in the presence of sodium-chloride, be capable of converting a further quantity of silver-sulphide into chloride as follows, being itself converted into cuprous sulphide:

$$\overset{216}{\mathrm{Ag^2S}} + \overset{128}{\mathrm{2CuCl}} = \overset{216}{\mathrm{2AgCl}} + \overset{128}{\mathrm{Cu^2S}}.$$

The production of cuprous chloride may also be determined by the presence of metallic silver in the ore by the following reaction:

$$\overset{''}{\mathrm{Cu}}\mathrm{Cl^2 + Ag = AgCl + CuCl.}$$

Heat facilitates the production of chloride, and the silver-sulphide is more readily converted into chloride when it is combined with antimonial sulphide.

In order to submit the ores to this preliminary treatment, they are ground very fine with water in a mill resembling a porcelain mill. The sludgy mass is laid out on a paved floor in heaps called *torta* or *montone*, upon which from 1 to 5 per cent. of common salt is sprinkled, and the whole well stirred together either with shovels or by treading under the feet of mules. Some days afterwards it is mixed with from 0·5 to 1 per cent. of *magistral*, consisting essentially of cupric and ferrous or ferric sulphates, and prepared by roasting cuprous pyrites. Sometimes roasted iron-pyrites is used, but a magistral containing copper is preferred. At this stage of the process chemical action takes place; part of the sodium-chloride, reacting with the sulphates of the magistral, yields sodium-sulphate, with cupric and ferric or ferrous chlorides, which give rise to the formation of silver-chloride as above described.

The decomposition of the silver-chloride is effected by means of mercury. The quantity employed for this purpose and for the actual amalgamation of the silver generally amounts to about six times the weight of the silver in the ore. It is added in three equal portions at intervals of 15 or 20 days, and is thoroughly incorporated with the mass of ore. The day after the first portion of mercury has been added, the mass is tested by washing a portion of it with water, to ascertain from the appearance of the amalgam whether the process is going on properly. It is essential to the success of the operation that there should not be any cupric chloride remaining when the mercury is added to the heap, because the reaction which would take place between it and the mercury, resulting in production of mercurous chloride, would unnecessarily augment the waste of mercury. If the mercury appears very grey and much subdivided, too much magistral has been used, and consequently the mass contains a large amount of mercurous chloride: in that case chalk is added. If, on the contrary, the mercury is very brilliant and liquid, there is not enough magistral, and more has to be added. When the mercury separated in the test presents a slightly grey dull appearance, and runs together rapidly when separated into globules, the process is going on well.

About fifteen days after the first portion of mercury has been added, it will have combined with enough silver to form a pasty amalgam; then a further quantity is added, and after another interval of rest, the third portion is added. This operation lasts altogether two or three months, according to the nature of the ore, the temperature, &c. If the amalgam is pasty at the end of the operation, a further quantity of mercury is added to liquefy it, and the whole mass is washed with water in large wooden vats fitted with paddles on vertical shafts. The amalgam thus separated is pressed in sacks to strain off excess of mercury, and then distilled.

At some places this method of treatment is practised without the use of magistral, and merely with salt and mercury. In those instances it is probable that the ores contain sufficient sulphides for the production of cupric or ferrous sulphates by the action of atmospheric oxygen during the mechanical preparation of the ore.

The ores worked in this way in South America and Mexico are generally sorted, so as to contain from 20 to 40 ounces of silver to the ton, the richer parts being picked out and smelted.

The consumption of mercury in decomposing silver-chloride, and the waste attending the several operations, are said to amount, in the Mexican method, to about twice the weight of the silver obtained. It has been proposed to recover the mercury left in the washed residue as mercurous chloride by treating it with hypochlorite of calcium or nitrate of sodium, and then adding excess of hydrochloric acid so as to convert the mercurous chloride into mercuric chloride, which could be washed out, and the mercury precipitated by copper, while the solution of cupric chloride thus obtained would serve in the place of magistral for subsequent working.

Since the decomposition of silver-chloride may be effected in the wet way by contact with other metals besides mercury, the consumption of mercury in that way might be prevented. With this object De Lecca proposed, in 1586, to modify the treatment by using iron plates together with the mercury, but this suggestion was little regarded at the time.

For the amalgamation of rich ores, **Alonso Barba** devised a method with the same object, which consisted in grinding the ores in copper pans with successive additions of salt, magistral, and mercury. The silver-chloride being in this case decomposed by copper, less mercury was requisite; but the extraction of the silver was incomplete.

2. *European Amalgamation.*—The method of extracting silver from its ores by means of mercury was made known in Europe about the middle of the seventeenth century, and Barba's modification of it was the starting-point from which it came to be adopted. The first attempts to work silver-ores by amalgamation were made in the Austrian States by v. **Born**, and after successive improvements, works were also erected at Freiberg, Neusohl, and other places on the Continent, where it was extensively practised.

The principal points of difference from the Mexican method are:—1. The conversion of the silver-compounds in the ore into chloride by treatment in the dry way by roasting with salt; 2. The decomposition of the silver-chloride by copper or iron instead of mercury.

The silver ores which are treated by amalgamation in Saxony contain silver-sulphide combined or mixed with arsenical and antimonial sulphides, pyrites, blende, &c. Both rich and poor ores can be worked by this method with equal advantage; but since the proportion of salt and mercury to be used would depend upon the amount of silver in the ores, and since this varies from 20 to 500 ounces per ton, the ore is sorted, so that the mass to be operated upon may contain from 60 to 70 ounces of silver per ton, and a uniform mode of treatment may be adopted.

It is necessary that the ore should contain sulphides in sufficient amount to produce the requisite chemical reactions during the roasting, and to ascertain whether this is the case, a portion is melted with glass, borax, and resin in an assay-crucible under a cover of sodium-chloride. It should yield about 30 per cent. of matt. When there is a deficiency of sulphides, iron-pyrites or ferrous sulphate is to be mixed with the ore.

In the preparatory treatment, the finely-ground ore is roasted with 10 or 12 per cent. of common salt in a reverberatory furnace. The charge is put into the furnace moist, gently heated at first, and stirred continually until it is dry, so as to prevent its caking; it is then raked up into a heap along the hearth, and after the lumps have been broken, it is spread out evenly, and stirred about while the heat is being increased to redness. This stage of the operation (*Anfeuern*) generally occupies about two hours. Meanwhile steam and some vapours of arsenic and antimony are given off. As the temperature rises to redness, the sulphides begin to be decomposed by reacting with atmospheric oxygen, and then the combustion of the sulphur generates so much heat that no fresh fuel is required to keep up the temperature during this stage of the process (*Abschwefeln*), which also lasts about two hours. The disengagement of sulphurous acid, together with arsenic and antimonial vapours, causes the mass to become pulverulent and porous, and when it ceases the temperature begins to fall. The heat is then raised considerably, for the purpose of decomposing the sulphates which have been produced. A fresh evolution of sulphurous acid together with chloride-vapours then begins, causing the mass to swell up. During this stage of the process (*Gutrösten*) the sulphates react with part of the sodium-chloride, yielding sodium-sulphate, ferric chloride, &c., while some hydrochloric acid and chlorine are disengaged, and the silver is converted into chloride. Care must be taken not to continue this part of the operation too long, since the silver-chloride might be melted or decomposed, and thus the efficiency of the subsequent operations would be interfered with, and the yield of silver consequently reduced. After about an hour, the charge is drawn from the hearth. It then contains, besides various oxides and the earthy ingredients of the ore, silver-chloride, cupric and ferric chlorides and sulphates, sodium-chloride and sodium-sulphate, and some unaltered sulphides.

During the roasting, the charge loses about 10 per cent. by weight, and some silver is carried away in the vapour given off, for which reason the smoke is passed through soot-chambers and condensers. The flue-dust thus deposited contains unaltered particles of ore, with carbon, various saline substances, and about 30 or 40 ounces of silver per ton. This silver is often in the state of antimoniate, a salt which is always produced when argentiferous and antimonial minerals are roasted together (Plattner). The formation of this salt causes a further loss of silver, from the fact that it is not convertible into chloride by means of chlorine, but only by hydrochloric acid.

The roasted ore is screened and sifted from the lumps, which are ground and roasted again with salt. The fine powder is ground in a mill, and passed through a bolting-cloth to reduce it to an extremely fine state of division. This mechanical treatment is of great importance for the perfect separation of the silver by treatment with mercury.

The decomposition of the silver-chloride (*Anquicken*) is generally effected by stirring the roasted ore with water and iron or copper in strong wooden casks mounted horizontally in a framework, and made to revolve by machinery:

$$\overset{216}{2AgCl} + \overset{56}{Fe} = Fe''Cl^2 + Ag; \text{ or } \overset{108}{AgCl} + \overset{64}{Cu} = CuCl + Ag.$$

This reaction is greatly facilitated by the presence of an acid, and when two metals act simultaneously, it takes place more rapidly than when only one is present. In this case the more electro-positive metal is converted into chlorine by the reduction of the silver. Thus when copper and mercury are used together, mercurous chloride only is produced. With iron and mercury, on the contrary, only ferrous chloride is produced, together with silver-amalgam.

The stirring with metallic iron or copper has also the effect of converting ferric chloride into ferrous chloride. Cupric chloride is decomposed in the same way, and unnecessary production of mercurous chloride is thus prevented.

The quantity of iron consumed in this process is more than equivalent to the silver-chloride decomposed, and amounts to about 60 per cent. of the silver obtained: the excess being partly due to the solvent action of salts in the roasted ore, and partly to the precipitation of other metals besides silver.

When copper is used instead of iron, a much purer amalgam is obtained; but copper acts more slowly, and even when used in large proportion, it is not so effective as iron in extracting the silver.

The decomposition of silver-chloride by either iron or copper is also much facilitated by the presence of alkaline chlorides, especially when the solution is strong. This is most probably owing to the solubility of silver-chloride in such solutions, and to the consequently increased chemical action. This silver-chloride is reduced more rapidly by mercury, in the presence of a concentrated solution of alkaline chloride, than it is by either iron or zinc alone.

After this operation has been completed, and the silver has been reduced to the metallic state, a quantity of mercury, equal to about half the weight of the roasted ore, is put into each cask, and the stirring is continued again for about twenty hours. During this operation the contents of the cask are examined from time to time, to ascertain whether the proper quantity of water has been added, and to test the condition of the charge.

The casks are next filled with water and made to revolve slowly for about two hours, after which time the greater part of the amalgam will have separated from the sludgy mass and collected together, so that it can be drawn from the casks. It is filtered through canvas bags to separate excess of mercury, and distilled in iron retorts.

The pressed amalgam contains about 85 per cent. of mercury, and from 10 to 12 per cent. silver, with varying amounts of copper, lead, antimony, &c. The strained mercury contains about one ounce of silver in the hundredweight.

The sludgy mass (*tailings*) remaining in the amalgamating casks still contains disseminated particles of amalgam and mercury. It is run into a wash-tun (*agitator, Waschbottige, cuve*), mixed with a large quantity of water and stirred with paddles. The amalgam which collects at the bottom of the agitator is much more impure than that taken direct from the casks. The lighter portion of the tailings is run off from side-openings at different levels of the agitator, and the heavier portion is again treated with mercury in the casks, or dried, ignited, and used in the smelting-works. It sometimes contains 140 ounces of silver per ton. The finer portion of the tailings also contains some silver, from 2 to 5 ounces per ton.

The mother-liquor from the tailings contains sodium-chloride and sulphate, with other salts, such as ferrous and manganous sulphates, small quantities of phosphates, arsenates, and fluorides, &c. It is concentrated in leaden pans, or frozen in winter to obtain the sodium-sulphate.

The loss of silver and mercury in this operation is subject to great variation; the former amounts to about 5 or 10 per cent. of the quantity contained in the ore. Of this from 2 to 4 per cent. is either volatilised in the roasting, or lost in the grinding and sifting of the ore, and in melting the metal. From 3 to 5 per cent. of the silver generally remains in the tailings. A small portion of the mercury is converted into mercurous chloride, which is not decomposible by iron. Much more remains mechanically disseminated among the tailings, and is washed away in the mother-liquor. The presence of lead, arsenic, and other metals, which are easily reduced and amalgamated, augments considerably the waste of mercury. At Freiberg it amounts to about fifteen ounces per ton of ore, and 87 per cent. of that is washed away in the mother-liquors, or remains in the tailings.

The advantages of the amalgamation method over smelting, consist in the smaller loss of silver, the greater simplicity of the operations, the more rapid extraction of the metal, saving in fuel, and the absence of injurious vapours. On the other hand, it is not applicable to ores containing lead or copper. Although lead amalgamates very readily when in the metallic state, still in the treatment of ores containing lead, only a small part of this metal is amalgamated. This is probably because very little of the lead is reduced, the greater part remaining in the state of chloride or sulphate, which are not decomposed unless there is a very large excess of iron in the amalgamating casks. Copper is partly taken up by the mercury, and part remains in the tailings. If these are not sufficiently rich to be worked, that portion of the copper is lost. Consequently, ores containing more than 7 per cent of lead or 1 per cent. of copper are not treated by the amalgamation method.

Auriferous silver-ores likewise cannot be advantageously worked by this method, because the greater part of the gold remains in the tailings after amalgamation, and is lost. Comparative trials have shown that silver obtained from such ores by smelting, contained more than twice as much gold as that obtained by amalgamation. The reason of this is, that though gold amalgamates very readily with mercury, still in the treatment of silver-ores by this method, it is less rapidly acted upon than the silver, which is reduced from the silver-chloride in a finely-divided spongy state, favourable to its amalgamation.

The nature of the earthy ingredients of the ore has also some influence on the working: thus clay renders the mass tenacious in the amalgamation; heavy spar makes it dense; calcareous substances reduce the consumption of iron and of mercury by decomposing the chlorides, but they also lessen the yield of silver. In this respect a judicious admixture of quartzose and calcareous ores is most advantageous.

The method of amalgamation is applied not only to silver-ores but also to the matt (*Kupferstein*) and the coarse copper (*Schwartzkupfer*) obtained in smelting argentiferous copper-ores. (See COPPER, ii. 31.)

In the Mansfield district, silver was formerly extracted in this way from copper-matt, after it had been roasted with salt to convert the silver into chloride. The tailings were afterwards smelted with quartz, fluor-spar, and slag to obtain the copper.

At Schmöllnitz, in Hungary, black copper, containing from 85 to 89 per cent of copper, and 200 or 300 ounces of silver per ton, is worked by amalgamation. The metal is reduced to powder by stamping while red-hot and then grinding. It is mixed with from 7 to 9 per cent. of salt, and roasted in a reverberatory furnace. The amount of sulphur in the metal, being no more than from 0·5 to 1 per cent., would be insufficient in this case to determine evolution of chlorine by its oxidation to sulphuric acid; consequently the production of silver-chloride in the roasting must be effected chiefly by the reaction of sodium-chloride with the metal.

The silver-chloride is decomposed by means of copper, and the amalgamation otherwise conducted as already described (p. 282). If iron were used instead of copper to decompose the chloride, the metal obtained would contain a large amount of copper.

The loss of silver is said to be less than 5 per cent., and the waste of copper about 2 per cent. The waste of mercury, however, amounts to 40 ounces per ton of coarse copper.

At Cziklowa, in the Bannat, coarse copper containing 16 ounces of silver per ton is roasted with 10 per cent. of salt and 3 or 4 per cent. of pyrites.

At Offenbanya, in Transylvania, coarse copper containing 10 per cent of lead is roasted for six hours with 18 per cent. of salt and 3 per cent. of nitre, to facilitate the production of lead-sulphate, which is not decomposed in the amalgamation.

The compound of arsenic and antimony with nickel, cobalt, iron, and other metals, which is termed *speis*, produced in lead-smelting, and especially in the preparation of smalt from nickeliferous cobalt-ores, often contains silver which is extracted by amalgamation.

The speis from the Saxon smaltworks at Schneeberg contains from 10 to 100 ounces of silver per ton. It also contains bismuth and sulphur. The powdered material is roasted to oxidise the metals: part of the arsenic is volatilised as arsenious acid; a great part, however, remains in the state of arsenic acid combined with the basic oxides. The roasted product is sifted, to separate any melted or unoxidised particles, then ground fine, mixed with 8 per cent. of salt and 2 per cent. of ferrous sulphate, and again roasted to convert the silver into chloride. More arsenious acid is volatilised, and probably some arsenic as chloride. The product of this roasting is ground very fine, and treated with mercury in casks.

The amalgam requires to be well washed with water to remove bismuth-oxide. The tailings contain 5 ounces of silver per ton, and are smelted for nickel. The total loss of silver is said to be about 15 per cent.; the waste of mercury amounts to 10 or 15 ounces per ton.

At Poullaouen, in Brittany, some of the ores from the Huelgoet mines, consisting of metallic silver, antimonial silver, and silver-chloride disseminated through quartz, ochre, and clay, are treated in a manner which combines both the Mexican and European methods. After the mechanical preparation of the ore, containing about 20 ounces of silver per ton, it is mixed with water and 10 per cent. of magistral, consisting chiefly of sodium-chloride, with some ferrous sulphate, alum, and a very small amount of cupric sulphate. This mixture is left for about 15 days in tubs, to allow of the production of silver-chloride, and the subsequent treatment conducted as already described.

The extraction of silver is effected to within 3 ounces to the ton.

The waste of mercury amounts to from 10 to 80 ounces per ton of ore.

The amalgamation method is now largely practised in California and Nevada in working silver-ores, and great improvements have been made in connection with it. Iron pans with mullers, for grinding the ore either in the raw or roasted state, have been substituted for the barrels with great advantage. By this means the silver or silver-compounds of the ore are more effectively brought in contact with the chemicals and mercury, and the amalgamation is much facilitated. The application of heat by steam-pipes has also been found very advantageous.

One of the most troublesome circumstances connected with the extraction of silver by amalgamation is the conversion of the mercury into a pulverulent condition, known as "flouring," when it is liable to be washed away in the tailings, together with silver it has combined with. Considerable loss may be caused in this way; and as this effect is due to the combination of sulphur, oxygen, &c. with a portion of the mercury, it has been proposed to introduce a small amount of sodium into the mercury used for amalgamation. From the great chemical affinity of this metal for sulphur and oxygen, it prevents the mercury from becoming "floured," and materially reduces the waste of this metal and the loss of silver. An amalgam containing about 30 per cent. of sodium is used for the purpose, and added to the mercury so as to make the proportion of sodium about 1 or 2 per cent. The presence of sodium in the mercury also appears to facilitate very considerably the amalgamation of the silver. (See Crooke's Specifications, Nos. 391 and 2229, dated 11th February and 30th August, 1865.)

The use of caustic alkali for the same purpose has also been tried and found advantageous, though probably in a less degree than the sodium-amalgam.

Extraction of Silver as Chloride and Sulphate.

The solubility of silver-chloride in a strong solution of sodium-chloride has been taken advantage of for the purpose of extracting silver from copper matts and ores without the aid of mercury. The silver is converted into chloride by roasting with salt, and the roasted product is digested with a concentrated solution of salt in wooden vats. The silver-solution is drawn off and passed through a series of vats containing precipitated copper, which separates the silver, while a solution of copper is produced, from which the copper is recovered in a state fit to be used again, by passing through another series of vats containing iron. The liquor from which the copper has been precipitated, is left for some time exposed to the air, till a great part of the iron has been deposited as a basic ferric salt; it then contains some sodium-sulphate produced in the roasting, and is either evaporated to obtain that salt, or treated with calcium-chloride to furnish sodium-chloride for future use. (Augustin.)

A still more simple and inexpensive method of extracting silver is based upon the facts that silver-sulphate is soluble in water, and that it requires a higher temperature for decomposition than any of the other soluble sulphates containing heavy metals which are produced during the roasting of copper-matt or of silver-ores with pyrites. The success of this method of treatment depends mainly on the proper roasting of the material from which silver has to be extracted, so that the whole of the silver may be obtained in the state of sulphate, while the cupric and ferrous or ferric sulphates are decomposed. In the roasting the heat is to be gradually raised during the space of three or four hours to dull redness, and lastly increased within about two hours to cherry-red. The progress of the roasting is ascertained from time to time by testing a portion of the charge with water. It should give a faintly bluish solution, and the amount of silver rendered soluble may be estimated volumetrically with a salt-solution of known value. When the proper condition has been reached, the charge is drawn from the furnace and digested with water, and the silver is precipitated from the solution by copper. (Ziervogel.)

The average loss of silver by this method is said to be only 8 per cent.

The use of alkaline hyposulphite has been proposed as a solvent for silver-chloride in the working of ores, &c., the silver being precipitated from the solution as silver-sulphide by means of alkaline sulphide, while a solution of hyposulphite is reproduced. (Percy.)

In the case of very poor argentiferous materials, such as the residue from the burning of pyrites in the manufacture of sulphuric acid, it has been proposed to volatilise the silver as chloride, and collect it in condensers.

When the silver obtained by this method is very impure, it is sometimes purified by cupellation with lead. Attempts have been made to separate the metals with which the silver is alloyed, by digesting with dilute sulphuric acid in leaden pans, the residue left by distillation after it has been heated to redness in contact with atmospheric air. By repeating this treatment several times, a large portion of the foreign metals are separated, but the purification is incomplete and the cost is considerable. More frequently the silver is refined by melting in cast-iron crucibles. By this means the foreign metals are oxidised and form a slag, which floats on the surface of the melted silver and is skimmed off. Some charcoal-powder is then sprinkled on the metal, the crucible covered, and the heat kept up for a time, the metal being stirred in the meanwhile with an iron rod. When the charcoal is consumed, this operation is repeated until the metal exhibits the required degree of purity. It is then cast into ingots. This refined metal ought not to contain less than 70 per cent. silver, and the alloy should consist entirely of copper.

The refuse of the refining is melted with potash and some nitre under sodium-chloride, and a silver regulus is obtained, together with a rich matt, which is mixed with the ore for amalgamation, and a slag which is sent to the smelting-works. B. H. P.

SILVER ALLOYS. For most of the useful purposes to which silver is applied, the pure metal would be too soft to resist sufficiently the wearing-away of the surface by friction. The presence of a small amount of copper in the metal very considerably increases its hardness, without much affecting the colour, and consequently silver is generally used in the state of an alloy with copper.

Silver may be alloyed with most other metals. None of the alloys are so soft and ductile as pure silver, though generally more so than the metal with which it is alloyed. The presence of small quantities of other metals—such as antimony, arsenic, bismuth, tin, and zinc—renders silver brittle and liable to crack when rolled, but to a less extent than is the case with gold or even with copper.

1. With Aluminium.—The alloys of these metals are much harder than pure aluminium, and when the aluminium amounts to twice as much as the silver, they are even more fusible than aluminium, and may therefore be used for soldering that metal. The alloy containing 3 per cent. of silver is not acted upon by sulphuretted hydrogen: that containing 5 per cent. of silver has a fine white colour, takes a good polish, has about the same degree of hardness as British standard-silver, and is tolerably malleable. Equal parts of aluminium and silver give a brittle alloy.

2. With Antimony.—A very small proportion of antimony alloyed with silver is sufficient to render the metal liable to crack in rolling. Alloys of silver and antimony occur as minerals.

3. With Bismuth.—Equal parts of silver and bismuth form a crystalline brittle alloy, of 10·709 specific gravity. Bismuth-oxide being fusible, this metal can be separated from silver by cupellation in the same way as lead.

4. With Copper.—Silver and copper may be melted together in any proportion. The alloys are almost as ductile as silver; and they have much greater hardness and elasticity, and are capable of taking a much higher polish than pure silver. Those containing less than half their weight of silver are white.

The most important alloys of silver and copper are those employed for coinage, and for the manufacture of silver utensils and ornaments, &c. The standard value of the alloy used for these purposes varies in different countries. In England "*standard silver*" contains 7·5 per cent. copper: its specific gravity is 10·20.

In France there are three standard alloys: one, containing 95 per cent. of silver, for medals and plate; the second, containing 90 per cent., for coin; and the third, containing 80 per cent., for jewelry-work.

In Germany and Austria there are two standards for coin, of different values—one containing 90 per cent., the other 87·5 per cent. silver. The alloy used for silver-plate varies from 70 to 81 per cent.

Silver-solder contains about 66 per cent. silver with zinc and copper.

When alloys of silver and copper solidify gradually, they do not remain homogeneous throughout. According to the amount of silver they contain, the inner or outer portions of the mass contain a larger proportion of silver than the remainder. Levol states that this separation does not take place with the alloy consisting of 71·9 per cent. silver and 28·1 copper. (Ann. Ch. Phys. [3] xxxvi. 220.)

Although the alloys of silver with copper are white, even when containing a large amount of copper, still the colour is not so fine as that of pure silver. Such alloys, after being manufactured, are therefore submitted to an operation by which the copper is superficially oxidised, and dissolved out, so as to leave a film of pure silver. This is termed *whitening* (*blanchiment; Ansieden*).

5. With Gold. This metal may be alloyed with silver in all proportions. Levol regards the alloys of these metals in equivalent proportions as being incapable of separating by gradual cooling. (Ann. Ch. Phys. [3] xxxix. 163.)

Alloys of gold and silver in various proportions occur native. (G. Rose, Pogg. Ann. xxiii. 161.—Awdejew, *ibid.* liii. 153.—Boussingault, Ann. Ch. Phys. [2] xxxiv. 408; xlv. 440.—*Gmelin's Handbook*, vi. 247.)

6. With Lead.—Silver may be melted with lead in all proportions. These alloys when slowly cooled, separate, so that the interior of the mass contains a much larger proportion of silver than the outside. (Levol, Ann. Ch. Phys. [3] xxxix. 163.)

7. With Mercury.—This metal combines with silver at the ordinary temperature, forming one of the soft alloys called amalgams, which mixes with an excess of mercury, but may be separated as a pasty mass by squeezing in wash-leather. Silver-amalgam occurs native, sometimes crystallised (iii. 889).

8. With Nickel.—The alloy containing 13·4 per cent. of nickel, is greyish-white, and takes a good polish. It is highly magnetic. The alloy used for coin in Switzerland contains 10 per cent. of nickel. It is very hard, and not so white as the alloys commonly used for coin.

9. With Platinum.—Alloys of silver with platinum are much less ductile than pure silver. The alloy containing 64·3 per cent. platinum, has a colour intermediate between those of the two metals. It cannot be rolled without cracking. Silver containing only 0·07 of platinum is very brittle, and cannot be cupelled; even as little as 0·05 greatly impedes the cupellation. Sulphuric acid dissolves the silver from these alloys. Nitric acid dissolves part or all of the platinum as well as the silver, according to the proportion of the two metals.

10. With Tin.—Alloys of this metal with silver are nearly as white as pure silver. They are brittle and generally hard, that containing 20 per cent. of tin being about as hard as bronze.

11. With Zinc.—These alloys are of a bluish-white colour. Döppler's reflector metal consists of 80 pts. silver and 20 pts. zinc.

SILVER ASSAY. The estimation of the amount of silver in coin, alloys, ores, &c., for practical purposes. This operation may be conducted either in the wet way, by precipitating the silver as chloride from the solution of a known weight of the substance to be assayed (see SILVER, DETECTION AND ESTIMATION OF, p. 298), or in the dry way by cupellation with lead, so as to obtain the pure silver.

In operating upon ores containing metallic silver and oxidised silver-compounds, they are mixed with eight or ten times as much litharge, and twice as much black flux, and melted in earthen crucibles. The lead reduced by the carbon of the black flux dissolves the silver, and collects as a button at the bottom of the crucible, while the remainder of the litharge and the alkaline carbonate combine with the silicious and earthy ingredients of the ore, forming a slag.

Ores containing sulphur or arsenic may be melted with litharge alone in sufficient proportion to oxidise those substances, and the lead reduced at the same time will be sufficient to dissolve the silver. If the amount of sulphide should be very large in proportion to the silver, it is better to separate some of the sulphur by roasting the ore, or to oxidise it by melting it with nitre before the treatment with litharge.

Argentiferous galena may be assayed by melting it with one-and-a-half times its weight of black flux, and about one-fourth its weight of small iron nails, to obtain a button of metal. Or it may be melted with three or four-tenths of its weight of nitre, which oxidises the sulphur, forming potassium-sulphate, while the lead and silver are reduced. The addition of sodium-carbonate or litharge as a flux is often necessary and convenient in moderating the reaction between the nitre and sulphides.

The button of metal obtained by any of these operations consists of an alloy of silver and lead. The separation of these metals is effected by *cupellation* (*coupellation; Abtreiben*). This operation is founded on the fact that when such an alloy is melted and exposed to a current of atmospheric air, the lead is oxidised, while the silver remains unaltered. The separation of the lead is facilitated by melting the alloy upon a *cupel* (*coupelle; Capelle*), made of bone-earth powder compressed so as to be sufficiently porous to absorb about its own weight of melted lead-oxide, which is thus removed from the metal as the oxidation advances, until at last there remains only the pure silver.

In the assay of argentiferous copper-ores, the first step is to obtain a button containing the entire quantity of both metals. For this purpose ores which do not contain sulphur, arsenic, or antimony, but consist chiefly of oxygen-compounds of copper with earthy admixtures, may be melted at once with black flux sufficient to reduce the metal, and with a flux to convert the earthy ingredients into liquid slag. Borax or litharge may be used as the flux, care being taken to avoid, in the one case, loss by intumescence, and, in the other, the reduction of much lead in proportion to the silver and copper.

Argentiferous copper-ores containing sulphides must be first roasted by gradually heating the powdered ore in a shallow capsule, until sulphurous acid is no longer given off. Great care must be taken at first to prevent any partial fusion of the ore, and, when arsenic is present, it must be very slowly volatilised—otherwise the vapour may carry away some silver. After the ore is fully oxidised, the heat is to be raised sufficiently to decompose the sulphates produced. The roasted ore may then be melted with three or four times its weight of black flux. The button of copper and silver thus obtained is cupelled with lead, to separate the copper from the silver, and the silver is weighed.

1. *Silver Assay in the dry way: Cupellation.*—The assay of alloys of silver and copper by cupellation is of considerable practical importance. When such alloys are melted in contact with atmospheric air, the copper is oxidised, as in the case of an alloy of silver and lead: but the copper-oxide being infusible at the temperature, it cannot be absorbed by the cupel, and its separation requires a solvent. For this reason lead is added in the cupellation of silver alloys containing copper: it serves a twofold purpose—facilitating the fusion of the alloy by acting the part of a solvent to it at a temperature much below the melting-point of either silver or copper, while the oxide it yields during the cupellation melts, and dissolves the copper-oxide produced at the same time.

Karsten's Table (p. 289).

Lead.	Copper.	Copper remaining after Cupellation.	Absorbed as Oxides by the Cupel.	
			Lead.	Copper.
100	100	78·75	5·00	1
200	100	70·12	7·10	1
300	100	60·12	7·70	1
400	100	49·40	7·90	1
500	100	38·75	8·10	1
600	100	26·25	8·15	1
700	100	19·75	8·00	1
800	100	8·75	8·70	1
900	100	5·62	9·50	1
1000	100	1·25	10·10	1
1050	100	0·	10·50	1

The amount of copper capable of being dissolved in this way by lead-oxide, so as to be absorbed by the cupel, varies according to the temperature. The relative proportions of copper and lead absorbed as oxides by the cupel also vary, even at the same temperature, according to the proportion of these metals in the alloy. Karsten, by cupelling copper with different proportions of lead at one and the same temperature, obtained the results given in the preceding table.

Besides these total differences, the proportion of copper-oxide dissolved when an alloy of lead with excess of copper is cupelled, varies throughout the operation. At the commencement it amounts to only 0·13 of the lead-oxide, and at the end to 0·36, or more than a third. When the proportion of lead to copper is too small, the melted oxides are not sufficiently liquid, at the temperature proper for cupellation, to be readily absorbed by the cupel. In this case the oxide accumulates above the metal, and eventually stops the oxidation. The assay is then said to be *chilled* (*noyé; ersaufen*). Therefore, in order to separate the whole of the copper from an alloy of silver with this metal, it is necessary to use enough lead. The complete separation would always be effected with any alloy by using the maximum proportion of lead, or as much as would be necessary with pure copper. But, since this operation is always attended with a loss of silver, which increases in proportion to the time it lasts, and to the amount of metal oxidised, it is indispensable to render this loss as small as possible. For that reason only so much lead is to be used as may be actually necessary, according to the amount of copper in the alloy to be assayed.

The proportion of lead requisite for effecting the separation of copper from silver by cupellation is to some extent influenced by the amount of silver in the alloy. Experience has shown that, in cupellation, copper is less readily oxidised when it is alloyed with silver than when pure; and that, consequently, a larger proportion of lead must be used, relatively to the copper, the greater the amount of silver in the alloy.

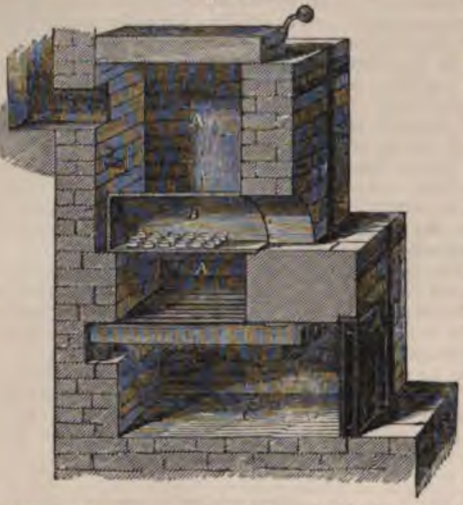
Composition of Alloy.		Quantity of Lead for 1 part of Alloy.	Ratio.	
Silver.	Copper.		Lead.	Copper.
1000		0·3		
	50	3	60	1
900	100	7	70	1
800	200	10	50	1
700	300	12	40	1
600	400	14	35	1
500	500		32	1
400	600	16—17	27	1
300	700		23	1
200	800		20	1
100	900		18	1
	1000		16	1

It is remarkable that when the copper amounts to more than one-half of the alloy, the same proportion of lead is necessary for all alloys, whatever may be the amount of copper they contain. Even when pure silver is melted on a cupel, a little lead must be added to make the metal form a button; if less than three-tenths its weight of lead is used, the button is not properly formed, and the lead is not separated unless the heat be raised considerably, which causes great loss of silver. When, on the contrary, more than that proportion of lead is used, the cupellation takes place readily, but the loss of silver is greater, because the operation lasts longer.

The furnace in which cupellation-assays are made is represented in *fig.* 745. The most important part of it is the *muffle*, B. This is a semicylindrical vessel made of clay, and closed at one end. It is fixed in the furnace in such a manner that it can be entirely surrounded with the burning fuel when the furnace is in use. At the sides of the muffle there are longitudinal openings, through which a draught is produced by the chimney; and when the door of the muffle is opened, a current of atmospheric air is thus made to pass through the muffle over the cupels.

In using this furnace, it should be kept entirely filled with fuel which will burn without smoke; and when the temperature has been raised to the proper degree, it can easily be regulated according to requirement. When the cupels have become hot, and the sides of the muffle are at a bright red heat, verging upon white, the necessary quantity of lead is first placed in the several cupels; and when it is melted, the weighed quantities of the alloys to be assayed, wrapped in thin paper, are quickly but gently slipped into the melted lead, great care being taken to prevent any portion of the contents of the cupels being thrown out.

Fig. 745.



After the cupels are charged, the muffle is closed for a few seconds, that the pieces of alloy may melt and dissolve in the lead. At the moment the door is removed, the contents of each cupel should present the appearance of bright liquid metal with a convex surface.

As soon as air is admitted into the muffle, oxidation commences; white fumes of lead-oxide are given off; and the bright surface of the metal becomes covered with a thin iridescent film of melted oxide, presenting brilliant spots, which move rapidly about over it. As the oxidation advances, the melted oxide is absorbed by the cupel, producing round the metal a dark patch, which gradually extends, while the metal decreases in bulk and becomes more globular. At the end of the process, when the last portion of oxide is being formed, the metal appears to be revolving rapidly, and its surface becomes very bright and iridescent; then the motion suddenly ceases, and the iridescence disappears with a kind of flash, during which the button is scarcely perceptible; after a few seconds it presents the appearance of pure silver. This last stage of the process is called the *brightening* (*éclair; Blicken*).

Owing to the fact that melted silver absorbs oxygen gas, it is necessary to remove the cupels containing the buttons of silver very gradually from the muffle, in order that they may cool slowly and not *spit* (*rocher; spratzen*), since this might occasion some loss.

When this operation has been well performed, the button of silver should separate easily from the cupel; its upper surface should be bright and smooth; the under-surface, dull and crystalline, but clean and compact. When the button is bluish above and bright underneath, without adhering at all to the cupel, it contains lead. When the upper surface of the button is flattened, dull, and wrinkled, it has either spit, or too little lead has been used and the oxidation has not been complete.

The temperature at which cupellation is conducted has a great influence on the result. Since silver is sensibly volatilisable, it is on this account essential that the temperature should not be too high. On the other hand, the heat must be sufficient to complete the oxidation of the copper and lead, and to render the oxides perfectly liquid and capable of being absorbed by the cupel. From the greater length of time occupied by the process at a low temperature, the loss of silver by volatilisation might be as great as if it took place more rapidly at an excessive heat. Experience has shown that the heat is too great when the cupels are nearly white hot and scarcely distinguishable from the metal they contain, and when the fumes appear slight and rise quickly to the crown of the muffle. In this case the oxide would be too liquid, and would carry with it into the cupels some minute particles of silver. On the contrary, the heat is too low when the fumes appear dense, creeping along the sole of the muffle, and when the oxide, being insufficiently liquid to be absorbed, collects in a ridge round the metal. In this case the loss of silver is less; but the oxidation is incomplete, and the button is likely to contain some lead. These two sources of error always obtain simultaneously, and they compensate each other more or less according to the temperature at which the operation is conducted. The best results are obtained when the cupels are only red-hot, and when the melted metal is distinctly visible and much more luminous than the cupel.

The rapidity of the current of air passing through the muffle also influences the result. Too quick a current might cause the formation of oxide more rapidly than the cupel could absorb it, or, by lowering the temperature, it might render the oxide insufficiently liquid to be absorbed by the cupel; and in either case the process would be interfered with in the same manner as if the proportion of lead to copper were too small. With too slow a current of air, the process would go on very slowly, and there would be a loss of silver in consequence of the operation lasting too long.

The most oxidisable of the various metals which may be present in an alloy are chiefly separated during the first stage of the cupellation, and towards the end, the lead-oxide formed may be almost pure, or contain only cupric oxide. Iron, tin, and zinc are oxidised with such rapidity, that alloys containing any large amount of these metals cannot be cupelled without the assay becoming chilled, or incrusted in the cupel.

The appearance of the cupels after the operation affords some indication of the kind of metal alloyed with the silver. Lead gives the cupel a pale-yellow colour; bismuth gives a slightly orange-yellow; copper gives a grey, dirty red, or brown colour, according to the quantity. Iron produces black scoriæ, which collect at the commencement of the oxidation about the edge of the cupel. Tin gives grey scoriæ, and causes incrustation when present in large amount. Zinc produces a very luminous flame, and leaves a yellowish ridge on the cupel; its presence causes loss of silver, by augmenting the volatilisation, or by spitting. Antimony gives a yellow scoria, and makes the cupel crack when present in any large amount.

When the buttons of silver have solidified, they are detached from the cupels with pliers, brushed to clean off fragments of bone-earth or oxide adhering to the underside, and then weighed. The results thus obtained give the amount of silver in the alloy too low, because there is always a loss of silver in cupellation, which in the case of ordinary alloys may amount to as much as 0·005. In the cupellation of alloys containing a large amount of silver, this loss is proportionately less than in the cupellation of alloys containing but a small amount of silver. Consequently it is necessary to apply a correction to the actual results of the assays, according to the value of the alloy in silver, as shown in the following table:—

Actual amount of Silver.	Amount found by Cupellation.	Correction for loss of Silver.	Actual amount of Silver.	Amount found by Cupellation.	Correction for loss of Silver.
1000	998·97	1·03	500	495·32	4·68
975	973·24	1·76	475	470·50	4·50
950	947·50	2·50	450	445·69	4·31
925	921·75	3·25	425	420·87	4·13
900	896·00	4·00	400	396·05	3·95
875	870·93	4·07	375	371·39	3·61
850	845·85	4·13	350	346·73	3·27
825	820·78	4·22	325	322·06	2·94
800	795·70	4·30	300	297·40	2·60
775	770·59	4·41	275	272·42	2·58
750	745·48	4·52	250	247·44	2·56
725	720·36	4·64	225	222·45	2·55
700	695·25	4·75	200	197·47	2·55
675	670·27	4·73	175	173·88	2·12
650	645·29	4·71	150	148·30	1·70
625	620·30	4·70	125	123·71	1·29
600	595·32	4·68	100	99·12	·88
575	570·32	4·68	75	74·34	·66
550	545·32	4·68	50	49·56	·44
525	520·32	4·68	25	24·78	·22

This loss of silver, however, is not constant even for the same alloys, but varies according to the mode in which the operation is conducted. For the sake of greater certainty, therefore, a *proof* assay with pure silver, or with an alloy of known value, should be made with each batch of assays, in order to ascertain whether the loss of silver be really the same as that indicated in the table for that alloy or for pure silver. The correction to be applied to the results of the assays made at the same time is then to be regulated according to the result obtained with the proof-assay. When the operation is conducted with proper care, the corrected results may indicate the amount of silver in the alloys to within 2 or 3 pts. in a thousand.

In many instances, cupellation is a very convenient method of estimating, approximately, the amount of silver in alloys and ores, but when great accuracy is required it is better to employ the wet method of assay devised by Gay-Lussac.

2. *Silver Assay by the wet process.*—This method of estimating silver consists in precipitating the metal as chloride from the solution of a known weight of the alloy, and in using for that purpose a solution of common salt containing a known amount of salt. By weighing or measuring the quantity of this solution which is just sufficient

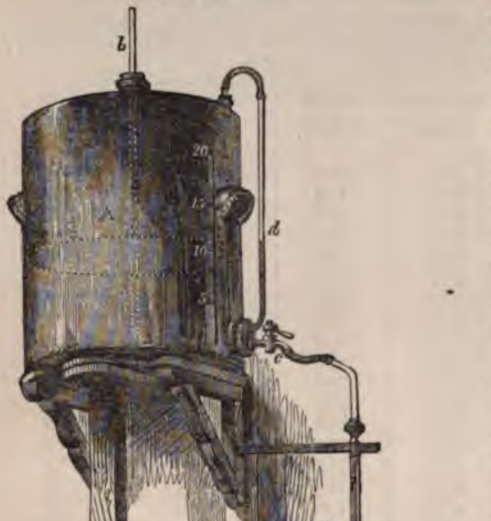
to convert the whole of the silver into chloride, it is easy to ascertain the amount of silver in the alloy. Silver-chloride separates so readily from a liquid containing nitric acid in excess, that the exact point at which all the silver is precipitated may be observed with great precision, and much more accurate results may be obtained in this way than by cupellation.

The *normal solution* is made of such a strength that 1000 grain-measures are equivalent to 10 grains of silver, or 100 cubic centimetres equivalent to 1 gramme. In many instances the normal solution may be used in the same way as any other volumetric reagent, by simply observing the volume required for perfect precipitation, and then multiplying the quantity of silver represented by 1 grain-measure or by 1 cubic centimetre by the number of grain-measures or centimetres of solution used. The amount of silver in ores and other substances may often be conveniently estimated in this way.

For the purpose of attaining a greater degree of accuracy in the results, another solution, containing only one-tenth as much salt as the normal solution, may be used for completing the precipitation. For greater convenience, in shaking the liquid to facilitate the separation of the silver-chloride, the silver-solution should be contained in a stoppered bottle.

In the valuation of alloys containing a tolerably constant and approximatively known amount of silver, such as silver coin and the bars of alloy prepared for coining, it is far preferable to take a quantity of the alloy which will contain rather more than 10 grains, or 1 gramme of silver, and to add to the solution of it in nitric acid 1000 grain-measures or 100 cubic centimetres of the normal solution at once. There will then remain only so much silver in solution as there have been in excess of 10 grains or 1 gramme. The precipitation of this portion of the silver, which should not amount to more than 2 or 3 thousandth parts, is to be effected with the decimal solution.

Fig. 746.



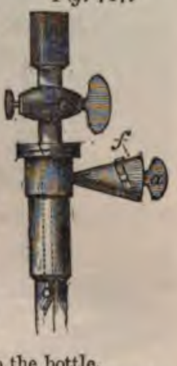
The apparatus requisite for this operation, when a large number of assays have to be made, is shown by *fig.* 746. A is the reservoir for holding a large supply of the normal solution, which can be drawn off as required by the stopcock *c*. The tube *b*, open at both ends, passes to the bottom of the reservoir, and is tightly fitted into the neck with a cork, so that there cannot be any loss by evaporation, and air can enter the reservoir only through the tube *b*.

The gauge *d* shows the quantity of solution in the reservoir.

The pipette *g*, for measuring the normal solution, has a long narrow neck and a very small aperture at the lower end, which can be closed with the finger. It is supported on a wooden frame firmly fixed to the wall, and the upper end is fitted with a collar having a conical valve (*f*) at the side. Above this collar, and forming one piece with it, is an ordinary stopcock *e*, the tube of which extends downwards through the collar into the neck of the pipette, as shown on a larger scale in *fig.* 747. To the upper side of the stopcock *e* is fitted a glass tube containing a thermometer, and communicating with the stopcock *c*.

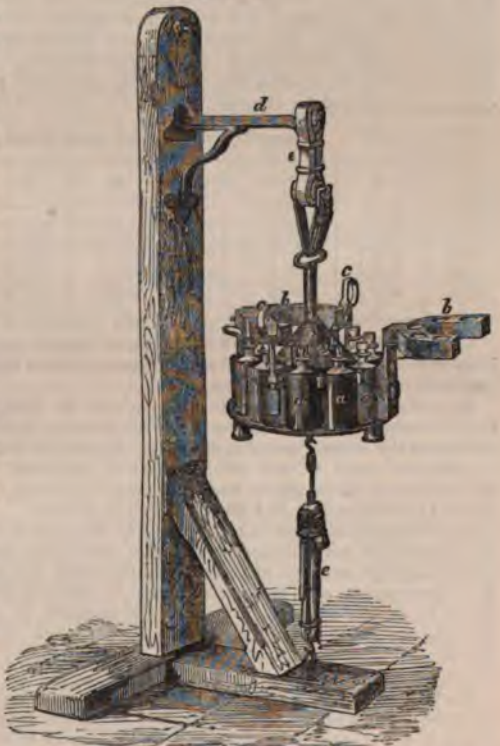
When the left forefinger is placed on the beak of the pipette, and the cocks *c* and *e* are opened, the solution cannot flow into the pipette unless the valve *f* is opened to allow the air to escape from the pipette. As soon as the pipette is filled to a little above the mark *n* on its neck, indicating the requisite volume, the cock *e* is closed; then the valve *f* is closed, and the finger removed from the beak of the pipette.

Fig. 747.



The bottle containing the solution from which silver is to be precipitated is put into the holder *h*, which is fitted to a metal plate bearing also a receptacle *i* for waste solution, and a support for a piece of sponge *k*. This metal plate slides freely between grooves from *l* to *m*, in such a way that the sponge or the mouth of the bottle containing the silver-solution may be brought exactly under the beak of the pipette. To run off from the pipette the excess of solution, the receptacle *i* is placed below the beak, and the valve *f* is cautiously opened just enough to let the level of the solution sink to the mark on the neck of the pipette. Then the valve is closed and the slide moved, so that the sponge is brought against the beak of the pipette, to wipe off the drop of solution hanging to it. As soon as that is done, the slide is moved back till the mouth of the bottle is under the beak of the pipette, and by opening the valve *f* the measured solution is allowed to fall into the bottle.

Fig. 748.



These assays are generally made in series of ten, the bottles and stoppers belonging to them being numbered and placed in a stand, which can be immersed in hot water to facilitate the solution of the alloy in nitric acid. After the metal has completely dissolved, the bottles are allowed to cool, and the nitrous vapour is displaced by blowing into the bottles through a piece of bent tube. The proper quantity of normal solution is then measured into each bottle from the pipette; the stoppers are put into the bottles; and they are transferred to an agitator (*fig.* 748), which holds ten bottles, and is suspended between two vulcanised caoutchouc springs, so that the whole of the bottles may be shaken at once.

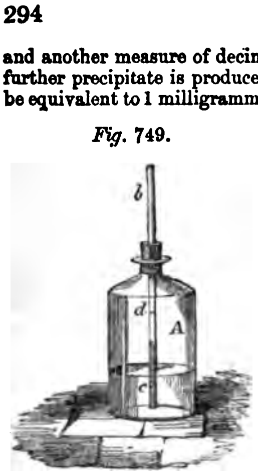
After shaking the bottles for a minute or two, they are taken out and ranged upon a black shelf, with ten compartments numbered to correspond with the bottles. When the liquid in each is clear, the stoppers are taken out and hung upon wires attached to each compartment, and a cubic centimetre of the decimal solution is run into each bottle by means of a small tubular pipette, which is fitted through a cork into the bottle, A (*fig.* 749), containing the decimal solution. In adding the decimal solution it should be allowed to flow gently down the side of the bottle, after placing the beak of the pipette, *b*, against the neck of the bottle. By this means the silver-chloride in the bottle is not disturbed, and if the liquid contains silver it is at once rendered turbid.

For each of the bottles in which a precipitate is produced by the measure of decimal solution, a mark is made on its compartment of the shelf; the bottles are again shaken, and another measure of decimal solution added—this operation being repeated until no further precipitate is produced. Supposing each cubic centimetre of decimal solution to be equivalent to 1 milligramme of silver, and 100 cubic centimetres of the normal solution to precipitate exactly 1 gramme of silver, the quantity of silver would be found by adding to 1000, the number of cubic centimetres of decimal solution requisite to complete the precipitation. If, for instance, a certain quantity of alloy (q) requires, over and above the 100 cubic centimetres of normal solution, 5 cubic centimetres of decimal solution, then the quantity (x) of silver would be 1·005 grm. The percentage (x') of silver in the alloy may then be found by a simple calculation:

$$x' : 1000 = x : q$$

And when, as in the assay of alloys that are supposed to be tolerably uniform in value, q is a constant quantity containing as a minimum 1 grm. of silver, a table may be constructed which will indicate the silver value of the alloys in thousandths, by reference to numbers corresponding with the number of cubic centimetres of decimal solution used in each instance.

Fig. 749.



The quantity (q) of alloy containing 1 grm. of silver will of course vary according to the silver value of the alloy, and the tables will relate only to particular alloys. In this country the standard of silver coin is 925 parts of silver in 1000 parts of alloy, and consequently 1·081 grm. should contain 1 grm. of silver. The quantity of alloy taken for the assay is 1·085 grm., which at the exact standard would contain 1·003625 grm. of silver, and would then require 3·5 cubic centimetres of decimal solution to complete the precipitation, and less or more according as the amount of silver in the alloy were below or above the standard. The following table expresses the value of the alloy, according to quantity of decimal solution used, within the limits of variation allowed for standard-silver:

Quantity of Alloy for Assay 1·085 *gramme.*

	0	1	2	3	4	5	6	
0	921·6	922·6	923·5	924·4	925·3	926·2	927·2	0
0·25	921·9	922·8	923·7	924·6	925·6	926·5	927·4	0·25
0·50	922·1	923·0	923·9	924·9	925·8	926·7	927·6	0·50
0·75	922·3	923·6	924·2	925·1	926·0	926·9	927·9	0·75

The numbers in the first and last columns express fractions of thousandths, which it is quite possible to estimate, after some practice, from the density of the last precipitate produced by the decimal solution.

Supposing, as in the example above given, the quantity of decimal solution used were 5 measures, then the silver value of the alloy in thousandths would be found at the top of the column under 5, or 926·2. If the fifth measure of decimal solution gave a precipitate equal to only ·0005 instead of ·001 grm. silver, then the silver value of the alloy would be rather less, and it would be found in the third line of the column under 4, corresponding to 4·50 or 925·8 thousandths.

If the amount of silver in any one of the alloys is so much below the standard that the measure of normal solution is rather more than sufficient to precipitate all the silver, the first measure of decimal solution will not of course give any precipitate. It is customary in such cases to add two or three measures of a solution of silver, which is exactly equivalent, measure for measure, to the decimal solution of salt; marking the number on the board with a *minus* sign before it, and then adding decimal salt solution. A better plan is to repeat the assay with a rather larger quantity of alloy.

Since it is difficult, by reason of evaporation and change of temperature, to ensure the constant equivalence of the measure of normal solution to the quantity of silver which it is prepared to precipitate, it is best never to attempt doing so, and accurate results may be obtained with greater certainty otherwise. For this purpose the exact value of the measure of normal solution is estimated from time to time with each set of assays by means of pure silver, of which 1·001 grm. is dissolved and treated with a measure of normal solution as a *proof* assay.

If a measure of the normal solution should happen to be exactly equivalent to 1 grm. of silver, then the first measure of decimal solution will produce a precipitate in this proof-assay, but the second measure will not produce any. If, however, a second and third measure of decimal solution be required to complete the precipitation in the proof-assay with the 1·001 grm. pure silver, then the measure of normal solution at the time will be only equivalent to 1·001 – ·003 = ·998 grm. silver, and a corresponding *minus* correction must be applied to all the other assays. Thus, for instance, in the case of one which requires 5 measures of decimal solution to complete precipitation, only 3 measures would relate to the quantity of silver over and above 1 grm. The actual quantity of silver would be 1·003 grm., and the silver value of the alloy, in thousandths, 924·4. If, on the contrary, the first measure of decimal solution gave only a very slight precipitate in the proof-assay, equal to ·00025, then the measure of normal solution would be equivalent to 1·0075 grm. of silver, and a *plus* correction of 0·75 would have to be applied to the results of the assays, before reading off the silver values of the alloys from the table, as already described.

With the exception of mercury, other metals do not interfere with the accuracy of the result obtainable by this method.

The approximate estimation of the silver value of the alloy, which is necessary in this method of assay, may be made by cupellation, or with a salt solution and burette in the usual way. B. H. P.

SILVER, BISMUTHIC. See Bismuth-Silver (i. 597).

SILVER, BLACK. }
SILVER, BRITTLE SULPHIDE OF. } See Stephanite.

SILVER, BROMIDES OF. The protobromide or argentic bromide, AgBr, occurs native as *bromargyrite*, *bromyrite*, or *bromic silver*, in the district of Plateros, and at the mine of San Onofre in Mexico; also with chloride of silver at Chañareillo in Chile, and at Huelgoet in Bretagne. It is usually found in small concretions, rarely in cubo-octahedrons. Hardness = 1—2. Specific gravity = 5·8—6. It is sectile, has a bright yellow or greenish colour, and splendent lustre. The Mexican mineral contains 57·56 per cent. silver (Berthier); the Chilian 57·43 per cent. (Field); calc. 57·45 silver and 42·55 bromine.

Argentic bromide is formed artificially by precipitating nitrate of silver with bromide of potassium. The precipitate is yellowish-white, curdy, insoluble in water and in acids, soluble in ammonia, but much less so than the chloride: according to Pohl (Wien. Akad. Ber. xli. 627), 100 pts. of aqueous ammonia, of specific gravity 0·986, dissolve 0·051 pts. of silver-bromide at 80°. It dissolves in concentrated aqueous bromide of potassium and in other alkaline bromides; also in hyposulphite of sodium, but not so readily as the chloride, and is precipitated from the solution by bromide of potassium.

Argentic bromide melts below a red heat. It is coloured greyish-violet on exposure to light, but not so strongly as the chloride. According to H. Vogel (Jahresb. 1861, p. 284), the product consists of argentous bromide, Ag^2Br. The reduction is retarded by free nitric acid, but greatly accelerated by nitrate of silver, the argentous bromide being then mixed with metallic silver, resulting from reduction of the nitrate itself. Argentic bromide is not decomposed by acids, but chlorine converts it into chloride of silver, with evolution of bromine.

The hemibromide, or argentous bromide, is produced, as above mentioned, by the action of light on argentic bromide; also by treating the corresponding oxide, Ag^4O, with hydrobromic acid. (H. Vogel.)

SILVER, CARBIDES OF. The compound Ag^4C is said by Gay-Lussac to be formed when silver is fused in a crucible in contact with lampblack. Other compounds of silver and carbon are obtained as residues in the ignition of organic silver-salts, viz. Ag^2C as a yellow residue from cuminate of silver (Gerhardt and Cahours, Ann. Ch. Phys. [3] l. 76); also as a dull white fused metallic mass, by intense ignition of silver-cyanide (Liebig and Redtenbacher, Ann. Ch. Pharm. xxxviii. 129). According to Thaulow, however (Berz. Jahresb. xxxiii. 81, 228), this last product consists of paracyanide of silver (iv. 342). The compound AgC remains as a grey powder when aqueous pyroracemate of silver is heated for some time in the water-bath. The residue left in the dry distillation of the same salt appears to be a mixture of Ag^2C and AgC (Berzelius, Pogg. Ann. xxxvi. 28). According to Regnault (Ann. Ch. Pharm. xix. 153), the monocarbide AgC is likewise obtained by heating maleate of silver.

The carbides of silver are dissolved by nitric acid, with separation of carbon, and leave metallic silver when subjected to prolonged ignition in contact with the air.

SILVER, CHLORIDES OF. Silver forms two chlorides analogous to the bromides. The protochloride or argentic chloride, AgCl, occurs native as *horn-silver* or *kerargyrite*, sometimes in cubes, octahedrons, regular dodecahedrons, and other monometric forms, but more frequently in waxy masses, sometimes columnar; no cleavage. Hardness = 1—1·5. Specific gravity = 5·31—5·43 (**Domeyko**). It has a pearl-grey, greenish, or whitish colour, turning brown on exposure, and a resinous lustre passing into adamantine. Streak shining. Translucent in various degrees. Fracture somewhat conchoidal, sectile. Klaproth found, in specimens from various localities, 73·6 to 76 per cent. silver: the formula requires 75·25 per cent. Horn-silver occurs in veins of clay-slate, accompanying other ores of silver; also with several copper ores, calcspar, heavy spar, &c. It is most abundant in Peru, Chile, and Mexico; it was formerly obtained in the Saxon mining district, but is now rare; it also occurs in Siberia, at Kongsberg in Norway, in Alsace, in Cornwall, and at Huelgoet in Bretagne. At Andreasberg, in the Hartz, an earthy variety is met with called *buttermilk ore*, which, according to Klaproth, contains 24·64 per cent. silver, 8·28 hydrochloric acid, and 67·08 alumina.

Argentic chloride is thrown down as a white precipitate, at first very bulky and curdy, when hydrochloric acid or a soluble chloride is added to any soluble salt of silver except the hyposulphite: also, together with argentic hypochlorite, by passing chlorine gas into a solution of argentic nitrate. (**Naquet**, Jahresber. 1860, p. 201.)

Precipitated argentic chloride has a specific gravity of 5·7 (**F. Mohr**, Pogg. Ann. cxiii. 655). It is wholly insoluble in *water*, so that the minutest quantity of a soluble chloride in aqueous solution may be detected by adding to it a drop of solution of silver-nitrate. The precipitate is likewise quite insoluble in *nitric acid*, even on boiling, also in dilute *hydrochloric acid*. Strong hydrochloric acid, however, dissolves it, and the solution, when left to evaporate, deposits the argentic chloride in octahedrons. The chloride dissolves easily in *ammonia*, and crystallises therefrom as the ammonia evaporates. According to **Pohl** (Wien. Akad. Ber. xli. 627), 100 pts. of aqueous ammonia of specific gravity 0·986, dissolve 1·492 pts. argentic chloride at 80°. Argentic chloride dissolves in strong solutions of *alkaline chlorides*, forming crystallisable double salts, which are decomposed by water, the silver-chloride being then precipitated. It dissolves easily also in *sodic hyposulphite*, and is not precipitated therefrom by chloride of potassium; but bromide or iodide of potassium added to the solution, throws down bromide or iodide of silver (**Field**. Zeitschr. Ch. Pharm. 1861, p. 126). The chloride is likewise converted into iodide or bromide of silver by digestion with solution of bromide or iodide of potassium, and on this reaction Field has founded a method of determining the proportions of chlorine, bromine, and iodine when they occur together in a mixture (see BROMINE, ESTIMATION OF. i. 678). *Cyanide of potassium* dissolves chloride of silver, forming chloride of potassium and argento-potassic cyanide. *Soluble sulphites* also dissolve argentic chloride.

Argentic chloride melts at about 260°, forming a transparent yellowish liquid, which, on cooling, solidifies to a horny, translucent, sectile mass. It is not decomposed by heating with charcoal, but is easily reduced by heating in a current of hydrogen, hydrochloric acid being evolved, and metallic silver separated; also by ignition with *alkaline carbonates*, an alkaline chloride being then formed, and a mixture of oxygen and carbonic anhydride evolved: *e.g.*—

$$4AgCl + 2Na^2CO^3 = 4NaCl + 2CO^2 + O^2 + 2Ag^2$$

Zinc, iron, and other easily oxidisable metals, in contact with water, quickly reduce precipitated argentic chloride to the metallic state, still more quickly if the water is acidulated with sulphuric acid. Even the fused chloride laid upon a plate of zinc or iron, and covered with acidulated water, is converted after a few days into a spongy mass of metallic silver. Weak alkaline leys do not act upon argentic chloride, but when it is boiled with a strong solution of *potash*, chloride of potassium is formed, and dense black silver-oxide is produced; the addition of *glucose* to the mixture quickly reduces the oxide to the metallic state. A similar reduction takes place when the chloride is boiled with glucose and aqueous carbonate of sodium; and this process is recommended by **Böttger** (Compt. rend. xl. 969) for obtaining pure silver from the chloride, instead of the reduction by zinc above mentioned, inasmuch as, if the zinc contains lead, which is frequently the case, that metal, being insoluble in dilute sulphuric acid, will remain mixed with the silver. **Brunner** (J. pr. Chem. xci. 254) adds chloride of silver dissolved in ammonia, by drops or in a fine stream, to a clear boiling solution of 1 pt. glucose and 3 pts. crystallised sodic carbonate in 40 pts. water, keeping up the boiling without intermission. **C. A. Müller** (Jahresber. 1864, p. 283) effects the reduction:—*a*. By boiling 6 pts. silver-chloride for half an hour with 9 pts. soda-ley, of 1·333 specific gravity, 1½ pts. clarified honey, and 8 pts. water. *b*. By digesting 6 pts. silver-chloride in the cold with 9 pts. soda-ley, 4½ pts. honey, [illegible] ammonia (specific gravity 0·925); or *c*. By digesting 5 or 6 pts.

silver-chloride at 25° for a month with 60 pts. ammonia and 9 pts. honey. (See also H. Vogel, J. pr Chem. lxxxvi. 321; Jahresb. 1862, p. 223.)

Argentic chloride quickly acquires a dark greyish-violet colour when exposed to light, the change being due to a partial or, according to some authorities, a total separation of the chlorine. The most probable view, first propounded by Wetzlar (*Gmelin's Handbook*, vi. 161), is that the reduction is only partial, resulting in the formation of a subchloride of silver. According to H. Vogel (Pogg. Ann. cxix. 497; Jahresb. 1861, p. 285), the dark-coloured compound is the hemichloride, Ag^2Cl, and is exactly similar to the product obtained by treating argentous oxide, Ag^4O, with hydrochloric acid. The reduction is retarded by strong sulphuric or nitric acid, and by ferrous salts (which absorb the chemical rays), and completely arrested by fuming sulphuric acid or mercuric chloride. In a solution of argentic nitrate, on the contrary, it takes place more quickly than in the air or under pure water, and the reduced chloride is mixed with a small quantity of metallic silver, resulting from reduction of the aqueous nitrate. Paper charged with argentic chloride is very sensitive to light, and is the material used for positive photographs, the unaltered chloride being afterwards removed by a solution of sodic hyposulphite (iii. 693; iv. 625).

Ammonio-chloride of Silver.—Dry chloride of silver slowly absorbs ammonia-gas to the amount of 17 per cent., forming the compound $3NH^3.2AgCl$, which easily gives off its ammonia when heated, and may therefore be used for the preparation of pure ammonia-gas—or of liquid ammonia, if heated in a sealed tube. Fused chloride of silver takes up only a very small quantity of ammonia (H. Rose).—A saturated solution of argentic chloride in ammonia, left to stand in a vessel not perfectly closed, deposits rhombic crystals of the ammonio-chloride, often a quarter of an inch long. A dilute solution deposits pure argentic chloride (Faraday). The ammoniacal solution is quickly reduced by zinc and copper, the silver separating as a grey mossy powder. Lead acts in the same manner, but slowly; antimony and cadmium imperfectly; iron, bismuth, and mercury, not at all. (Fischer.)

Chloride of Silver and Ammonium, or *Ammonio-argentic Chloride*, $(NH^4)Cl.AgCl$, may be obtained in crystals by placing a solution of sal-ammoniac in one arm of a U-tube, a solution of argentic nitrate in the other, the two being prevented from mixing by a plug of asbestos in the bend of the tube, and connecting them by an arc of silver plate or wire; the end dipping into the sal-ammoniac becomes covered after a while with tetrahedral crystals of the double salt (Becquerel, *Gmelin's Handbook*, i. 401). A solution of argentic chloride in boiling aqueous sal-ammoniac deposits, on cooling, nothing but argentic chloride.

Bario- and *Potassio-argentic Chlorides* are likewise obtained in tetrahedral crystals by the electrolytic method just described. (Becquerel.)

Sodio-argentic Chloride separates on cooling from a solution of argentic chloride in a hot saturated solution of common salt, in cubes, having the same form and aspect as those of common salt, but blackening when exposed to light. A more dilute salt-solution likewise dissolves chloride of silver when hot, but deposits it unchanged on cooling. The crystals of the double salt are resolved by a sufficient quantity of water into argentic chloride, and a solution of sodic chloride. (Wetzlar.)

Osmio-argentic chloride, $2AgCl.OsCl^4$, is produced on adding silver-nitrate or an ammoniacal solution of silver-chloride to a solution of sodio-osmic chloride (iv. 243), as a dingy greyish-green precipitate, which, in contact with ammonia, is converted into the minium-coloured compound $2AgCl.OsCl^4.2NH^3$. (Claus, Jahresb. 1860, p. 216; 1863, p. 299.)

Hemichloride of Silver, or **Argentous Chloride,** Ag^2Cl.—This compound is most readily formed by treating argentous oxide with hydrochloric acid, or by precipitating a soluble argentous salt (the citrate, for example) with common salt. Its formation by the action of light on argentic chloride has been already mentioned. According to Wetzlar, silver-leaf immersed in solution of ferric or cupric chloride is quickly converted into brown laminæ of argentous chloride, which must be immediately taken out of the liquid and washed with water, as otherwise they will be converted into argentic chloride. Argentous chloride is also formed on bringing silver in contact with solution of sal-ammoniac, or of cupric chloride containing that salt.

Argentous chloride heated to the temperature at which argentic chloride melts, is resolved into the latter compound and metallic silver; the same decomposition is quickly produced by the action of ammonia.

SILVER, CHLOROBROMIDE OF. The chloride and bromide of silver occur crystallised together, in various proportions, in cubes and cubo-octahedrons, also massive. The minerals thus constituted vary in hardness from 1 to 1·5; in specific gravity from about 5·75 to 6·2; and have an olive or greyish-green colour, with resinous and somewhat adamantine lustre.

Analyses.—*a. Embolite* from Chañareillo, in Chile (Field, Chem. Soc. Qu. J. x. 239).—*b.* The same (Field).—*c.* The same, from the Colorado mine, near Copiapo: regularly crystallised; specific gravity = 5·8 (Plattnex, Pogg. Ann. lxxvii. 134; lxxviii. 417).—*d.* Chañareillo (Field).—*e. Megabromite*, from Chile: crystallised in cubes and octahedrons; green; specific gravity = 6·234 (Richter, Ramm. Mineralch. p. 989).—*f. Microbromite*, from Copiapo; grey-green, becoming darker on exposure to light; specific gravity = 5·75—5·76:—

SILVER, DETECTION AND ESTIMATION OF. 1. *Reactions in the dry way.*—Silver compounds mixed with *sodic carbonate*, and heated upon *charcoal* by the inner flame of the blowpipe, are reduced, yielding brilliant white metallic globules, without any incrustation of the charcoal. Heated with *borax* in the outer flame on platinum-wire, they are partly reduced and partly dissolved, yielding a white opaline glass. With *microcosmic salt* they yield in the outer flame a yellowish glass, which becomes opaline when the amount of silver is large. By daylight this glass appears yellowish, and by candlelight reddish.

2. *Reactions in Solution.*—The most characteristic reaction of saline silver-compounds in solution, is the formation of silver-chloride. Silver-salts which are insoluble in water may generally be dissolved by nitric acid, and the solution gives the same reactions as the soluble salts.

Hydrochloric acid and soluble chlorides produce a white curdy precipitate of silver-chloride, which is insoluble in boiling water and in dilute nitric acid, but is readily dissolved by ammonia. On exposure to light it gradually acquires a violet tinge, and eventually becomes black. The admixture of a small proportion of mercurous chloride prevents or retards the coloration of silver-chloride on exposure to light. In very dilute solutions of silver, the separation of the chloride precipitate takes place but slowly, and they present for some time a whitish opalescent appearance.

A precipitate of lead-chloride is distinguishable from silver-chloride by its solubility in boiling water; a precipitate of mercurous chloride is distinguishable by its insolubility in ammonia, and by turning black with that reagent.

Potassium-iodide produces a slightly yellowish-white precipitate of silver-iodide, which is soluble in excess of the reagent, very sparingly soluble in ammonia, and insoluble in dilute nitric acid.

Potassium-cyanide produces a white curdy precipitate of silver-cyanide, which is readily soluble in excess of the reagent, and insoluble in dilute acids.

Sulphydric acid and *ammonium-sulphide* produce a black precipitate of silver-sulphide, which is insoluble in ammonium-sulphide, in dilute acids, and in ammonia.

Ammonia or *potash* produces in neutral silver-solutions a brown precipitate of silver-oxide, which dissolves very readily in ammonia and in ammoniacal salts.

Alkaline carbonates produce a white precipitate of silver-carbonate, which is soluble in ammonia and carbonate of ammonium.

Sodic phosphate produces in neutral solutions a yellow precipitate of tribasic silver-phosphate, which is soluble in ammonia and nitric acid.

Oxalic acid produces in neutral solutions a white precipitate of silver-oxalate, which is soluble in ammonia, and sparingly in nitric acid.

Potassium-chromate produces a dark-brown precipitate of silver-chromate, which is slightly soluble in water, and soluble in ammonia and dilute nitric acid.

Stannous chloride in excess produces a brownish-black precipitate of metallic silver.

Ferrous sulphate produces in neutral solutions a white precipitate of metallic silver.

Zinc produces a precipitate of metallic silver; it also separates silver from silver-chloride in presence of water.

3. *Estimation and Separation.*—Silver may be separated from most other metals, and estimated with great precision as chloride. For this purpose the substance is to be dissolved either in water or nitric acid; the solution mixed with a slight excess of nitric acid, and with hydrochloric acid, as long as any precipitate or milkiness is produced, then warmed in a dark place until the precipitate has separated, and the liquid has become perfectly clear. The chloride is then collected upon a filter of known

weight, washed with acidulated water, dried, and weighed. This is the most accurate but also the most troublesome plan of weighing. The filter may be burnt, but in that case it is necessary to burn it after having separated the precipitate from it, so as to prevent as much as possible the reduction of silver. The small portion of chloride which cannot be detached from the paper is decomposed, and remains as silver in the filter-ash. The slight error which would be caused by weighing this as chloride can be rectified by warming the ash in a porcelain crucible with a few drops of nitric acid for some minutes, then adding hydrochloric acid, and evaporating to dryness. The remainder of the chloride may then be added, the whole heated till it begins to melt, and then weighed. (Compare i. 904.)

Silver may also be estimated as cyanide by adding potassium-cyanide to the solution, until the precipitate, which is at first produced, is redissolved; then adding nitric acid in slight excess, and warming. The precipitated silver-cyanide is collected on a weighed filter, dried at 100°, and weighed.

Estimation as Metallic Silver.—In the case of silver-salts from which the metal is reduced by simply heating them, this method of estimation may be conveniently adopted. The substance should be gradually heated in a porcelain crucible till the whole of the carbon is burnt.

Volumetric Estimation of Silver.—The readiness with which silver-chloride subsides in a liquid from which it is precipitated admits of the point of perfect precipitation being observed with great precision. (See SILVER ASSAY.)

The separation of silver from other metals and their salts is generally unattended with any difficulty. From solutions containing *zinc, manganese, iron, nickel, cobalt, copper, bismuth, cadmium, gold, platinum*, it may easily be separated by precipitation as chloride. From *lead* it may be separated in the same way, when the proportion of lead to silver is not large. Or both metals may be precipitated as cyanides, the silver-cyanide dissolved by an excess of the reagent, the insoluble lead-cyanide separated by filtration, and the silver-cyanide precipitated from the solution by nitric acid. Or the neutral solution may be heated with an alkaline formiate, until there is no longer any evolution of carbonic acid. Silver only is reduced, and may be collected by filtration, ignited, and weighed.

From *mercury* in the state of mercuric salts, silver may be easily separated as chloride. When silver is associated with mercurous compounds, it is best to convert them, by heating with nitric acid, into mercuric compounds, and then precipitate the silver as chloride.

From *tin, antimony, arsenic*, or *mercury*, the best method of separation is to precipitate the metals as sulphides, and heat the precipitate carefully in an atmosphere of chlorine gas, gradually raising the temperature to dull redness, so as to distil off the volatile chlorides. The silver-chloride remaining may be weighed, or the silver reduced by heating it in a current of hydrogen gas.

4. The *atomic weight of silver* has been determined in connection with those of chlorine and potassium (i. 905). Stas obtained, as the mean of a great number of experiments conducted by different processes, the number 107·943 (i. 456). B. H. P.

SILVER, FAHL-ORE. See TETRAHEDRITE.

SILVER, FLUORIDE OF. *Argentic Fluoride*, AgF. Produced by dissolving argentic oxide or carbonate in aqueous hydrofluoric acid. The solution when evaporated in a vacuum, or concentrated over the water-bath, and then left to stand, deposits large, transparent, colourless, hard prisms, mostly aggregated lengthwise, consisting of the hydrated fluoride, $AgF.2H^2O$ (Frémy, Jahresber. 1856, p. 87.—Pfaundler, *ibid.* 1862, p. 305). Marignac, on the other hand (*ibid.* 1857, p. 129), obtained the fluoride in quadratic octahedrons, containing $AgF.H^2O$. The dehydrated crystals are deliquescent, and when left over oil of vitriol, especially in a vacuum, give off water and hydrofluoric acid, and are converted on the surface into a yellow oxyfluoride (*infra*). When fused, they give off their water and leave the anhydrous fluoride AgF—not, however, quite pure, inasmuch as hydrofluoric acid and oxygen are given off at the same time (Pfaundler). When chlorine gas is passed over fused silver-fluoride, chloride of silver is formed, and fluorine is set free (ii. 673). The aqueous solution of silver-fluoride gives with hydrochloric acid a precipitate of chloride, and with potash a precipitate of oxide of silver. It is easily decomposed also by organic acids, yielding precipitates of the corresponding silver-salts, which are in this way more easily prepared than from the ordinary solution of argentic nitrate, inasmuch as they are much less soluble in free hydrofluoric than in nitric acid. (Pfaundler.)

Argentic Oxyfluoride, $Ag^4F^2O.H^2O$ or $AgF.AgHO$.—This compound is formed when a solution of the fluoride is strongly concentrated over the water-bath; also, as already observed, when the crystals of the hydrated fluoride are left to stand over oil of vitriol. It forms brass-yellow crystalline spangles, which dissolve in water with

Many other minerals—as lead, copper, iron-ores, &c.—are also regarded as silver-ores, when they contain a sufficient quantity of silver for profitable extraction (p. 279).

SILVER, OXIDES OF. Silver forms three oxides, represented by the formulæ Ag^4O, Ag^2O, and Ag^2O^2.

Hemioxide of Silver, or **Argentous Oxide,** Ag^4O. *Suboxide* or *Quadrantoxide of Silver.*—This oxide, discovered by Wöhler in 1839 (Ann. Ch. Pharm. xxx. 1), is obtained by passing hydrogen-gas over argentic oxalate, mellitate, or citrate heated to 100°, half the acid being then set free, and a dark-brown argentous salt remaining. The free acid may be removed by water, which dissolves only a small quantity of the argentous salt, but forms a brown-red or portwine-coloured solution. Argentous salts are also produced in some instances by passing hydrogen into ammoniacal solutions of argentic salts (Wöhler, Ann. Ch. Pharm. cxiv. 119). From the solid salts or their solutions, the argentous oxide is separated by caustic potash as a black precipitate. According to Geuther (*ibid.* cxiv. 121), argentous oxide is formed by the action of cuprous hydrate on solution of argentic nitrate. Wöhler (*ibid.* ci. 363) has also obtained it, mixed with metallic silver, by repeatedly boiling argentic arsenite with soda-ley.

Argentous oxide, when pure, does not change colour in drying, and does not acquire metallic lustre under the burnisher. Hydrochloric acid and hydrobromic acid convert it into argentous chloride and bromide respectively. By oxygen-acids and by ammonia it is resolved into argentic oxide and metallic silver.

According to Faraday (Ann. Ch. Phys. [2] ix. 107), a solution of argentic oxide in ammonia deposits, on exposure to the air, a body which is grey by reflected light, bright yellow in thin layers by transmitted light, and melts when heated, giving off oxygen, and leaving metallic silver.

Protoxide of Silver or **Argentic Oxide,** Ag^2O. This oxide is obtained in the pure state—

1. By heating argentic carbonate to 200°.

2. By decomposing a solution of silver-nitrate with caustic alkalis, certain precautions being, however, necessary to prevent the simultaneous formation of carbonate. *a.* The silver-solution is poured into a hot saturated solution of baryta, in such quantity as to leave the liquid with a distinct alkaline reaction; and the precipitate is left to settle in a corked flask, then drenched with cooled de-aërated water, in closed vessels. The oxide thus obtained is a brown powder, becoming black when dried at 60° or 70°.—*β.* By mixing concentrated hot solutions of potash and argentic nitrate, the oxide is at once obtained in the form of a black powder, which settles down quickly and is easy to wash.

3. By precipitating a cold solution of argentic nitrate with hydrochloric acid, washing the precipitated chloride with cold water—then levigating it with a small quantity of water, and pouring it into boiling potash-ley of specific gravity 1·25 to 1·3, so slowly as not to interrupt the boiling, the argentic chloride is decomposed, and the pure oxide is obtained as a soft bluish-black powder. If it be not completely soluble in nitric acid, it must be triturated in a porcelain mortar with fresh potash-ley and again boiled.

4. Argentic oxide is also formed when silver is very strongly heated in the oxy-hydrogen flame, or in the electric arc.

Argentic oxide is a brown or black powder of specific gravity 7·143 (Herapath), 7·250 (Boullay). According to Bineau (Compt. rend. xli. 509), it dissolves in 3,000 pts. of water, forming a solution which yields a precipitate with chlorides and phosphates, has a faint alkaline reaction, and a nauseous metallic taste. Argentic oxide is a strong base, and neutralises acids completely, forming the argentic salts. According to H. Rose (Pogg. Ann. lxxxv. 304), the recently precipitated and still moist oxide absorbs carbonic acid from the air. After drying at 60° or 70°, it is anhydrous. It gives off a certain quantity of oxygen at 100°, also when exposed to sunshine; but whether argentous oxide or metallic silver is thereby produced is not exactly known. At a stronger heat it is quickly resolved into metallic silver and oxygen.

Argentic oxide is easily reduced by oxidable substances. According to Böttger (J. pr. Chem. xc. 32), the following substances are set on fire when triturated with it in the dry state, even on paper:—sulphide of gold, black sulphide of antimony, realgar, orpiment, milk of sulphur, selenium, amorphous phosphorus, and tannic acid. Creosote also burns with scintillation when dropped on dry argentic oxide. The oxide is reduced to metallic silver completely by aqueous phosphorous acid, partially by aqueous sulphurous acid, with simultaneous formation of argentic phosphate or sulphate. Under water it is reduced to metal by contact with zinc, tin, or copper, but not by iron or mercury (Fischer). Aqueous hypochlorous acid converts it into argentic chloride, with evolution of oxygen (Balard). It is not altered by potash-ley or soda-ley, but strong aqueous ammonia converts it into fulminating silver (p. 300.)

Peroxide of Silver or **Argentic Dioxide,** Ag^2O^2.—Discovered by Ritter in 1814. It is formed when a concentrated solution of argentic nitrate is electrolysed, with two thick platinum-wires for poles, and is deposited in crystals on the positive pole, while metallic silver separates at the negative pole. The crystals, however, always contain argentic nitrate, either in combination or mechanically enclosed (Fischer, J. pr. Chem. xxxii. 108.—Gmelin and Mahla, Ann. Ch. Pharm. lxxxii. 289). According to Schönbein (J. pr. Chem. xli. 321; lxxiv. 324), pure argentic dioxide may be prepared by the action of ozone on pulverulent silver. It dissolves in cold nitric acid, to a deep brown liquid, which remains undecomposed at ordinary temperatures, deposits the dioxide when considerably diluted with water, and is resolved by heat into oxygen and argentic nitrate.

Argentic dioxide, when cautiously heated, gives off oxygen, and leaves the protoxide; but when quickly heated to 110°, it suddenly gives off oxygen with slight explosion. Hydrochloric acid converts it into argentic chloride, with evolution of chlorine. When thrown into ammonia, it rapidly eliminates nitrogen gas, and runs about in the liquid till it is dissolved. Sulphuric and nitric acid convert it into argentic salts, with evolution of oxygen. Hydrogen reduces it only when heated, but then with slight explosion. When thrown into hydric peroxide, it is quickly resolved into metallic silver and oxygen.

SILVER, OXYGEN-SALTS OF. Silver forms two classes of oxygen-salts, corresponding with the argentic and argentous oxides. The argentic salts are formed by dissolving metallic silver in oxidising acids, or by double decomposition. The nitrate, chlorate, and perchlorate are easily soluble in water; the rest are insoluble or sparingly soluble. Their reactions have already been described (p. 298.)

Argentous salts are produced by the action of reducing agents on argentic salts. Wöhler originally prepared them by gently heating argentic salts in a current of hydrogen (p. 309). In many cases, however, they are more easily obtained by passing hydrogen gas into an ammoniacal solution of an argentic salt heated to about 90°; in this manner Rautenberg (Ann. Ch. Pharm. cxiv. 119) has obtained the chromate, molybdate, and tungstate.—*Argentous chromate* is thus produced, even at ordinary temperatures, mixed, however, with a little metallic silver (to which it is completely reduced at 50°). It is a black powder, which is immediately reddened and dissolved by strong nitric acid; dilute nitric acid dissolves it with green colour, the chromic acid being reduced to chromic oxide.—*Argentous molybdate*, $Ag^4O.2MoO^3$, has been already described (iii. 1041).—*Argentous tungstate*, $Ag^4O.2WO^3$, is a black glittering powder, which under the microscope exhibits crystals apparently with rhombic faces. Nitric acid dissolves the silver from it, separating yellow tungstic acid; potash, on the other hand, extracts the tungstic acid, and separates argentous oxide. An ammoniacal solution of argentic arsenate is turned brown by hydrogen gas, and very slowly deposits a small quantity of a black powder. A solution of ferrous sulphate immediately reduces argentic arseniate and triargentic phosphate to a black powder, consisting of argentous oxide mixed with metallic silver; argentic oxalate is reduced by the same solution to metallic silver. (Jahresb. 1860, p. 200.)

A solution of *argentous citrate* or *mellitate* decomposes gradually on exposure to the air, and immediately on boiling into metallic silver and argentic salt. The same salts dissolve easily in ammonia, forming a yellowish-red liquid. Common salt added to these solutions throws down brown argentous chloride.

SILVER, PHOSPHIDE OF. When phosphorus is thrown upon melted silver, a phosphide is formed, from which part of the phosphorus separates as the fused mass solidifies, and then burns in the air. Phosphide of silver is also formed by fusing silver with glacial phosphoric acid and charcoal (Pelletier), or argentic phosphate with charcoal (Landgrebe). The phosphide obtained by the first and second methods is white, granular, and crystalline, splits under the hammer, but may be cut with a knife; it contains 20 per cent. phosphorus (AgP requires 22·3 per cent.). That prepared by Landgrebe's method is scoriaceous, brittle, sectile, exhibits a silvery lustre when filed, and contains 33·2 per cent. phosphorus (AgP^2 requires 36·4 per cent.).

When finely divided silver is gently heated in phosphorus-vapour, a blackish-grey phosphide, Ag^2P^3, is obtained, of specific gravity 4·63, easily soluble in dilute nitric acid, insoluble in hydrochloric acid: it is difficult to prepare, as if the heat applied is rather too high, some of the phosphorus is driven off. When a solution of silver-nitrate is treated with phosphoretted hydrogen-gas, a precipitate is formed, which, according to Landgrebe's somewhat doubtful statements, is a phosphide containing 15·5 per cent.

phosphorus, agreeing nearly with the formula Ag^3P^2. According to H. Rose, however, it consists of pure silver. (Handw. d. Chem. vii. 966.)

SILVER, RED, or **RUBY.** This name includes two silver-ores, both consisting of argentic sulphantimonites—viz., dark-red silver-ore, or pyrargyrite, $2Ag^2S.Sb^2S^3$, (iv. 740), and light red silver-ore or proustite, $2Ag^2S.Sb^2S^3$ (iv. 764).

SILVER, SELENIDE OF, Ag^2Se. Silver acquires a black tarnish by contact with the vapour of selenium, selenious acid, or selenhydric acid. The compound is easily formed by melting silver and selenium together. Selenhydric acid passed into a solution of silver, forms a black precipitate, which becomes dark-grey when dry, and melts without decomposition at a red heat, forming, when cold, a silver-white somewhat malleable mass. It is not completely deprived of its selenium by roasting, or even by fusion with alkalis or borax; iron unites with it, forming a dark-grey compound. Selenide of silver dissolves in boiling nitric acid, the solution containing argentic selenite. On fusing the precipitated selenide with more selenium, it is converted into the diselenide, Ag^2S^2, which melts to a specular mass, retaining its selenium on ignition, but giving it up when roasted.

Selenide of Silver and Lead.—The mineral naumannite, found at Tilkerode in the Hartz, consists of isomorphous mixtures of the selenides of lead and silver. It occurs in cubes, with perfect cubic cleavage; also massive, granular, and in thin plates; hardness $= 2·5$; specific gravity $= 8·0$; lustre metallic, splendent; colour and streak iron-black. A specimen, analysed by G. Rose, contained 23·53 per cent. Se, 65·56 Ag, and 4·91 Pb; another, analysed by Rammelsberg, gave 26·52 Se, 11·67 Ag, and 60·15 Pb ($= 98·34$). The first is nearly $PbSe.13Ag^2Se$; the second $(4—5)PbSe.Ag^2Se$.

Selenide of Silver and Copper, $AgCu'Se$ or $Ag^2Se.Cu^2Se$.—This is the composition of eukairite from Småland, Sweden (ii. 605).

SILVER, SELENIOCYANATE OF. See SELENIOCYANATES (p. 220).

SILVER, SULPHIDE OF. *Argentic Sulphide*, Ag^2S.—This, which is the only known compound of silver and sulphur, occurs native as silver-glance or argyrose, in cubes, octahedrons, rhombic dodecahedrons, and intermediate forms, occasionally also with faces of the trapezohedron and triakis-octahedron (ii. 125, 126). The crystals are often distorted and irregularly developed, or aggregated in tooth-shaped, step-shaped, dendritic, striated, filiform, or capillary groups; it also occurs in amorphous masses, and as an earthy deposit. The crystals exhibit cubic and dodecahedral cleavage. Hardness $= 2·5$. Specific gravity $= 7·196—7·365$. Lustre metallic; colour and streak blackish lead-grey; opaque; fracture small, conchoïdal, uneven. Before the blowpipe, on charcoal, it melts, swells up strongly, gives off sulphurous anhydride, and finally leaves a fused button of silver. Silver-glance occurs in veins traversing gneiss, granite, mica-slate, &c., and often in very large masses, in Saxony, Bohemia, Hungary, Norway, Siberia, Mexico, Peru, Chile, and other localities. It is seldom found quite pure, being usually more or less mixed with the sulphides of lead, copper, and iron. Pure argentic sulphide contains 87·1 per cent. silver. Klaproth found in a crystallised specimen from Freiberg 85·3, and in a massive variety from Joachimsthal 85 per cent. silver. Lindaker found in a crystallised variety from the same locality, 14·46 per cent. sulphur, 77·58 silver, 3·68 lead, 1·53 copper, and 2·02 iron ($= 99·27$).

Acanthite is a trimetric variety of argentic sulphide occurring at Joachimsthal in the Erzgebirge, in small crystals of specific gravity 7·31—7·36, isomorphous with copper-glance (ii. 76).

Argentic sulphide is formed artificially by fusing silver with excess of sulphur. According to Durocher (Compt. rend. xxxii. 823), it may be obtained in the crystalline state by mixing sulphydric acid gas with the vapour of argentic chloride. Becquerel also obtained it crystallised by filling one arm of a U-tube with solution of potassic sulphydrate, the other with argentic nitrate, and connecting the two liquids by an arc of silver. The end dipping into the alkaline sulphydrate then became covered with beautiful prisms of sulphide of silver and potassium, which were gradually decomposed by the nitric acid carried over to them, yielding sulphate of potastium and octahedral crystals of argentic sulphide. The compound is likewise formed by the action of sulphydric acid on metallic silver (p. 278), and as a brown or black precipitate when sulphydric acid gas is passed into silver-solutions.

Artificial argentic sulphide has a density of 6·85 (Karsten). After fusion, it solidifies to a lead-grey, metallic-shining, malleable mass, soft enough to be cut with a knife, and to be used for forming medallions with the die. Faraday supposed that argentic sulphide conducts electricity, like a metal, without decomposition, its conducting power however increasing with rise of temperature, like that of an electrolyte;

Hittorf, however, has shown (Pogg. Ann. lxxxiv. 1) that when free from metallic silver it conducts only in proportion as it is decomposed.

Argentic sulphide is insoluble in water, ammonia, cyanide of potassium, and dilute nitric acid; strong nitric acid however dissolves it, with separation of sulphur. It is very slowly decomposed by ignition in the air, and if the temperature is not very high, argentic sulphate is produced, which requires a very strong heat to decompose it. When ignited in hydrogen, it gives off sulphydric acid, but it is difficult to remove the whole of the sulphur even in this way. Chlorine gas does not decompose it in the cold, and acts but slowly upon it when heated (H. Rose). It is not decomposed by solution of cupric chloride, unless chloride of sodium is also present, in which case argentic chloride and cuprous sulphide are produced.

Argentic sulphide may be fused in all proportions with metallic silver. The fused sulphide is quickly decomposed by iron, with formation of ferrous sulphide and separation of metallic silver containing iron. Lead acts in like manner, the excess of lead, however, taking up the whole of the silver.

Argentic sulphide is used, in conjunction with other metallic sulphides, for producing black designs on engraved silver; this art is called *niello*. It has also been used as a hair-dye, the hair being washed first with a silver-solution (generally ammoniacal), and then with a solution of monosulphide of potassium.

Argento-cuprous Sulphide, AgCuS or $Ag^2S.Cu^2S$. *Argentiferous Copper-glance. Stromeyerite.*—A mineral intermediate in composition between argentic sulphide and copper-glance, and crystallising in trimetric forms, isomorphous with the latter; also occurring massive and embedded. Hardness = 2·5 to 3·0. Specific gravity = 6·2 to 6·3. It is sectile, has a dark steel-grey colour, shining streak, and subconchoïdal fracture. It melts before the blowpipe to a grey semi-malleable bead, gives with fluxes the reactions of copper, and when cupelled with lead, leaves a button of silver.

Analyses: *a.* From Schlangenberg in the Altai: massive (Stromeyer, Schw. J. xix. 325).—*b.* From Rudelstadt in Silesia: crystallised (Sander, Pogg. Ann. xl. 313):

	a.	*b.*		Calculated.

Argentic sulphide occurs in combination with the trisulphides of arsenic and antimony, in several varieties of fahl-ore,—viz., brongniardite, freibergite, freieslebenite, polybasite, proustite, pyrargyrite, stephanite, and xanthocone. (See SILVER-ORES, p. 301.)

SILVER, SULPHOCYANATE OF. See SULPHOCYANATES.

SILVER, SULPHO-HYPOPHOSPHITE and **SULPHOPHOSPHITE OF.** See PHOSPHORUS, SULPHIDES OF (iv. 601, 602).

SILVER, TELLURIDE OF, Ag^2Te.—This compound occurs native as *Hessite* or *Telluric Silver*, in coarse-grained masses apparently monometric and granular. Hardness = 2—3·5. Specific gravity = 8·3—8·9. It is slightly malleable, has a lead-grey or steel-grey colour, and metallic lustre. Heated in an open tube, it melts but does not fume. Before the blowpipe on charcoal, it melts at a bright-red heat, leaving a somewhat brittle button of silver. With fluxes it forms in the outer flame a yellowish, in the inner flame a dark-red glass, becoming grey on cooling. It dissolves in nitric acid, the solution depositing crystallised argentic tellurite.

Analyses: *a.* From the Savodinskoi mine in the Altai (G. Rose, Pogg. Ann. xviii. 64).—*b.* Nagyag in Transylvania: specific gravity = 8·31—8·45 (Petz, *ibid.* lvii.

470).—*c.* Retzbanya in Hungary; *α.* massive; *β.* granular, with green deposit (Rammelsberg):

Gold . .	. .	. .	0·69		
Iron . .	0·24	0·50			
	99·62	99·71	100·00		97·5

The formula Ag^2Te requires 37·27 per cent. tellurium and 62·73 silver.

Argento-auric Telluride, $4Ag^2Te.Au^2Te$, of specific gravity 8·72—8·83, found at Nagyag, contains, according to Petz, 34·98 per cent. tellurium, 46·76 silver, and 18·26 gold.*

Sylvanite (*q. v.*) or *Graphic Tellurium*, and *Nagyagite* or *Foliated Tellurium* (iv. 1), are likewise tellurides of gold and silver, but contain lead and antimony in addition.

SILVER, VITREOUS. Native argentic sulphide.

SILVER-ACETYL, C^2Ag^2H. (Berthelot, Bull. Soc. Chim. 1866, i. 180.)—An organic radicle, the compounds of which are obtained by the action of acetylene on ammoniacal solutions of silver salts.†

The *chloride*, C^2Ag^2HCl, is a white curdy precipitate, decomposed by boiling nitric acid, with formation of argentic chloride. Boiling hydrochloric acid decomposes it, reproducing acetylene. It does not dissolve perceptibly in ammonio-argentic chloride.

The *oxide*, $(C^2Ag^2H)^2O$.—This compound (hitherto regarded as acetylide of silver or silver-acetylene, C^2Ag^2) is produced by the action of acetylene on an ammoniacal solution of the nitrate or other oxysalt of silver, washing the precipitate with ammonia, then with distilled water, &c.

Phosphate of Silver-acetyl is a yellow curdy precipitate, decomposed by hydrochloric acid, with formation of acetylene and argentic chloride; nitric acid reproduces phosphoric acid. The sulphate is a greyish-white precipitate, exhibiting analogous reactions. An ammoniacal solution of argentic benzoate treated with acetylene yields a yellow precipitate which turns white during washing, and is found to consist entirely of oxide of silver-acetyl.

SILVER-GLANCE. Native argentic sulphide (p. 304).

SILVER-PURPLE. A dilute neutral solution of argentic nitrate mixed with stannous nitrate, or an ammoniacal solution of argentic nitrate mixed with stannous chloride, yields a brown or purple-brown precipitate, the so-called "silver-purple," the colour of which varies according to the mode of preparation. It contains tin, silver, and oxygen, and is perhaps an argentous stannate. (Handw. d. Chem. vii. 966.)

SILVER-VITRIOL. Argentic sulphate.

SIMARUBA. The bark of *Simaruba officinalis*, Dec. (*Quassia Simaruba*, L.) has long been used in medicine. It contains a bitter principle, like that of quassia-bark, and a trace of essential oil. According to Buchner, the alcoholic extract is poisonous, and acts in the same manner as the extract of quassia-bark: two grains killed a rabbit in twenty-four hours.

SIMILOR. An obsolete name for an alloy of zinc and copper containing from 6 to 9 pts. copper to 1 pt. zinc (ii. 49).

SINAMINE, $C^4H^6N^2$ = $\left.\begin{matrix}CN\\C^3H^5\\H\end{matrix}\right\}N$.—A basic compound discovered by Robiquet and Bussy in 1839 (Ann. Ch. Phys. [3] lxxii. 328), and further examined by Will (Ann. Ch. Pharm. lii. 1). It contains the elements of thiosinamine *minus* 1 atom of sulphydric acid, $(C^4H^8N^2S - H^2S)$, and may be regarded as ammonia, NH^3, in which 1 at. H is replaced by cyanogen, and another by allyl. It is produced in the decomposition of thiosinamine by various metallic oxides: *e.g.*—

$$\underset{\text{Thiosinamine.}}{C^4H^8N^2S} + PbO = \underset{\text{Sinamine.}}{C^4H^6N^2} + PbS + H^2O.$$

Preparation.—1. One part of thiosinamine and 5 pts. of mercuric oxide are rubbed together, without application of heat; the mass when cold is exhausted with ether; the filtrate evaporated; the viscid residue dissolved in hot water; and the solution left to crystallise (Robiquet and Bussy).—2. Pulverised thiosinamine is triturated with recently precipitated and well-washed hydrate of lead; the mixture is heated in the water-bath, till a sample diluted with water and filtered no longer produces a black colour with fresh oxide of lead and potash; the entire mass is then repeatedly boiled, first with water and then with alcohol, because the sinamine is obstinately retained by the sulphide of lead; the whole of the decoctions are evaporated to a syrup; and the crystals, which form after several months, are taken out, and freed from the syrup by gentle pressure between paper (Will). The syrup is distinguished from the crystals by its smaller amount of water; if the hydrate of lead obtained from the acetate was not well washed, the syrup contains also basic acetate of lead. (Will)

---

* After deduction of 15·25 per cent. insoluble matter.

† Ammoniacal solutions of cuprous salts treated with acetylene, yield in like manner salts of cupros-acetyl, C^2Cu^2H.

Properties.—The crystals of sinamine contain $2C^4H^6N^2.H^2O$; they are white, shining triclinic prisms, which lose their lustre *in vacuo* over sulphuric acid. At 100° they melt, and give off two-thirds of their water, the melted mass forming when cold a syrup, which slowly recrystallises. By longer exposure to 100°, the whole of the water is driven off, and on cooling, anhydrous sinamine remains, as a white, opaque, slightly crystalline mass. It is inodorous, but tastes strongly and persistently bitter. It dissolves in water, alcohol, and ether. The aqueous solution has a strong alkaline reaction, and is precipitated by tannin.

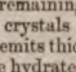
Decompositions.—1. Sinamine heated in a retort in the oil-bath, gives off ammonia from 160° to 200°, without blackening, and leaves a yellow resinous body almost insoluble in water, but dissolving sparingly in alcohol, and forming an alkaline solution. Its solution in hydrochloric acid becomes milky when mixed with ammonia, and if subsequently heated, again deposits resinous matter; the hydrochloric acid solution forms a white precipitate with mercuric chloride, and yellow with platinic chloride (Will).—2. A cold mixture of aqueous sinamine and hydrochloric acid does not give off ammonia, or become turbid on the addition of potash; but after the hydrochloric acid has been boiled, potash eliminates ammonia from it, and throws down a basic substance, which behaves like the resinous body remaining when sinamine is heated (Will). *Hydrochloric acid gas* passed over the crystals is absorbed without fusion; the resulting mass, when gently heated, suddenly emits thick white fumes of sal-ammoniac, and leaves a tumefied residue (Will).—4. The hydrated crystals, exposed to a stream of *sulphydric acid gas*, quickly assume a sulphur-yellow colour, without losing water; and if then gently heated, melt to a transparent liquid, which takes up an additional quantity of sulphydric acid, and becomes liver-coloured; but if still subjected to the action of heat, not however rising to 100°, gives off the water of crystallisation, together with sulphydrate of ammonium. Ultimately there remains a transparent, liver-coloured, inodorous mass, amounting in weight to 94·88 per cent. of the crystals. This mass forms, with water or alcohol, a solution which colours lead-salts light-red, and does not precipitate sulphide of lead till it is boiled. (Will.)

Sinamine-salts.—Sinamine expels ammonia from ammoniacal salts; it also precipitates the salts of lead, iron, and copper. Nevertheless, it does not form solid salts with any acid except oxalic acid, with which it slowly yields crystals (Will). The acid solutions impart a yellow colour to fir-wood. (Hofman, Ann. Ch. Pharm. xlvii. 55.)

Sinamine with Mercuric Chloride, $C^4H^6N^2.Hg''Cl^2$.—The solution of sinamine in aqueous hydrochloric acid forms, with excess of aqueous mercuric chloride, a precipitate which, on account of its tendency to decompose in washing, must be merely collected on a filter, strongly pressed, and dried *in vacuo* over oil of vitriol.

Platinum-compound.—Aqueous sinamine mixed with a small quantity of hydrochloric acid, forms, with platinic chloride, yellowish-white flakes, which settle down slowly, so that the filtered liquid, after standing for several hours, yields a fresh precipitate, the filtrate from that yields another, and so on. All the precipitates exhibit about the same amount of platinum (viz., about 39·6 per cent.) after drying in a current of air at 115°; hence the precipitate is perhaps $C^4H^6N^2.2HCl.Pt^{iv}Cl^4$. (Will.)

Sinamine forms a resinous precipitate with *nitrate of silver*. (Will.)



Ethylsinamine, or **Sinethylamine,** $C^6H^{10}N^2 = \left.\begin{matrix}CN\\C^3H^5\\C^2H^5\end{matrix}\right\}N$. (Hinterberger, Ann. Ch. Pharm. lxxxiii. 348.)—Produced by decomposing thiosinethylamine with hydrate of lead. When the two substances are heated together till a filtered sample no longer blackens on the addition of lead-hydrate and potash, the resulting mass boiled with water and then with alcohol, and the solutions evaporated, a dark-yellow syrupy residue is obtained, which becomes almost wholly crystalline after a few months, and when pressed between bibulous paper and recrystallised from ether, yields pure sinethylamine.

Sinethylamine crystallises in needles arranged in dendritic groups: it tastes very bitter. At 100° it melts to a colourless liquid, which when touched with a cold body, quickly solidifies in a crystalline mass, the crystallisation spreading from the point of contact. It is insoluble in water, but dissolves in alcohol and ether, forming solutions which have an alkaline reaction.

Mercury-compound, $2C^{6}H^{10}N^{2}.3Hg''Cl^{2}$.—A solution of sinethylamine forms, with aqueous mercuric chloride, a white flocculent precipitate, which, when heated over the water-bath, melts to a yellow resinous mass, solidifying in the crystalline state on cooling.

Platinum-compound, $2C^{6}H^{10}N^{2}.2HCl.Pt^{iv}Cl^{4}$.—A solution of sinethylamine in hydrochloric acid forms, with platinic chloride, reddish-yellow feathery crystals, yielding by analysis 31·55 per cent. platinum, the formula requiring 31·24 per cent.

SINAPIC ACID, $C^{11}H^{12}O^{5} = \left.\begin{matrix}(C^{11}H^{10}O^{3})''\\ H^{2}\end{matrix}\right\}O^{2}$. (Von Babo and Hirschbrunn, Ann. Ch. Pharm. lxxxiv. 19.)—An acid produced, together with sincaline, by boiling sulphocyanate of sinapine with potash or baryta-water:

$$\underset{\substack{\text{Sulphocyanate of}\\ \text{Sinapine.}}}{C^{16}H^{23}NO^{5}.CNHS} + 3KHO = \underset{\substack{\text{Sinapate of}\\ \text{Potassium.}}}{C^{11}H^{10}K^{2}O^{5}} + \underset{\text{Sincaline.}}{C^{5}H^{13}NO} + \underset{\substack{\text{Sulphocy-}\\ \text{anate of}\\ \text{Potassium.}}}{CNKS} + 2H^{2}O.$$

The best mode of preparing it is to boil the sulphocyanate of sinapine with potash-ley, supersaturate with hydrochloric acid, and purify the resulting precipitate by crystallisation from alcohol of 60 per cent. By boiling the sulphocyanate with baryta-water, the acid is obtained as an insoluble barium-salt, from which it may be separated by sulphuric acid and alcohol.

Sinapic acid crystallises in small prisms, sparingly soluble in cold, somewhat more freely in hot *water*, slightly in cold, easily in hot *alcohol*, insoluble in *ether*. It is nearly insoluble in most other acids: *nitric acid*, however, dissolves it, with red colour, apparently forming oxalic acid and a nitro-compound. *Chlorine-water* colours it, first rose-red, then purple-red, without dissolving it.

Sinapic acid melts between 150° and 200°, and solidifies from fusion in the crystalline state. When subjected to dry distillation, it turns brown, and yields a colourless oil, which, as well as the residue, forms with ammonia-gas a yellow body, slightly soluble in water.

Sinapates.—Sinapic acid forms easily soluble salts with the alkalis, sparingly soluble salts with the earths and other metallic oxides. All the sinapates, excepting the barium-salt, decompose with great facility. The solution of sinapic acid in potash- or soda-ley quickly turns red on exposure to the air, the colour afterwards changing to green and brown. The ammoniacal solution turns red-brown on exposure.

A neutral solution of potassic sinapate forms white precipitates with *chloride of calcium*, and with solution of *alum*; the latter precipitate, treated with chlorine-water, assumes first a rose-red and then a dirty-red colour. With *ferric chloride* it forms a rose-red or sometimes a purple-red precipitate, with formation of ferrous oxide. From solution of *copper-* and *lead-salts*, it throws down precipitates which soon turn blue-green; with *mercuric* and *silver-salts*, white precipitates which decompose, with separation of metal, especially on addition of more alkali.

Sinapate of Potassium is precipitated from the aqueous solution by absolute alcohol in iridescent laminæ, which soon change after the alcohol has been poured off.—The *barium-salt*, $C^{11}H^{10}Ba''O^{5}$, is prepared by precipitating the neutral ammonium-salt with chloride of barium (avoiding an excess of the latter, which would redissolve a portion of the precipitate), or by boiling sulphocyanate of sinapine with baryta-water, out of contact with air. The precipitate is to be washed with water free from carbonic acid.

SINAPINE, $C^{16}H^{23}NO^{5}$. (O. Henry and Garot, J. Pharm. xvii. 1; xx. 63.—Pelouze, Ann. Ch. Phys. [2] xliv. 214; J. Pharm. xvii. 271.—Boutron and Robiquet, J. Pharm. xvii. 279.—Fauré, *ibid.*—O. Henry and Plisson, Ann. Ch. Phys. [2] xlvi. 198.—Winckler, Repert. Pharm. xli. 169; lxvii. 257.—Simon, Pogg. Ann. xliii. 651; xliv. 593.—Boutron and Frémy, J. Pharm. xxvi. 50.—v. Babo and Hirschbrunn, Ann. Ch. Pharm. lxxxiv. 10.—Gm. xiv. 524.)—An organic base, existing as a sulphocyanate in white mustard-seed. This salt was first extracted from the fatty oil of white mustard by Henry and Garot in 1825, who at first regarded it as an acid, and called it *sulphosinapic acid*; afterwards, however, they found that the pure substance was neutral, and named it *sulphosinapisin*. Berzelius called it *sinapine*. Its true nature was first recognised by v. Babo and Hirschbrunn, who assigned to the base contained in it (the true sinapine) the formula $C^{32}H^{24}NO^{10}$, which was altered by Gerhardt to $C^{32}H^{23}NO^{10}$, or $C^{16}H^{23}NO^{5}$.

Sinapine is known only in aqueous solution and in combination with acids. The aqueous solution is obtained by gradually adding baryta-water to an aqueous solution of the acid sulphate as long as a precipitate is thereby formed: an excess of baryta must be carefully avoided, as it would immediately induce the decomposition of the base into sinapic acid and sincaline (p. 308). The aqueous solution of sinapine has a deep yellow colour, a distinct alkaline reaction, and is not precipitated either by alcohol or by ether. When evaporated it assumes a dark-brown colour, and leaves a perfectly amorphous residue. The solution forms precipitates with many metallic salts—green with cupric, yellow with mercuric, grey-brown with argentic salts: these precipitates, on standing or warming, are reduced to the metallic state. From solution of auric chloride, sinapine immediately precipitates metallic gold.

Salts of Sinapine.—These salts are colourless and more stable than the free base. Their solutions, mixed with potash or baryta-water, turn yellow, and the sinapine thereby separated is instantly resolved into sinapic acid and sincaline.

Hydrochlorate of Sinapine, obtained by decomposing the sulphate with chloride of barium, crystallises in needles very soluble in water. The solution mixed with *platinic chloride*, forms a resinous precipitate which immediately turns brown when slightly heated.

The *nitrate*, obtained also by double decomposition, crystallises in very soluble needles.

Sulphates.—The *acid sulphate*, $C^{16}H^{23}NO^5.H^2SO^4.4aq.$, is produced on adding a small quantity of strong sulphuric acid to a hot concentrated solution of the sulphocyanate in alcohol of 90 per cent., and separates on cooling in considerable quantity, so that the liquid appears completely filled with it. The crystals may be freed from adhering sulphuric and sulphocyanic acids, by washing with absolute alcohol. It forms rectangular plates, having a strong acid reaction, easily soluble in water and in boiling alcohol, nearly insoluble in ether. The crystals give off their water at 100°.—The *neutral salt*, obtained by neutralising the acid salt with baryta-water and evaporating the filtrate, is a crystalline easily soluble mass.

Sulphocyanate of Sinapine, $C^{17}H^{24}N^2SO^5 = C^{16}H^{23}NO^5.CNHS$. *Sinapine* of Berzelius; *Sulphosinapisin* of Henry and Garot.—This salt, as already observed, exists ready-formed in white mustard-seed; also, according to Henry and Garot, in the seed of black mustard and of *Turritis glabra*.

Preparation.—1. Dry mustard-powder, exhausted with ether and thereby freed from fixed oil, is treated with cold absolute alcohol as long as the alcohol acquires a reddish-yellow colour; the residue is boiled with alcohol of 90 per cent.; then pressed; and the boiling and pressing are repeated twice more. The hot-filtered tinctures yield, after half the alcohol has been distilled off, colourless crystals of sulphocyanate of sinapine, an additional quantity of which may be obtained from the mother-liquors by further evaporation and addition of sulphocyanate of potassium. Sulphocyanate of potassium likewise precipitates sulphocyanate of sinapine from the above-mentioned extracts prepared with cold alcohol.

2. Mustard-flour, freed from fixed oil by pressure in the oil-mill, is exhausted with cold and then with hot alcohol of 80 per cent.; and about half the alcohol is distilled from the united tinctures in a salt-bath, or so much, that a sample of the residue separates on cooling into two equal layers, consisting of oil and sulphocyanate of sinapine. If the concentration is carried too far, the sulphocyanate of sinapine no longer crystallises; and, on the other hand, if a sufficient quantity of the alcohol be not distilled off, part of the sinapine remains dissolved in the alcoholic oily layer, and is somewhat difficult to obtain in the form of crystallised sulphocyanate; the best way of effecting this is to add a small quantity of alcoholic sulphocyanate of potassium. The upper layer is removed; the lower watery liquid is either left to itself for a week, or as long as sulphocyanate of sinapine continues to crystallise from it; and the crystals are collected on linen, separated from the viscid mother-liquor by means of a centrifugal machine, moistened with alcohol, strongly pressed between filtering-paper, and recrystallised from alcohol of 90 per cent., then from a small quantity of boiling water, with addition of animal charcoal;—or better, the lower watery layer is mixed with alcoholic sulphocyanate of potassium, and the crystals which separate are purified as above. The mother-liquors also yield an additional quantity of sulphocyanate of sinapine on addition of sulphocyanate of potassium. (v. Babo and Hirschbrunn.)

3. Bruised white mustard-seed, freed from the greater part of the fixed oil by pressure at 50°, is exhausted with ether; the residue is digested with 7 pts. of alcohol of 80 per cent., then with 2 pts. more; the alcohol is distilled off from the tinctures till the residue is reduced to one-fourth of the weight of mustard-powder used; this residue is set aside for 14 days to crystallise; and the crystals, after being freed by ether from a red-brown matter, are purified by repeated crystallisation from water and alcohol, with addition of animal charcoal. (Winckler.)

Winckler also digests white mustard with 3 pts. of alcohol of 80 per cent.; evaporates the tincture to half the weight of mustard used; treats the residue, which is covered with oil-drops, with ether, as long as the ether is thereby coloured; and purifies the residual sulphocyanate of sinapine by solution in water and recrystallisation as above. A similar process is adopted by Simon, who however, at each extraction of the mustard-flour, uses only enough alcohol to moisten it, and subjects the whole to strong pressure; by this treatment, the exhaustion is effected more quickly than when a larger quantity of alcohol is used.

Properties.—Sulphocyanate of sinapine crystallises in loose tufts of white pearly needles (Henry and Garot); in colourless, nearly transparent, glassy prisms, mostly rectangular, truncated, grouped in stars and thin nodules (Winckler). It is neutral, inodorous, tastes bitter, and afterwards hot like mustard. It melts when heated (at 130°, according to v. Babo), forming a yellow liquid, which solidifies to a gummy mass on cooling (Winckler). It dissolves with yellow colour in *water* and in *alcohol*, in greatly increased quantity when the liquid is hot, and crystallises on cooling; also in *ether*, *sulphide of carbon*, and *oil of turpentine*. (Simon.)

Decompositions.—1. Sulphocyanate of sinapine decomposes when strongly heated, giving off stinking products, and leaving charcoal (Henry and Garot); also combustible gases (Winckler). The vapours do not smell of sulphuretted hydrogen, sulphide of carbon, or hydrocyanic acid. In the course of the decomposition, volatile bases are evolved, together with gases and empyreumatic oils, which burn with luminous flame and formation of sulphurous acid (v. Babo and Hirschbrunn).—2. It dissolves readily in *oil of vitriol*, with greenish-yellow colour and slight rise of temperature, turns brown when the solution is heated, and then chars (Winckler). Sulphocyanic acid is likewise evolved (v. Babo and Hirschbrunn).—3. In contact with *iodine*, it immediately assumes a light yellow-brown colour, and when heated melts, gives off iodine, and leaves a brown-red brittle resin (Winckler).—4. Its aqueous solution is coloured by *chlorine*, first brown-red, then red, and finally yellow, with formation of sulphuric and evolution of hydrocyanic acid (Henry and Garot). According to v. Babo and Hirschbrunn, no formation of hydrocyanic acid takes place in this and similar cases.—5. With *nitric acid* of specific gravity 1·4, or less, it immediately assumes a deep red colour, giving off red vapours, and when heated turns yellow, with formation of sulphuric acid (Henry and Garot, and others).—6. When sulphocyanate of sinapine is boiled with *peroxide of manganese* and dilute sulphuric acid, the distillate contains hydrocyanic acid, and the residue contains a substance which dissolves in water, with dark brown-red colour (Winckler).—7. It dissolves with yellow colour in *caustic potash-ley*, and if the liquid be immediately supersaturated with hydrochloric acid, separates out unaltered, provided the solution is sufficiently concentrated; but when boiled with potash, soda, or baryta-water, it is resolved, as above mentioned (p. 308), into sinapic acid, sincaline, and sulphocyanic acid (v. Babo). It is likewise coloured yellow by *ammonia*, *strychnine*, *morphine*, and *quinine*, but not by *narcotine* or *salicin* (Winckler). A trace of tobacco-smoke is sufficient to produce this colouring (v. Babo and Hirschbrunn).—8. The behaviour of sulphocyanate of sinapine to *dilute acids* and saline solutions is the same as that of other sulphocyanates. *Ferric salts* are for the most part immediately reddened by it, but sometimes it is obtained in a peculiar condition, in which it does not redden ferric salts till heat is applied. (Will; v. Babo, and Hirschbrunn.)

SINAPIS. See Mustard (iii. 1067).

SINAPISINE. The name given by E. Simon (Pogg. Ann. xliii. 652; xliv. 593; l. 379), to a white, scaly, crystalline substance, which he obtained from black mustard-seed, by extraction with alcohol and ether. The examination made of it was, however, very imperfect, and the later statements contradict the earlier.

SINAPOLINE. *Diallyl-carbamide. Diallyl-urea.* $C^7H^{12}N^2O$ =  $\left.\begin{matrix}(CO)''\\(C^3H^5)^2\\H^2\end{matrix}\right\}N^2$.—
An organic base discovered by Simon (Pogg. Ann. l. 377), and further examined by Will (Ann. Ch. Pharm. lii. 25). It is formed from cyanate of allyl, by addition of water and elimination of carbonic anhydride, in the same manner as urea is formed from cyanic acid:

$$\underset{\text{Cyanic acid.}}{2CNHO} + H^2O = \underset{\text{Urea.}}{CN^2H^4O} + CO^2$$

$$\underset{\text{Cyanate of Allyl.}}{2CN(C^3H^5)O} + H^2O = \underset{\text{Diallyl urea.}}{CN^2(C^3H^5)^2H^2O} + CO^2.$$

It may be obtained very pure by boiling cyanate of allyl with water, but is more generally prepared from sulphocyanate of allyl (oil of mustard) by the action of hydrate of lead or baryta-water:

$$2CN(C^3H^5)S + 3PbH^2O^2 = CN^2(C^3H^5)^2H^2O + 2PbS + PbCO^3 + 2H^2O$$

The oil of mustard is digested in the water-bath with recently precipitated and well-washed hydrate of lead, till the latter is no longer blackened. The residue is treated with boiling water, and the solution is filtered from the insoluble sulphide and carbonate of lead: the sinapoline then crystallises on cooling.

The oil of mustard may also be boiled with baryta-water; the liquid evaporated to dryness when quite free from odour; and the sinapoline extracted from the residue by alcohol or ether. Potash or soda acts in a similar manner, but gives rise also to secondary products.

Sinapoline crystallises from aqueous solution in shining laminæ, unctuous to the touch, fusible at the temperature of boiling water, soluble in alcohol and ether. The aqueous solution is alkaline to test-paper.

Sinapoline does not dissolve in aqueous potash at ordinary temperatures, but at the boiling heat of the liquid, it melts, without giving off ammonia, to an oil which solidifies on cooling and is soluble in water.

Sinapoline does not lose weight at 100°; at a higher temperature it partly volatilises and partly decomposes.

Salts of Sinapoline.—Sinapoline dissolves easily in acids, and is separated from the solutions by ammonia. In dry hydrochloric acid gas it melts without warming; and is converted into a thick mass of the *hydrochlorate*, $C^7H^{12}N^2O.HCl$, which gives off vapours of hydrochloric acid on exposure to moist air, and is partially decomposed by water, with separation of sinapoline.

The aqueous solution of sinapoline forms precipitates with mercuric and platinic chloride.

SINCALINE, $C^5H^{15}NO$. (v. Babo and Hirschbrunn, Ann. Ch. Pharm. lxxxiv. 22.)—An alkali produced, together with sinapic acid, by boiling sulphocyanate of sinapine with potash or baryta (p. 308). To prepare it, sulphocyanate of sinapine is heated with baryta-water, till the sinapate of barium is completely separated; the filtrate, mixed with a slight excess of dilute sulphuric acid, is freed from sulphocyanic acid by precipitation with aqueous sulphate of iron or copper: the liquid is filtered from the precipitated sulphocyanate of copper; the filtrate precipitated by baryta-water; carbonic acid is passed through it; and the solution filtered from the carbonate of barium is evaporated on the water-bath: carbonate of sincaline then remains behind. By neutralising the carbonate with aqueous hydrochloric acid, digesting the hydrochlorate with oxide of silver, and evaporating the solution filtered from the chloride of silver and excess of oxide, in a vacuum or on the water-bath, sincaline is obtained as a colourless or brownish crystalline mass.

Sincaline does not volatilise without alteration; when distilled it gives off combustible vapours having an odour of methylamine, and leaves a carbonaceous residue. It has a strong alkaline reaction, and when exposed to moist air, becomes heated, deliquesces, and rapidly absorbs carbonic acid. It precipitates most metallic oxides from their solutions, even lime, baryta, and mercuric oxide. The precipitates which it forms with aluminic and chromic salts redissolve in excess of sincaline, and the chromic precipitate is reprecipitated on boiling, like a solution of chromic oxide in potash.

Sincaline dissolves *sulphur*, and on adding a mineral acid to the solution, sulphydric acid is given off, and sulphur is precipitated, which renders the liquid milky.

Salts of Sincaline.—The *carbonate*, *hydrochlorate*, and *nitrate* are extremely deliquescent. The *chloro-aurate*, $C^5H^{15}NO.HCl.AuCl^3$, is precipitated as a yellow crystalline powder slightly soluble in cold water. It dissolves easily in boiling water, and crystallises on cooling in tufts of needles. The *chloroplatinate*, $2C^5H^{13}NO.2HCl.Pt^{iv}Cl^4$, is obtained by evaporating a mixture of the hydrochlorate and platinic chloride, in splendid orange-coloured prisms or hexagonal plates.

SINESIC ACID. The name given by Lewy (Ann. Ch. Phys. [3], xiii. 446) to a fatty acid which he obtained by heating Chinese-wax with potash-lime, and to which he assigned the formula $C^{24}H^{48}O^2$.

SINETHYLAMINE. Syn. with ETHYLSINAMINE (p. 307).

SINISTRIN. This name was given by Marquart (Ann. Ch. Pharm. x. 91) to inulin prepared from dahlia-roots by boiling with water, because it turns the plane of polarisation to the left: it appears, under the microscope, to consist of opaque white spherules, disintegrates quickly in cold water, and dissolves to a colourless liquid at 75°. Inulin prepared from the roots by washing with cold water is called by Marquart synantherin: it exhibits under the microscope transparent spherules, and dissolves when boiled with water, leaving a few thin films. In other respects it resembles sinistrin.

SINNAMINE. Syn. with SINAMINE.

SINOPITE. *Bole of Sinope. Rubrica.*—A ferruginous bole occurring in masses with fine earthy fracture, in Cappadocia. It is of brick-red colour, spotted with white, dull, opaque, friable, adheres strongly to the tongue, and breaks up in water into coarse lumps, without becoming plastic like clay, or crumbling to a sandy powder like fuller's earth. It was used in ancient times as a pigment. Contains, according to Klaproth's analysis, 32 per cent. silica, 26·5 alumina, 21·0 ferric oxide, 17·0 water, and 1·5 (= 97·0) chloride of sodium. Before the blowpipe it burns hard and black.

SINTER. A name applied to incrustations, on rocks or elsewhere, from mineral waters. According to the nature of the deposit, it is distinguished as calcareous sinter (calcspar or arragonite), silicious (quartz or opal), ferruginous (pitticite), arsenical (scorodite), &c.

SIPEERINE. *Sipirine, Sepeerine.* An alkaloïd existing, together with bebirine, in the bebeeru or greenheart-tree (*Nectandra Rodiæi*), a lauraceous tree growing in Guiana. It was discovered by Rodie in 1834, and examined more particularly by Maclagan (Ann. Ch. Pharm. xlviii. 106). [For the mode of preparation see Bebirine, i. 526.]

Sipeerine forms a dark red-brown, shining, non-crystalline, resinous mass, separating from the vessel in which it is prepared in scales. It is very slightly soluble in water, easily in alcohol, either anhydrous or hydrated, but is insoluble in ether. It neutralises acids, forming olive-brown salts.

SIPOPIRA, or **SEBIPIRA.** The commercial name of the bark of *Sebipira major*, a tree growing in Brazil. The bark contains tannin, fat oil, resin, sugar, &c. (Handw. d. Chem. vii. 730.)

SISMONDIN. A mineral resembling chloritoïd, occurring in the chlorite-slate of St. Marcel in Piedmont. Melts with great difficulty before the blowpipe to a blackish glass. Analysed by Delesse (Ann. Ch. Phys. [3] ix. 388) and v. Kobell (J. pr. Chem. lviii. 40):

SiO^2.	Al^2O^3.	FeO.	MgO.	H^2O.	Undecomposed.			
24·1	43·2	23·8	—	7·6	—	=	98·7	Delesse.
25·75	37·50	21·00	6·20	7·80	0·50	=	98·75	v. Kobell.

The magnesia appears to have been overlooked in the first analysis.

SISSERSKITE. The name given by Haidinger to iridosmine from Sissersk in the Ural, having nearly the composition $IrOs^3$ or $IrOs^4$, to distinguish it from the variety found at Newjansk, the composition of which may be represented by $IrOs^8$. As, however, the two varieties crystallise in the same form, it is probable that they are not distinct mineral species, but that osmium and iridium crystallise together isomorphously in various proportions.

SISYMBRIUM. Hedge-mustard (*Sisymbrium officinale*) contains, according to Pless, allylic sulphocyanate unmixed with oxide.

SITIC ACID. The name given by Berzelius to Liebig's œnanthic acid (iv. 174).

SIXE. Gmelin's name for propylene, C^3H^6.

SKAPOLITE. Syn. with Scapolite.

SKLERETINITE. Syn. with Schleretinite (p. 204).

SKLEROCLASE, or **SCLEROCLASE.** The name applied by v. Waltershausen to diplumbic sulpharsenite, $2PbS.AsS^3$, which he regards as one of the constituents of binnite (i. 583).

SKOGBÖLITE. Nordenskiold's name for the tantalite of Skogböle in Finland, distinguished by a comparatively high specific gravity, small proportions of manganese and tin, and dark brown colour of its powder.

SKOLECITE. Syn. with Scolecite.

SKOLOPSITE. A silicate from the Kaiserstuhl in the Breisgau, occurring in lumps, with granular structure and splintery fracture. Hardness = 5·0 nearly. Specific gravity = 2·53. Colour smoke-grey, greyish, or reddish-white. Translucent on the edges. Slightly brittle. Before the blowpipe it fuses like vesuvian, with intumescence and spluttering, to a shining greenish-white glass enclosing small bubbles. With borax it slowly forms a colourless bead; with phosphorus-salt the same, and a skeleton of silica; with soda it yields the reaction of sulphur. In the pulverulent state it is easily decomposed by hydrochloric acid, with separation of gelatinous silica. It contains, according to the mean of v. Kobell's analyses (J. pr. Chem. xlvi. 484), [illegible] silica, 17·9 alumina, 2·5 ferric and ferrous oxides, 8·9 manganous oxide, 15·5 lime, 2·2 magnesia, 11·5 soda, 1·3 potash, 4·1 sulphuric anhydride, and 0·9 chloride of sodium, which may be approximately represented by the formula

$Na^2SO^4 . 6(M^2 ; \bar{M}'')SiO^3 . \overset{\prime\prime\prime}{\bar{Al}}{}^4Si^3O^{12}$.

SKORIAN. Breithaupt's name for a variety of spinel, closely allied to hercinite, and containing, according to John, 63·0 per cent. alumina, 23·0 ferrous oxide, 6·0 magnesia, 6·0 silica, together with magnesia and other constituents not determined. It occurs at Bischofsheim in the Rhöngebirge, and at Hinter-Hermsdorf, near Schandau in Saxony. (Handw. vii. 999.)

SKORILITE. A scoriaceous mineral from Juan del Rio del Calvaxio in Mexico, containing, according to R. Thomson (J. pr. Chem. viii. 506), 58·0 per cent. silica, 16·8 alumina, 13·3 ferrous oxide, 8·6 lime, and 2·0 water. It occurs in brown masses, containing numerous cavities. Streak white. Hardness = 2·0. Specific gravity = 1·70. Before the blowpipe it becomes lighter in colour, but does not melt. With fluxes it gives the iron reaction.

SKORODITE. Syn. with SCORODITE.

SKORZA, or **SCORZA.** A variety of EPIDOTE (ii. 489).

SKOTIN. Syn with Bucklandite, or lime and iron epidote.

SKUTTERUDITE. An arsenide of cobalt, $CoAs^3$, occurring at Skutterud, near Modum, in Norway (i. 1042).

SLIBOWITZ. *Slibowitza, Slivowitz.* An ardent spirit, prepared in Bohemia and Hungary, by distilling the fermented juice of plums.

SLOANITE. A mineral from the gabbro of Tuscany, occurring in radiated masses, cleaving distinctly parallel to the faces of an orthorhombic prism of 105°. It is white, opaque, with pearly lustre. Hardness = 4·5. Specific gravity = 2·441. Melts before the blowpipe, with intumescence, to a white enamel. Dissolves in acids, with separation of gelatinous silica. Contains, according to Bechi (Sill. Am. J. xiv. 64), 42·2 per cent. silica, 35·0 alumina, 8·1 lime, 2·7 magnesia, 0·3 soda and potash, and 12·5 water: probably a decomposed zeolite.

SMALT. A beautiful blue glass, prepared (chiefly in Saxony) by melting roasted cobalt-ore with silica and potash. The ore (arsenide or sulpharsenide containing nickel, copper, and iron) is first roasted to such a degree as to oxidise the cobalt and leave the nickel, iron, and copper in combination with arsenic and sulphur. Four or five parts of this roasted ore are then mixed with 10 pts. of ground calcined quartz and 4 pts. of potassic carbonate, and the mixture is slowly melted in pots arranged on a furnace resembling that used in glass-houses. The oxide of cobalt then unites with the fused potassic silicate, forming a deep blue glass, while the mixed arsenides and sulphides of nickel, copper, and iron fuse and collect at the bottom of the pot, in the form of a brittle metallic-looking mass called speiss, which is used for the preparation of nickel. The pot is then skimmed, and the glass is ladled out and poured into cold water, by which it is split into innumerable fragments. The broken glass is stamped to powder and ground under water between granite stones, in a vessel through which a gentle stream of water is constantly flowing. The water carrying the powdered smalt in suspension is made to pass through a number of depositing vessels, so arranged that the overflow of each shall pass into the next. Moreover, each of these vessels is larger than the one which precedes it, so that the time during which the washings are retained in them goes on progressively increasing, and the deposited particles continually increase in the minuteness of their subdivision, the colour becoming less intense the greater the degree of subdivision of the particles. (*Miller's Elements of Chemistry*, 3rd edit. ii. 555. For further details, see *Ure's Dictionary of Arts*, &c. i. 784, and *Handw. d. Chem.* vii. 1000.)

Smalt is essentially a potassio-cobaltous silicate, sometimes approaching nearly to the formula $(K^2O.Co''O).6SiO^2$. Its composition is, however, subject to considerable variation, as the following analyses by Ludwig (J. pr. Chem. li. 129) will show:—

	Norwegian: deep-coloured.	German: deep-coloured.	German: pale; coarse.
Silica	70·86	66·20	72·12
Potash and Soda	21·41	16·31	20·04
Cobaltous oxide	6·49	6·75	1·95
Alumina	0·43	8·64	1·80
Ferrous oxide	0·24	1·36	1·40
Arsenic Anhydride	trace	. .	0·08
Water and Carbonic Anhydride	0·57	0·92	0·46
	100·00	110·18	97·85

SMALTINE. Native cobaltous arsenide, $Co''As^2$ (i. 1041).

SMARAGDITE. A granular actinolite of emerald-green or grass-green colour, sometimes occurring intergrown with augite of similar colour. Mixed with garnet it forms the rock called eclogite, and occurs also in gabbro mixed with saussurite or labradorite.

SMARAGDOCHALCITE. Syn. with ATACAMITE (i. 429).

SMECTITE. A term sometimes used as a synonym of *fuller's earth*; applied also more particularly to an argillaceous mineral from Cilly in Lower Styria, analysed by Jordan, and another from Condé in France, analysed by Salvétat. (See SILICATES OF ALUMINIUM, p. 259.)

SMELITE. An aluminic silicate from Telkebanya in Hungary. (See SILICATES, *loc. cit.*)

SMILACHIN. The name given by Reinsch (Repert. Pharm. lxxxii. 145) to a crystalline substance which he obtained from the root of *Smilax China* (L.).

SMILACIN. Syn. with SARSAPARILLIN (p. 198).

SMITHSONITE. Syn. with Calamine, or native carbonate of zinc (i. 713).

SOAP. *Savon. Seife.*—In ordinary language, the term soap is applied only to the potassium- and sodium-salts of the fat-acids—stearic, palmitic, oleic acid, &c.,—produced by the action of potash and soda upon the fats; but in scientific language, the same term is extended to all the metallic salts of the fat-acids, among which the lime-soap obtained as a secondary product in the stearic acid manufacture, and the pharmaceutical preparation called lead-soap or lead-plaster, obtained by heating olive-oil with oxide of lead, may be particularised as being of practical importance.

The ordinary neutral fats—such as tallow, palm-oil, olive-oil, cocoanut-oil, &c.—are the glyceryl-salts or glyceric ethers of the fat-acids (see GLYCERIDES, ii. 881); and their conversion into soaps, or saponification, by the action of alkalis or other bases, is the converse of the process of etherification, consisting in the separation of the glyceryl and the acid-radicle, and an interchange between the glyceryl and the metal of the alkali, resulting in the formation of an alkaline salt of the fat-acid—that is to say, a soap—and glycerin: thus with stearin (neutral glycerylic stearate) and potash:

$$\begin{array}{ccccccc}
\left.\begin{matrix}(C^{18}H^{35}O)^3\\(C^3H^5)'''\end{matrix}\right\}O^3 & + & \left.\begin{matrix}K^3\\H^3\end{matrix}\right\}O^3 & = & \left.\begin{matrix}(C^3H^5)'''\\H^3\end{matrix}\right\}O^3 & + & \left.\begin{matrix}(C^{18}H^{35}O)^3\\K^3\end{matrix}\right\}O^3.\\
\text{Stearin.} & & \text{Potassic hydrate (3 at.).} & & \text{Glycerin.} & & \text{Potassic stearate (3 at.).}
\end{array}$$

The ordinary method of saponifying neutral fats consists in boiling them with solution of caustic potash or soda. Most fats require long-continued boiling with excess of alkali to convert them completely into neutral soaps; some, however (as lard, beef-marrow, and oil of sweet almonds), may be saponified by agitation with caustic alkali at ordinary temperatures. Alkaline carbonates also decompose the neutral fats when boiled with them; but the process, when conducted under the ordinary atmospheric pressure, is very tedious, and does not yield a perfect soap. Complete saponification may, however, be effected by boiling neutral fats with solutions of alkaline carbonates under increased pressure, as in the apparatus patented by Tilghman (ii. 886), in which a mixture of the neutral fat and alkaline solution is forced by a pump through a long coil of iron tubing heated to 350°—400° F.

The fat-acids (stearic, oleic acid, &c.), when already separated from glycerin, are easily saponified by the action of alkaline carbonates; in this manner soap is extensively prepared from the crude oleic acid or red oil (iv. 192), obtained as a bye-product in the manufacture of stearic acid. Resins also, which are chiefly mixtures of acid compounds, easily decompose alkaline carbonates and form soaps.

As the neutral fats occurring in the vegetable or animal body are not simple glycerides, but mixtures of several compounds of that class (stearin, palmitin, olein, &c.) it follows that the soaps resulting from their saponification will be mixtures of the potassium- or sodium-salts of two or more of the corresponding fat-acids, the soap being, *cæteris paribus*, more solid in proportion as the acids of higher melting-point and atomic weight predominate in it.

The properties of soap depend also in great measure on the alkaline base contained in it. Potash-soaps are deliquescent, and do not dry up when exposed in solution to the air, but retain so much water as to form a soft slimy jelly: when artificially dried they absorb a large quantity of moisture, and likewise become converted into a jelly. This kind of soap is called soft soap, in contradistinction to the soda-soap, or hard soap. The latter neither retains so much water, nor does it absorb so much as to render it soft; but hardens when exposed to the air, and with a certain amount of water forms a perfectly solid mass, in which it is difficult to make impressions with the finger.

100	parts of dry potassic	oleate	absorb from the air	162	parts of water.
100	,, ,, ,,	palmitate	,, ,,	35	,, ,,
100	,, ,, ,,	stearate	,, ,,	10	,, ,,
100	,, ,, sodic	stearate	,, ,,	7½	,, .

Soft soap is made from train-oil and the drying vegetable oils, such as linseed oil, hard soap from tallow, and the non-drying vegetable fats and oils, and mixtures of these with rosin. Rosin by itself forms a soft soap, either with potash or with soda.

Every kind of soap found in commerce contains a variable quantity of water, partly in chemical combination. Hard soap becomes harder by drying, so that at last it can be pulverised. Potash-soap decomposes the salts of sodium, *e.g.* common salt, or sulphate of sodium, forming chloride or sulphate of potassium, and a soda-soap. It is, indeed, in this indirect manner that hard (soda) soap is sometimes manufactured in Germany.

Soap is perfectly soluble in alcohol and in hot water. The aqueous solution is more thickly fluid and slimy than the alcoholic solution, but both solidify to a jelly at a certain stage of concentration; opodeldoc is soap mixed with alcohol in this state of concentration. Potash-soap is more readily soluble in water than soda-soap. This is better seen with the salts of the pure fatty acids than with ordinary soap. Stearate of sodium undergoes hardly any change when brought together with 10 parts of water, whilst stearate of potassium is converted by it into a thick jelly. Oleate of sodium is soluble in 10 parts of water, oleate of potassium in 4 parts, and forms a jelly even with 2 parts of water; palmitate of potassium is converted by 10 parts of water into a stiff transparent jelly.

Cold water does not dissolve the alkaline oleates, palmitates, and stearates, which constitute ordinary soap, without decomposition, the neutral salts being thereby resolved into alkali which dissolves, and into an acid salt which is precipitated. The same decomposition occurs when hot solutions of soap (particularly weak solutions) are cooled.

This reaction explains why, in using soap, even with the purest water, a whitish turbidity (*soapsuds*) is always obtained; the alkaline property of soapsuds is due solely to the liberation of a portion of caustic potash or soda, which removes the fatty impurities in water.

Soap is quite insoluble in a solution of *common salt* containing more than 1 part of salt in 400 of water: hence, on adding a certain quantity of salt to the contents of the soap-pan, consisting of soap already formed mixed with glycerin and excess of alkali, and continuing the boiling for a certain time, the soap ultimately separates completely from the watery liquid, and rises to the surface, in the form of a granular mass or curd, while the glycerin and alkaline salts remain dissolved at the bottom of the pan, constituting what are called "spent leys," and may be drawn off or pumped out. The soap may then be ladled out or run off into iron or wooden frames, and left to cool and solidify.

All varieties of soap are not separated with the same ease from their solutions, by means of salt. Thus soap made from cocoanut-oil requires a much larger quantity of salt to separate it from solution than soap made from tallow, the former being soluble in saline solutions, in which the latter is perfectly insoluble. Rosin-soap is affected by common salt in the same manner as the soaps from fat.

The same results as those obtained by the use of common salt are also produced, although in a less energetic manner, by chloride of potassium (which acts but slightly), alkaline carbonates, sulphate of sodium (also very weak in its action), acetate of potassium, and sal-ammoniac. In weak caustic ley, soap is perfectly soluble: in strong ley, on the contrary, or when the concentration of the ley is increased by boiling, the soap separates in the same manner as from a solution of common salt. For this reason, soap-boilers are in the habit of using weak ley, particularly in the beginning of their operations, as stronger ley, in separating the soap, would prevent the necessary amount of contact amongst the ingredients, and very much retard the process of saponification.

It is impossible, during the preparation of soap, entirely to avoid the presence of earths and metallic oxides. These, consequently, decompose a small portion of the soap, combining with the fatty acid, which they take from the alkali. Portions of lime and magnesia constantly accompany the caustic ley, and are brought with it into the boiling-pan, and the sides of the vessel are always sufficiently acted upon to impart a visible trace of iron or copper to the soap. The soaps formed with lime, magnesia, iron, and copper are not soluble, and they are much less rapidly softened by heat than the corresponding alkaline compounds. They are disseminated, however, in such a minute state of division throughout the mass of hot soap, as almost amounts to solution. As the soaps of iron and copper possess the colours peculiar to the salts of those metals, the whole mass of soap acquires by their presence a uniform greenish or blue colour, partly caused by the sulphur contained in the ley (particularly in soda-ley), forming sulphide of iron or copper. When a soap of this kind is allowed to cool rapidly, the cut surface presents a uniformly coloured appearance, something like wet slate. If the mass, however, cools slowly, the soaps of the earths and metallic oxides separate from the great bulk, and collect into larger or smaller groups in different parts with a certain degree of regularity, giving a *marbled* or *mottled* appearance to the cut surface. The substances which impart the mottled appearance to soap, are only held in suspension in consequence of its thick state of fluidity. The mottled appearance may therefore be entirely removed, and white soap produced, by adding a certain quantity of water, so that those substances may subside, while the soap is still in a perfectly liquid state in the boiling-pan. This additional quantity of water is not again separated, but remains with the soap. Great importance was formerly attached in commerce to the mottled appearance of the soap, as affording a sure indication that the amount of water in the soap cannot exceed a certain limit. Methods have, however, been discovered of imparting any kind of mottled appearance to soap containing much more water than the ordinary curd-soap, by mixing mineral colours with it when it has attained a certain stage of hardening. The dark-coloured mass formed by the subsidence of the impurities above mentioned is technilly called "niger" or "nigre," and is sometimes used for mottling other soaps.

Hard Soaps.—These soaps, as already observed, are made with non-drying oils, or solid fats, and soda. Their hardness is in proportion to the amount of stearic and palmitic acid which they contain. Soda-soaps, made with drying oils, such as linseed-oil, are pasty, and easily liquefied by a small quantity of water; in fact, they approach to the character of soft soaps made with potash.

The most important kinds of hard soap are those made with tallow and with olive-oil, the former material being used in England and other northern countries, the latter in the South of Europe.

The following description, by Mr. Gossage, of the English method of making hard soap, is taken from Richardson and Watts' *Chemical Technology* (i. [3] 679):—

"The fatty and oily materials which are used for the production of hard soaps in this country are tallow, palm-oil, and cocoanut-oil, also rosin, the whole of which are saponified by soda.

"The manufacturer provides himself with solutions of caustic soda of various strengths, called 'leys,' these being obtained by boiling together a solution of carbonate of soda and slaked lime, running off the first solutions, and washing the residual carbonate of lime with several affusions of water—the last liquors thus obtained being used for dissolving a fresh batch of carbonate of soda.

"It is a well-known fact that lime, in whatever proportion it may be used, does not effect the perfect decomposition of carbonate of soda, unless the latter is present as a weak solution. And as any alkali in the state of carbonate which may be introduced into the soap-copper is incapable of decomposing the neutral oils or fats, it becomes wasted; therefore the manufacturer uses solutions of carbonate of soda of such strength as will yield leys (solutions of caustic soda) having a specific gravity not exceeding 1·090.

"Soap-pans are made of various sizes, some being as large as 15 feet diameter and 15 feet deep, capable of yielding 25 to 30 tons of finished soap in one operation. They are at the present time constructed of wrought-iron plates joined together by rivets. The contents of these pans are usually caused to boil by the injection of free steam through a number of small holes in a circular bent pipe, which is in connection with a steam-boiler. The pans are also sometimes heated by means of fires placed underneath the lower part, or by steam-chambers formed round the lower part of the pans.

"The manufacturer charges his soap-pan at the commencement with a quantity of neutral oil or fat, and adds to this weak leys having a specific gravity of about 1·050°. He causes steam to be injected to produce ebullition and mixing. If the process goes on properly, the oil or fat which was previously floating on the surface of the ley becomes speedily combined therewith, producing a uniform milky emulsion, from which no watery particles separate on cooling. If this combination does not take place, the operator adds either water or weaker ley, and continues the boiling until the perfect emulsion is produced; at this period all taste of alkali in the compound has passed away—the tongue being used, in place of turmeric-paper, to ascertain the presence of free alkali. The combination of the oil or fat with the mineral alkali, or the displacement of the glycerin, having been thus fairly put in progress, the operator makes repeated additions of stronger leys, continuing the boiling until he finds the presence of free alkali in the compound; he then adds more oil or fat, or some rosin; he also continues to make repeated additions of stronger leys. In this part of the operation he takes care that there shall be no excess of alkali present in the compound at the period when the soap-pan has become nearly filled by the repeated addition of oils or fats and leys. He then adds common salt to the mixture, which, by its superior affinity for water, as compared with that of the saponaceous compound, effects the decomposition of the emulsion, and causes this to be separated into soap combined with a definite quantity of water, but not having its full proportion of alkali, and a solution of common salt, which latter contains the glycerin of the fats or oils employed. The soap floats in a granulated state on the surface of the solution, which is then called 'spent leys,' and should contain no free alkali. After a few hours for subsidence, the exhausted solution or spent ley is withdrawn from the soap-pan from under the imperfectly made soap, and is rejected as worthless.

"The workman commences his second operation by the addition of some weak ley to the imperfect soap, and by boiling he brings the contents of his pan again into a state of homogeneous mixture,—called the 'close state' as contradistinguished from the condition in which the soap is granulated and separated from the liquid contents of the pan; and if he has not already added his full complement of oils or fats, he completes the addition of these, adding also strong leys, until he finds the mixture has acquired a strongly alkaline taste. He then adds sufficient common salt to cause the separation of the soap from the alkaline solution, and boils the soap for some hours in the presence of the alkaline solution, to ensure the whole of the fatty matter being combined with alkali. If it is intended that the product should be framed as a 'curd' soap, it is allowed to remain quiescent for a few hours, so that the leys may subside; and the soap is then skimmed off and transferred to the 'frames,' in which it solidifies by cooling, and is then divided, by cutting with wires, into slabs and bars ready to be delivered to consumers. If the soap contains rosin as part of its acid constituents, it requires a further operation before framing. This consists in melting the curd-soap (after abstraction of the alkaline leys from the lower part of the pan) with the addition of water, and boiling the mixture by steam or fire, or both steam and fire, so as again to produce a homogeneous compound, containing an indefinite proportion of water, and allowing this compound to remain quiescent for two days, when a separation takes place, resulting in the elimination of a definite compound, containing about 65 p.c. of fatty acids, 6·5 of soda, and 28·5 of water. This forms the upper stratum of the contents of the soap-pan, underneath which is an indefinite compound, technically called 'nigre,' containing a much larger proportion of water. When it is judged that the separation of these compounds has been well effected by subsidence, the upper portion, or the definite compound, is usually taken out of the soap-pan by ladling, and transferred to frames, to solidify by cooling. The residual portion, which contains an excess of alkali as well as of water, is boiled up with salt and the addition of fatty materials, to form part of the succeeding boil of soap.

"The nigre, removed as above described, is particularly well adapted for making mottled soap. For this purpose it is treated with the usual finishing ley for a mottled soap, and boiled till it is fit to be transvased into the frames. The quantity of nigre obtained from one fitting or purifying operation is not enough to be conveniently boiled by itself; it should therefore be saved, and six or more batches operated upon at a time. Occasionally a portion of bone-fat may be added, and the soap finished as ordinary mottled soap."

The method of making olive-oil soap, as practised in France and Italy, and the modern German method of making tallow-soap, are similar in principle to the above. The old German method consisted in saponifying the tallow with potash, and converting the resulting potash-soap into a soda-soap by decomposition with common salt. This method, brought to great perfection by long experience, enabled the manufacturer to prepare an excellent soap from very impure materials; but the increasing price of potash, and the cheapening of soda, have caused it to be nearly abandoned for the modern method of saponification by soda alone. For details of these methods, and for figures and descriptions of the machinery used in soap-making, see *Chemical Technology*, vol. i. pt. 3.

Cocoanut-oil Soap; Marine Soap.—Cocoanut-oil differs in constitution from other vegetable oils and from tallow, and its reaction with saponifying agents is also quite peculiar. The soap prepared from it can only be separated from solution by very strong solutions of common salt; in fact, it is soluble in dilute brine, and is therefore serviceable for washing in saltwater: hence the name *Marine Soap.*

Cocoanut-oil soap is prepared with the strongest soda-ley, of specific gravity 1·16 (20° Bm.), and by using perfectly pure and caustic ley, and avoiding excess as much as possible, the process of salting out may be dispensed with. The saponification is facilitated by the addition of potash to the soda.

Pure cocoanut-oil soap hardens much too quickly to exhibit any distinct formation of curd, and is consequently incapable of marbling by itself: it is very white, translucent like alabaster, exceedingly light, and forms a good lather, but always possesses a disagreeable savour. No means have as yet been made known to remove this smell, although it appears that several manufacturers are possessed of the secret. An important property of cocoanut-oil soap is its power of combining with more water than can ever be communicated to tallow-soap, and this property of the soap frequently gives rise to dishonest traffic. Cocoanut-oil actually produces no greater quantity of soap than an equal weight of tallow, but the soap from the former can easily be made to absorb one-third more water or ley. Ordinary soap treated in the same manner, or containing the same quantity of water, would be so soft that it would yield easily to the pressure of the thumb; but cocoanut-oil soap neither exhibits any want of consistence or softness, nor does its appearance in any way indicate the fraudulent practice which has been adopted in its manufacture.

A remarkable fact observed by soap-boilers, but by no means satisfactorily explained, is that cocoanut-oil is saponified with so much the more difficulty the more rancid it has become.

In general, cocoanut-oil is not saponified alone, but is employed as an addition to tallow, &c., for the purpose of producing quickly-solidifying soaps containing a large proportion of water, which could not be obtained from tallow alone. It is even possible to prepare soap on a large scale in a few hours, without salt, and almost without fire, by the use of cocoanut-oil and tallow, which are merely warmed together with strong ley sufficiently to melt the fat, and kept in a constant state of agitation.

The different kinds of cocoanut-oil soap, which all belong to the class of soaps containing a considerable quantity of water, are marbled artificially. Marbling or mottling of this kind is not dependent upon the production of *Curd* and *Flux*, but is simply a mechanical effect, carried out in the following manner:—The blue or red colour (bole, &c.) is rubbed up with a residue of the soap, or better with a separate portion of good cocoanut-oil soap, until the whole acquires a uniform red or blue colour. This is now scooped into the form in alternate layers with the colourless soap, and by stirring the mass together, streaks and veins are produced in all directions.

Castor-oil Soap.—Castor-oil is readily saponified by strong soda-ley. The product is white, amorphous, and translucent, and possesses considerable hardness, even when it contains as much as 70 per cent. of water. (Soeber, Dingl. polyt. J. cxxxviii. 306.)

Palm-oil Soap.—This soap is boiled with caustic soda, nearly in the same manner as tallow-soap. It has an agreeable but powerful smell, and a yellow colour when the oil is used in an unbleached state, but is white, with a very slight odour, when the oil has been bleached. Palm-oil is seldom used as soap-stock without the addition of some other fat: 3 lbs. of palm-oil to 1 lb. of tallow forms a good soap. An inferior article, called "demi-palme," is obtained from 1 lb. of palm-oil with 4 lbs. of tallow.

Palm-soap, when carefully prepared from pure materials, possesses emollient properties, which, combined with an agreeable odour, render it well adapted for toilet purposes. In France a good toilet-soap is prepared from a mixture of 9 parts of palm-oil and 1 part of cocoanut-oil; and a demi-palme soap, also for the toilet, with 11 parts of white tallow, 3 parts of palm-oil, 1 part of cocoanut-oil, and 1 part of purified yellow resin.

Rosin (or Yellow) Soap.—Colophony at the boiling temperature, when it is perfectly fluid, combines with the alkalis much more rapidly and with greater ease than the fats themselves. The soap separates on the surface, when an excess of carbonate is used, or in presence of common salt, as a thick slimy brown mass, smelling strongly of rosin, and containing 15·8 per cent. of dry soda. The amount of water in this soap, although not exceeding 27 to 30 per cent., is nevertheless sufficient to communicate to the soap a smeary viscid consistence, which is not altered by long exposure to the air. The attraction of the soap for water is so great, that it becomes liquid on exposure, after having been previously dried artificially.

Although rosin-soap by itself is thus unfitted for use, an excellent and perfectly firm product is obtained by its combination in certain proportions with tallow and palm-oil soap. The amount of rosin in this mixture should not exceed one-third of the fat; 15 per cent. of rosin makes a good soap, but beyond that limit, the soap is depreciated in colour and firmness. The grease-stock of which this kind of soap is generally made consists of kitchen-fat, bone-fat, and red oil.

The best plan of preparing this soap, is to saponify the rosin and tallow separately, and to mix the two soaps in the boiler, where they are retained in a state of ebullition for some time, until a uniform mixture has been effected; salt is then added, and the soap brought into the moulds. It is not advisable to mix the separate soaps in the moulds, which is a plan sometimes adopted. In this country and in America, where rosin-soap was first manufactured, it is usual to add the rosin, in the form of coarse powder, with the last quantity of ley, to the fatty (palm-oil or tallow) soap, consequently before the boiling is finished; and to boil the mixture with the necessary addition of ley for completing the formation of the resinous compound. This point is attained when a cooled specimen presents the proper consistence, and leaves no film of rosin when used for washing the hands. The boiling finishes with the addition of some weak ley to the soap, which has already separated from the under-ley; this addition is made in order to facilitate the deposition of the impurities with which commercial colophony is always mixed; the soap is then carefully filled into the moulds.

Rosin-soap thus prepared has a brownish colour, which passes into that of yellow wax when palm-oil is used, and this of course requires no previous bleaching. It is very firm, somewhat rough to the touch, and very translucent. The best quality exhibits on the cut surface a fibrous structure like that of wood. It produces an excellent lather, but always retains the smell of rosin. The low price of rosin renders this soap cheap, and for common washing purposes, where the smell is not an objection, it is a highly useful product.

Red Oil or Oleic Soap.—This oily acid is much used for the manufacture of soap, the saponification being easily effected, inasmuch as the acid is already separated from the glycerin, and has merely to enter into combination with the alkali.

It may be prepared by boiling 1300 lbs. of soda-ley of 18° B. in the kettle, and treating it in separate portions during stirring with 1000 lbs. of red oil or oleic acid.

Oleic acid is also frequently used, together with tallow or beef-marrow—for instance, 3 pts. of oleic acid to 2 pts. of the neutral fat—also with rosin.

Campbell Morfitt has patented a process (1858, No. 588) for preparing soap with red oil or other fat-acid and carbonate of soda, in the form of *barilla, kelp, trona, sal-soda, soda-ash, bicarbonate of soda*, &c.

The red oil, or other fatty acid, is poured into an open pan with a fire beneath, or, preferably, into a kettle or tub, which it fills to one-third of the depth, and agitated and heated by steam twirl. If it is desired to make a grade of soap lower than toilet-soap, rosin is to be added in small lumps as soon as the oil has become hot. The proportion of rosin may range from 5 per cent. of the fat-acid used and upwards. When, after continued heating and stirring, the rosin becomes entirely dissolved, carbonated alkali, finely powdered, is to be added portionwise to the homogeneous mixture of fat and rosin, while the twirl is kept slowly revolving. When all the alkali is in, and the intumescence has subsided, the paste will begin to thicken, and will promptly assume the condition of soap. At this stage it is shovelled out into the frames, and left to settle.

For neutral soaps, the quantity of carbonated alkali should only slightly exceed the chemical equivalent proportion, and must be determined by calculation from the combining number of the fat-acid which constitutes the "stock." For strong soaps, the quantity may be increased several per cent. beyond that proportion. For toilet-soaps the rosin is omitted.

The relative proportions of fat, rosin, alkali, and water in this soap being adjusted at the beginning, there is no waste ley or any other residue; and the soap is said to come out promptly, and in greater perfection than can be readily obtained by the usual method of boiling soap upon caustic ley. The soap is always uniform in appearance and composition, and does not shrink or deteriorate by time and atmospheric influence. It wastes slowly in water, gives a rich lather, and whitens the clothes.

Soft Soap.—The substance commonly called "soft soap" is a more or less impure solution of potash soap in caustic ley, forming, at ordinary temperatures, a transparent smeary jelly. If an attempt were made to separate this soap from the ley by means of salt, the potash-soap would be converted into hard soda-soap by the chloride of sodium.

The materials employed in this country for making soft soap are whale-oil, seal-oil, linseed-oil, and tallow; on the Continent, hemp, linseed, camelina-oil, and poppy-oil (which belong to the class of drying oils, and do not become solid at 0° C.) are used; also the different varieties of rapeseed- and train-oils, which do not dry up, and become partially solid at 0° C. The former produce a softer kind of soap, the latter soap of firmer consistence; it is therefore usual to mix the oils in different proportions, according to the season of the year, choosing the drying oils in the winter, and the others for the summer, when the market-price admits of this selection being made.

In boiling soft soap, the weaker leys from 9° to 11° B. (specific gravity 1·06 to 1·08) are first used, and a moderate heat is applied, and kept up until complete combination is effected,—*i.e.*, until a thick sticky fluid falls in streaks from the stirrers; this ought to possess a shining appearance, and although it may be somewhat turbid, should not resemble soap separated by means of salt.

As soon as these characters clearly appear, the clarification is commenced by the gradual addition of stronger ley. This is kept up at intervals until the mass of soap assumes the appearance of a transparent slime, a drop of which let fall on a glass plate remains clear on cooling without exhibiting any fatty border, which would indicate incomplete saponification: if, on the other hand, there is an excess of ley, the drop is granular without lustre, and a grey skin gradually spreads over its whole surface. When the right proportions have been attained, the excess of water is removed by evaporation, the fire being increased and the evaporation accelerated by beating the froth with stirrers, so as to renew the air over its surface. As evaporation proceeds, the soap becomes thicker, its colour becomes darker, and less froth is produced. At last the froth is so much diminished that the soap sinks, and the bubbles are so far larger that they resemble films or lamellæ, which overlap and cover each other upon the surface. This is what the soapboilers term the *lamination*, and the noise occasioned by the process gives rise to the saying, "The soap talks." The soap is now really finished, but another specimen or test is taken before it is scooped out into the moulds. When this no longer shows any opaque zone, after having cooled for some time, or only in a very slight degree, it may be safely concluded that the proportions in the pan have been properly attained. The fire is then extinguished, the soap is left for some time longer in the pan to cool, and packed in small casks for sale.

There are two kinds of soft soap known in commerce, the composition of which is as follows:—

	First quality.	Second quality.
Fat-acids	50·0	40·0
Potash	11·5	9·5
Water, &c.	38·5	50·5
	100·0	100·0

Some kinds of oil, hempseed-oil for example, impart to the soap a green colour, which is much prized by consumers: hence it is often artificially produced, by mixing the soap with indigo precipitated by potash from its solution in sulphuric acid.

A so-called corn or grain is sometimes produced in soft soap by the addition of tallow. The soap then retains its ordinary character, but fine granular particles of a crystalline structure are observed in it, consisting probably of salts of stearic and palmitic acids. The formation of this grain requires a certain degree of heat, and can only be effected in the colder seasons of the year, at temperatures between 9° and 15° C. (48° and 59° F.). This process is called "figging;" it is practised merely from habit, and no useful object is gained by it. Attempts have been made to imitate this useless appearance in a manner calculated to injure the quality of the soap. Thus, for instance, slaked lime has been used, with the production of a lime-soap, and even starch has sometimes been mixed up with the soap.

All kinds of soft soap exhibit a strong alkaline reaction, and are characterised by a penetrating disagreeable odour, which, however, does not necessarily resemble that of the fats employed. The smell is most perceptible in soaps prepared from train-oil, and is due to the presence of potassic valerate.

Soft soap is used to some extent for washing coarse linen, but it is of far greater importance, as an indispensable and powerful detergent, in the linen-bleaching works.

Soda Soft Soaps.—According to Gentele's recent experiments on a large scale, the potash-base of soft soaps may in part be replaced by soda, without disadvantage to the resulting soap. The product has the characteristics of soft soap, but contains a little more water. The leys must be free from salt and other saline impurities, as they prevent the clarifying of the soap. The best proportion is 1 pt. of soda to 4 pts. of potash-ley. A mixture of 100 lbs. of red oil, 50 lbs. of tallow, and 3,750 lbs. of hempseed-oil makes a good stock for this soap.

All the soft soap (*savon vert*) made in Belgium and Germany contains about equal proportions of soda- and potash-soaps.

A soft soap of firm consistence (*white soft soap*) may also be made by melting together 75 pts. of tallow or tallow-oil, and 25 pts. of cocoanut-oil, and boiling the mixture with ley till the paste sharply bites the tongue. At this stage, salt solution of 20° B. is added, to give consistence to the paste, and the soap on cooling is then ready to be barrelled.

Toilet Soaps.—These soaps consist either of very pure ordinary curd-soap, or of soaps prepared by the cold process (p. 314) with lard, beef-marrow, or sweet-almond oil, and perfumed in either case with various essential oils. To refine an ordinary soap—which should, of course, be as free as possible from colour and impurity—for toilet purposes, it is reduced to shavings, and melted over a water-bath with rose and orange-flower water and salt, 24 lbs. soap being thus mixed with 4 pints of rosewater, 4 pints of orange-flower water, and two large handfuls of salt. The next day, if entirely cooled, the soap is cut up into small bars and dried in a shady place, then melted anew in the same quantities of rose and orange-flower water, and strained; afterwards cooled and dried again. This done, the soap will be free from bad odour. It must be powdered, and exposed for several days to the air, but protected from dust. It is then ready to receive the intended perfume, and to be moulded and pressed into the desired forms.

Another method is to melt 6 lbs. of best white soap in 3 pints of water, and when liquid to strain it through a linen cloth. It is then placed in a kettle with a pint of water and a tablespoonful of salt; a brisk fire is kindled under it; and the contents are whipped or stirred to make them foam and froth. The fire is then put out; the balling continued till the mass is sufficiently inflated; the fire again kindled; and the kettle kept on till its contents swell and foam. It is then emptied into the cooling frames, and after solidification taken out, cut into cakes, and pressed.

The perfumes used are chiefly volatile oils—viz., the oils of roses, bergamot, mallow, lavender, thyme, rosemary, lemon, verbena, vanilla, bitter-almond; nitrobenzene is also used instead of the last mentioned oil.

Toilet-soaps are coloured blue with ultamarine, red with vermillion, brown with an alkaline solution of burnt sugar. A peach-blossom tint is said to be produced by adding a little cream of tartar to soap which has been perfumed with bitter-almond oil.

Toilet Soft Soap, or *Shaving Cream*, is made by gradually beating 50 lbs. of lard with 75 lbs. of caustic potash-ley marking 17° Bm.

Glycerin Soap, which is used as a toilet-soap for softening the skin, is made by mixing glycerin with ordinary soap when transferred to the frames.

Light or *Flotant Soap*.—This soap is prepared by threshing or agitating a solution of soap, to which one-fifth or one-sixth part of water has been added, with a rouser or paddlewheel, until the lather has risen to twice the height of the soap-solution, and then transferring it to the moulds. A soap is thus obtained inflated with air, which gives it sufficient buoyancy to float on water.

Transparent Soap is prepared by drying ordinary soap in a stove, dissolving it in hot alcohol, leaving the solution at rest to allow the impurities to settle down, or removing them by filtration, the filter being supported on a funnel surrounded with hot water, then distilling off the alcohol till the residue acquires such a consistence as to solidify when cooled in metallic moulds.

Silicated Soaps.—Silicate of sodium (soluble glass) is a compound possessing considerable detergent power; in fact, the alkali contained in it is held in a state of feeble combination, similar to that in which it exists in soap made with fat. When mixed with ordinary soap, it forms a mixed soap of greatly reduced price, and very useful as a cleansing agent for domestic use, and in many manufacturing processes. Some of the so-called silicated soaps, however, are mere mechanical mixtures of silicious substances (such as fine sand, alumina, fuller's-earth, &c.) with ordinary soap: these are comparatively worthless.

The value of the true silicated soaps was recognised at the Great International Exhibition of 1862, by the award of a prize-medal to W. Gossage & Sons, for "Excellent Samples of Silicated Soaps." The manufacture of these soaps is now carried out on a most extensive scale.

For hard soaps, the soluble glass is prepared by melting together, in a reverberatory furnace, 9 pts. of soda-ash (containing 50 per cent. of caustic soda) with 11 pts. of clean sand; and for soft soaps, equal weights of carbonate of potash and sand. To effect solution, the glass, after being drawn off into moulds and quenched with water, is either ground in a mill and then boiled with alkaline water; or it is placed in lumps in an iron vessel having a false bottom, and water is poured into the vessel in sufficient quantity. The mixture of the soluble glass and soap is effected by a mechanical stirring apparatus worked by steam-power.

When it is desired to produce a compound soap having less detergent power than the compound soaps obtained by mixing genuine soaps of ordinary quality with solutions of soluble glass, a portion of the alkali contained in the solution may be neutralised by combining it with rosin or with fatty or oily acids. The combination is effected by boiling the rosin or the fatty or oily acids with solution of soluble glass, in the same manner as rosin and other soap-making materials are combined with alkali in the ordinary process of soap-making.

Gossage also reduces the quantity of free alkali in his silicated soap by neutralising it with sulphuric, hydrochloric, sulphurous, or carbonic acid, added either before or after the incorporation of the glass with the soap. The carbonic and sulphurous acids are passed into the liquid in the gaseous form.

Mixed Soaps of various kinds. Numerous processes have been devised and patented for reducing the cost of soap by mixing it with various substances—*e.g.* gelatin ground bones, dextrin, oleaginous seeds, potatoes, glue, wool, cotton, &c., some of which are said by the inventors to increase the detergent power of the soap; also for the so-called saponification of various kinds of animal refuse (such as stale fish, intestines, skins, hoofs, &c.) by boiling them with alkali; but most of the soaps thus prepared are worthless articles, or if they have any value at all, it is simply in proportion to the amount of genuine soap made from fat contained in them.

The late Dr. Normandy patented several processes for the preparation of "salinated soap." This soap contains the sulphates and carbonates of sodium and potassium, or sulphate and hydrosulphite of sodium, added while the soap is yet in paste. One process consists in adding to 80 lbs. of soap, 28 lbs. of sulphate of sodium, and 4 lbs. of carbonate of potassium, or 2 lbs. of carbonate of potassium and 2 lbs. of carbonate of sodium. Or, if the substanees are used singly, then to 80 lbs. of soap add only 32 lbs. of sulphate of sodium, 15 lbs. of carbonate of potassium, or 10 lbs. of carbonate of sodium. As this soap contains an excess of alkali, it may perhaps answer well for marine use.

The addition of these salts renders the soap harder, and, according to the inventor, renders it possible to prepare a useful soap from several cheap oils, which would otherwise yield a soap too soft for ordinary use. Sulphite and hyposulphite of sodium have also the property of removing the chlorine which bleached fabrics are apt to retain, and by which they are deteriorated.

(For further details respecting these mixed soaps, and various other patent soaps, see *Chemical Technology*, i. [3], 716.)

Railway and Waggon Grease.—The grease or soap used for diminishing friction on the axles of carriages is of two kinds. The one, called "locomotive grease," adapted for high velocities, is prepared by heating palm-oil, or a mixture of palm-oil and tallow, with a solution of sodic carbonate, whereby an imperfect soap is produced. The grease thus prepared is used for passenger-carriages, and lately also for such goods and mineral waggons as are provided with axle-boxes.

The other kind, called "antifriction" or "waggon-grease," is adapted for low speed, and is used for waggons having no axle-boxes. It was originally prepared by agitating rosin-oil (obtained by distillation of colophony) with milk of lime in a pulpy condition; but the present high price of rosin has compelled manufacturers to employ several cheaper substitutes for it—such as paraffin residues mixed with coal-tar, residues from candle-making, cotton-seed oil, fish-oil or footes, pitch-oil, the heavier parts of American petroleum, &c. (*Chemical Technology*, i. [3], 742; [5], 555.)

Analysis and Valuation of Soap.

The value of soap depends mainly on the amount of dry soap (the dry compound of alkali with the fatty acid) contained in it, and this is easily ascertained by exposing a weighed specimen, in the form of thin shavings, to the heat of a drying stove or over oil of vitriol till its weight no longer diminishes. The residue is dry soap, and the loss of weight is hygroscopic water, or water which has been purposely added to the soap, either in the pan after it has been brought to the state of curd, or after its transference to the frames.

To determine the proportion of fat-acid and alkali, the dried soap is decomposed by a measured volume of standard sulphuric acid, and the fat-acids and rosin which rise to the surface are collected on a weighed filter, washed with hot water, dried in a vacuum, and weighed. The weight expresses the joint amount of fatty and rosin-acids in the soap. Cold alcohol will dissolve out the fatty acid, together with a small quantity of rosin, and the filter dried in a vacuum, and weighed again, gives approximately the amount of rosin.

The nature of the fat-acids may be determined by their consistency and melting-point. If oleic acid greatly predominates, so that the fat-acids show but little tendency to solidify, the quantitative estimation may be facilitated by the addition of a weighed quantity of white wax.

The quantity of sulphuric acid neutralised by the alkali in the soap is determined by means of the quantity of a standard solution of caustic soda required to neutralise the excess of acid remaining after the decomposition (see ALKALIMETRY, i. 117, 261). This determines the quantity of alkali in the soap; and the total amount of water, alkali, and fatty acids deducted from the weight of soap analysed, gives the quantity of foreign matter present, which, if the soap is unadulterated, should not exceed 1 per cent.

The amount of alkali in soap may also be determined by incinerating the soap in a muffle. The residue then consists of sodic or potassic carbonate, which may be weighed, and the quantity of alkali thence calculated if the soap is genuine, or determined by the alkalimetric method if other substances are likewise present.

Cailletet (Bull. Soc. ind. de Mulhouse, xxix. 8) has proposed a method of analysis by which only one weighing is required—viz., that of the quantity of soap analysed. The soap (10 grammes), in thin shavings, is decomposed by a measured volume of sulphuric acid of known strength in presence of a measured volume of oil of turpentine. The fatty acids thus liberated dissolve in the oil of turpentine and increase its volume, and this increase, multiplied by the specific gravity of the fat-acid, determines its weight. The amount of alkali is then determined in the manner just described, and the water is estimated by difference: this, of course, implies that the soap is genuine, otherwise the difference will include the foreign matter as well as the water.

The standard acid is prepared by mixing 189·84 grammes of the strongest sulphuric acid, H^2SO^4, with sufficient distilled water to make up the volume to a litre at 15° C. Of this acid, 10 cubic centimetres neutralise 1·2 grammes of soda (Na^2O), and are therefore sufficient to decompose 10 grammes of soap, the amount of alkali in which never exceeds 12 per cent.

10 cubic centimetres of the standard acid and 20 cubic centimetres of oil of turpentine are poured into a tube containing 50 cubic centimetres, and divided into 100 equal parts. 10 grammes of the soap in thin shavings are then added, the tube is closed with a good cork, well shaken for a few minutes till the soap is dissolved, and then left at rest for a quarter of an hour, till the oily solution of the fat-acids has completely separated from the watery liquid.

The volume of this oily solution is now to be read off, a deduction of half a division, or $\frac{1}{4}$ cubic centimetre, being made to allow for the diminution of the capacity of the tube, and consequent rise of the level of the oil, occasioned by the thin film of watery liquid which adheres to the inner surface of the tube.

In an experiment made with olive-oil soap, the total volume of liquid in the tube after agitation and standing was 79·5 divisions, and that of the watery liquid 26 divisions: hence the volume of the oily solution was $79·5 - 26·5 = 53$ divisions, or 26·5 cubic centimetres. Deducting from this the volume of turpentine-oil added, the remainder ($= 6·5$ cubic centimetres), is the volume of the fat-acids in the soap.

To determine the specific gravity of these fat-acids, 10 grammes of the same soap were dissolved and decomposed by sulphuric acid; 10 grammes of white wax were then added. The union of this wax with the separated fatty acids was promoted by heating, the whole then left to cool, and the cake of wax separated from the liquid, dried between filtering-paper, and weighed. Its weight was 15·97 grammes, which diminished by 10 grammes, the weight of the wax added, gives 5·97 grammes as that of the fat-acids in the soap; and this divided by 6·5 cubic centimetres, the volume of the fat-acids obtained from the same quantity of soap, gives 0·918 for the specific gravity of these fatty acids. By similar experiments with different kinds of soap, the specific gravities of the fat-acids contained in them were found to be, on the average:

	Specific Gravity of Fat-Acids.
Olive-oil (Marseilles) soap	0·9188
Cocoanut-oil soap	0·940
Palm-oil soap	0·922
Tallow soap	0·9714
Soap from oleic acid	0·9003

When rosin-soap is shaken up with dilute sulphuric acid and oil of turpentine, scarcely any of the rosin is dissolved. If fat-acids are likewise present, these dissolve in the oil of turpentine; but the quantity of rosin dissolved is only sufficient to increase the volume of the turpentine-oil (20 cubic centimetres), by $\frac{15}{100}$ cubic centimetre. The undissolved rosin collects below the turpentine as a bulky layer, so that in this way the presence of rosin in a soap can easily be detected.

Bolley's Method.—One gramme of the soap is decomposed in a small beaker-glass with ether and acetic acid. Two layers of liquid are then quickly formed, the upper being an ethereal solution of the fat-acid (or rosin), and the lower an aqueous solution of alkaline acetate and of the salts contained in the soap, whilst insoluble admixtures are left in various forms, according to their particular nature. The two liquids are separated by a pipette; the ethereal solution is evaporated in a tared glass over the water-bath, and the residual fat-acid (or rosin) is weighed.

The watery liquid is evaporated to dryness in a platinum-dish, the residue is ignited, and the amount of alkali (remaining as chloride and sulphate) determined by the usual method.

Gräger's Method.—The soap, cut in thin shavings, is dissolved in alcohol of 30 per cent., the quantity of solvent used being such that 100 grammes of soap shall yield a litre of solution. All impurities are then left behind, together with a certain quantity of sodic or potassic carbonate; 10 cubic centimetres of the solution, clarified by standing, are then diluted with water, and precipitated by chloride of calcium. The precipitate, consisting of the calcium-salts of the fat-acids, is washed, dried at 100° C., and weighed. 100 parts of this precipitate correspond, according to Gräger, with 100·5 parts of anhydrous soap, that is of sodic stearate, the result not being perceptibly affected by the fact that the acid of soap is not pure stearic acid, but likewise contains palmitic and oleic acids.

The extreme limit of water in genuine hard soap is 20 per cent. for mottled, 25 for white, and 30 for yellow soap. The proportion of alkaline bases is mostly from 8 to 9 per cent., and that of the fat-acids from 60 to 70 per cent. In yellow soap, part of the fat is replaced by 10 to 20 per cent. of rosin, and soaps made from cocoanut-oil contain a much larger amount of normal water than those made from tallow or olive-oil. But the above proportions may be regarded as standards of comparison; and any deviation from them indicates a deterioration in the quality of the soap, either from excess of water, or from the substitution of some foreign substances for the normal constituent of the soap. (See further *Chemical Technology*, i. [3], 729; [5], 318.)

SOAPSTONE. *Soap-rock. Pierre de Savon. Seifenstein. Steatite* in part.—A soft massive mineral, occurring in veins in serpentine at the Lizard Point in Cornwall and elsewhere. It is brittle after drying, has a greasy lustre, and white, yellowish, bluish, or reddish colour; does not adhere to the tongue. Specific gravity = 2·20. Before the blowpipe it gives off water and blackens; thin splinters fuse with difficulty on the edges. Perfectly soluble in sulphuric acid.

Analyses.—*a.* From Lizard Point (Klaproth, *Beiträge*, ii. 180; v. 22).—*b.* From the same (Svanberg, Pogg. Ann. liv. 267; lvii. 165).—*c.* Gae Grease, Cornwall (Haughton, Phil. Mag. [3], x. 253).—*d.* Kynance Bay, Cornwall (Haughton).—*e* Frankenstein in Silesia: *Kerolite* (Maak, Schw. These analyses cannot be reduced to any single formula: indeed, it is doubtful whether any of the minerals to which they refer are definite compounds.

SOAPWORT. *Saponaria officinalis.*—The root of this plant, which contains saponin (p. 192), is used for washing and cleansing dresses, &c. (See *Ure's Dictionary of Arts*, iii. 719.)

SODA. This term, in scientific language, is applied to the anhydrous protoxide of sodium, Na^2O, or the hydrate, NaHO, but in technological language, it denotes also the neutral carbonate, Na^2CO^3 or $Na^2O.CO^2$. The mode of occurrence of this salt in nature and its properties have been described under CARBONATES (i. 702). It was formerly prepared from the ashes of marine plants, chiefly from certain species of salsola, some of which (viz., *Salsola clavifolia* and *S. Soda*) yield an ash containing more than 40 per cent. of neutral sodic carbonate. But the quantity obtained from these sources at the present day is altogether insignificant compared with that which is produced from common salt by the mode of decomposition invented by Lablanc, and consisting:

1. *In converting chloride of sodium into sulphate by heating it with sulphuric acid.*
2. *In converting the sulphate into carbonate by heating it with chalk or limestone and coal.*

A brief outline of this process is given under CARBONATES (i. 702), and a full account of it, with figures and descriptions of the apparatus used, will be found in Richardson and Watts's *Chemical Technology*, (i. [3], 204—295; [5], 234—265). In the present article we shall enter somewhat more fully into the theory of the second part of the process, the "balling process" as it is called, especially with reference to recent investigations.

Dumas suggested, for the explanation of Leblanc's process, a theory which may be expressed by the equation:

$$2Na^2SO^4 + 3CaCO^3 + C^9 = 2Na^2CO^3 + CaO.2CaS + 10CO.$$

T [illegible] which was for many years universally received as correct, supposes that the black ash or ball-soda contains an oxysulphide of calcium, $CaO.2CaS$. This compound has never been isolated, but its existence was assumed, because it was believed that if the calcium in the ball-soda existed as oxide and sulphide not combined together in the form of an insoluble oxysulphide, the carbonate of sodium and sulphide of calcium would, when brought in contact with water, immediately decompose one another, forming sulphide of sodium and carbonate of calcium. A similar theory of the process was given by Unger (Ann. Ch. Pharm. lxxxi. 328), who assigned to the supposed oxysulphide the composition $CaO.3CaS$. Kynaston (Chem. Soc. Qu. J. xi. 155) supposed the ball-soda to contain an insoluble compound of sulphide and carbonate of calcium, $CaCO^3.2CaS$.

Gossage however pointed out, in the specification of a patent obtained in 1838 (No. 7416), that the undissolved residue remaining from the lixiviation of black ash with water, consists almost entirely of monosulphide and carbonate of calcium, not chemically combined, but merely mixed; further, that this monosulphide of calcium is perfectly insoluble in water, and therefore does not decompose the sodic carbonate when the black ash is treated with water, such decomposition taking place only in so far as a portion of the monosulphide may have been converted into a soluble polysulphide during the treatment in the furnace.

These results are fully confirmed by the recent experiments of Dubrunfaut (Bull. Soc. Chim. 1864, i. 240), Scheurer-Kestner (*ibid.* 169), Pelonze (Compt. rend. [1866], liii. 314), and especially of J. Kolb (Ann. Ch. Phys. [4], vii. 318; Bull. Soc. Chim. 1866, ii. 11).

Dubrunfaut, by heating to redness a mixture of 1 at. sulphide of sodium and 1 at. chalk, obtained exactly 1 at. sodic carbonate and 1 at. calcic monosulphide, CaS.

Kolb treated in a soda-furnace two series of mixtures of chalk, carbon, and sodic sulphate, the first series being in the proportions corresponding to the equation of Dumas above given—the second corresponding to the equation:

$$Na^2SO^4 + CaCO^3 + C^4 = Na^2CO^3 + CaS + 4CO,$$

in which it will be observed that no oxide of calcium is formed. These two mixtures, when calcined and afterwards lixiviated under similar conditions, yielded exactly the same results. Hence Kolb concludes that the action of charcoal on a mixture of sodic sulphate and calcic carbonate in equal numbers of atoms yields sodic carbonate and calcic sulphide, easily separable by lixiviation at ordinary temperatures.

In this operation the reduction of the sodic sulphate by the carbon may be explained in two ways:

1. According to the ordinary theory, the exchange takes place as represented by the equation:

$$Na^2SO^4 + CaCO^3 = Na^2CO^3 + CaSO^4,$$

the carbon then acting on the calcic sulphate so as to reduce it to sulphide.

2. The charcoal may be supposed to exert a direct reducing action on the sodic sulphate, double decomposition then taking place between this compound and the calcic carbonate.

This latter view is confirmed by the experiments of Kolb, who finds that a mixture of sodic sulphate and chalk, calcined at a bright-red heat, yields nothing but sodic sulphate and quicklime.

The reduction of the sodic sulphate by charcoal might take place in two ways, viz.:

$$(1)\ Na^2SO^4 + C^4 = Na^2S + 4CO$$
$$(2)\ Na^2SO^4 + C^2 = Na^2S + 2CO^2.$$

But the composition of the gas evolved shows that the reaction takes place according to the second of these equations, and accordingly that the production of sodic carbonate should require the materials to be in the proportions deduced from the equation:

$$Na^2SO^4 + CaCO^3 + C^2 = Na^2CO^3 + CaS + 2CO^2.$$

But by actual experiment with these proportions in the soda-furnace, it is found that half the sodic sulphate remains unaltered, part of the charcoal being, in fact, employed in decomposing the chalk according to the well-known equation:

$$CaCO^3 + C = CaO + 2CO;$$

so that the action of the carbon is divided between the sodic sulphate and the chalk, in the manner shown by the equation:

$$Na^2SO^4 + CaCO^3 + C^3 = Na^2S + CaO + 2CO^2 + 2CO.$$

The chalk being decarbonised at the same time that the sodic sulphate is reduced, it follows that the carbonic acid of the chalk cannot contribute to the formation of the sodic carbonate. Kolb has in fact shown, by a series of analytical experiments, that the formation of sodic carbonate and calcic sulphide in the balling furnace is produced by the action of carbonic acid, parly resulting from the reduction of the sodic sulphide, partly existing in the gases of the furnace. Accordingly, when the mixture is heated in crucibles, so that it is not much exposed to the furnace-gases, a highly sulphuretted soda is obtained, whereas when it is heated in tubes traversed by a current of carbonic acid gas, a very pure sodic carbonate is obtained.

The temperature best adapted for the production of ball-soda is between the melting-point of bronze and of silver. Below the former, the reaction is incomplete; above the latter the soda is "burnt,"—that is to say, the sodic carbonate is decomposed, as shown by the following equation, yielding oxide and sulphide of sodium:

$$Na^2CO^3 + C = Na^2O + 2CO; \text{ and } Na^2O + CaS = Na^2S + CaO.$$

Kolb has also analysed a series of samples of ball-soda in the manufacture of which the coal had been replaced by wood-charcoal, peat, wood-shavings, &c. All these samples yielded similar results, whence it appears that the proportion of carbonaceous matter to be introduced into the mixture depends wholly upon its reducing power, which may be determined beforehand by an experiment with litharge.

The results show that the proportions required by theory are:

Sodic sulphate	100·0 parts
Chalk	70·4 „
Carbon	25·5 „

These proportions may, however, be considerably varied without sensibly affecting the result.

Action of Air and Water on Black Ash or Ball Soda (Kolb).—Dry air deprived of carbonic acid has no action on ball-soda, either at ordinary temperatures or at 100°; but at a red heat it converts the sulphide of calcium into sulphate, which in the subsequent lixiviation reconverts a certain portion of the sodic carbonate into sodic sulphate, and thereby diminishes the percentage of alkali in the product.

Carbonic anhydride in the dry state has no action on black ash (it does not act, indeed, either on lime or on sulphide of calcium); but in presence of moisture, it first converts the lime into carbonate, and then acts on the sulphide of calcium, forming carbonate and sulphydrate of calcium:

$$CaS + H^2O + CO^2 = CaCO^3 + H^2S; \text{ and } H^2S + CaS = CaH^2S^2.$$

When black ash is exposed to moist air, the lime contained in it is first hydrated by the aqueous vapour, and afterwards converted into carbonate. At the same time, any sulphide of sodium that may be present in the crude soda, is converted into hyposulphite, but the oxidation does not go any further. The sulphide of calcium, on the other hand, is oxidised by moist air, less quickly but more completely, being converted into calcic sulphate, which, as already observed, decomposes the sodic carbonate during lixiviation, and thereby diminishes the proportion of available alkali.

Another cause of the formation of calcic sulphate, and consequent deterioration of the ball-soda, is the presence of iron in the state of ferric oxide (not sulphide), which, in presence of moist air, reacts with the sulphide of calcium, forming lime and sulphide of iron, which latter becomes oxidised to sulphate; and this again in its turn reacts with the sulphide of calcium, forming ferrous sulphide and calcic sulphate:

$$Fe^2O^3.2SO^3 + 2CaS = 2FeS + 2CaSO^4 + O.$$

The same series of actions therefore recommences indefinitely, so that a very small quantity of ferric oxide is sufficient, under the influence of moist air, to convert a large quantity of calcic sulphide into sulphate. Hence the ball-soda should not be left exposed to the air longer than is necessary for the partial hydration of the lime contained in it, so as to facilitate its disintegration.

Action of Water.—By subjecting a given weight of ball-soda to the action of variable quantities of water for different times and at different temperatures, Kolb has obtained the following results:—

1. A given quantity of crude soda yields very different proportions of caustic soda and sodic sulphide, according to the quantity and temperature of the water with which it is treated, and the time of digestion.

2. The degree of causticity of the resulting solution is not sensibly affected by the quantity of water used, but increases with the time of digestion and with the temperature.

3. The proportion of sodic sulphide increases with the quantity of water, andmore particularly with the time of digestion and the temperature.

4. The decrease in the quantity of sodic carbonate not only corresponds with the quantity of caustic soda formed, but is also affected by the variation in the quantity of sodic sulphide: hence it would appear that the latter is formed at the expense of the carbonate.

5. The quantities of caustic soda and sodic sulphide do not appear to bear any definite relation to one another.

Kolb has likewise examined the action of water on pure sulphide of calcium, alone, and in presence of sodic carbonate, caustic soda, and lime. The results are as follows:

α. The quantity of calcic sulphide dissolved or decomposed by water is very small, but increases with the temperature and the duration of the digestion.

β. Lime has no sensible influence on the solubility of calcic sulphide; but a small quantity of caustic soda stops the solution almost entirely, especially at common temperatures.

γ. The decomposition of sodic carbonate by calcic sulphide: $Na^2CO^3 + CaS = Na^2S + CaCO^3$, which is considerable in very dilute liquids, diminishes on concentration, and ceases altogether in a solution saturated with sodic carbonate.

δ. The presence of caustic soda in small quantity (or, what comes to the same thing, of lime) prevents the action of calcic sulphide on sodic carbonate.

The accordance of these last results with the observed action of water on ball-soda affords a strong argument against the supposition that this substance contains an oxysulphide of calcium.

The following table exhibits the composition of black ash, as determined by different analysts. The arrangement of the basylous and acid elements in compounds is of course to a certain extent theoretical: thus, in the first three analyses, the oxide and sulphide of calcium are regarded as combined into an oxysulphide, whereas in the last three they are given separately:

SODA ALUM. $NaAl'''(SO^4)^2.12H^2O$.—Occurs native on the island of Milo, at the Solfatara near Naples, and near Mendoza, on the east of the Andes. (See SULPHATES.)

SODA COPPERAS. A sodio-ferric sulphate found in the alum-slate of Modum in Norway. (See SULPHATES.)

SODA SPODUMENE. Syn. with OLIGOCLASE (iv. 198).

SODA-LIME. A mixture of caustic soda and quick lime, used chiefly for nitrogen-determinations in organic analysis (i. 245).

SODALITE. A sodio-aluminic silicate, containing chlorine, occurring in dodecahedrons and other forms of the monometric system, with dodecahedral cleavage; sometimes in twin-crystals, having the form of a hexagonal prism, arising from the combination of two dodecahedrons; also massive. Hardness = 5·5—6. Specific gravity 2·26—2·37. Lustre vitreous, inclining to greasy. Colour grey, greenish, yellowish-white, and sometimes blue. Subtransparent—subtranslucent. Fracture conchoïdal—uneven. Before the blowpipe it melts to a colourless blistered glass.

Analyses (the chlorine being reckoned as chloride of sodium): *a.* From Vesuvius: colourless; specific gravity = 2·136 (Rammelsberg, Mineralch. p. 702).—*b.* From the same: green; very rare; small dodecahedrons with cubic faces, occurring in a limestone with vesuvian and nephelin.—*c.* Lamö near Brevig in Norway: blue, in elæolite (Bork, Pogg. Ann. lxxviii. 413).—*d.* From the Ilmen mountains near Miask: blue, in elæolite; specific gravity = 2·288 (E. Hofmann and G. Rose, *ibid.* xlvii. 377).—*e.* Lichfield, Maine: blue, in elæolite (Whitney, *ibid.* lxx. 431):

These analyses may be represented by the formula $NaCl.n(NaAl'''SiO^4)$. (compare the formula of haüyne, iii. 15), the sodium-chloride and the silicate being crystallised together isomorphously in varying proportions.

Sodalite occurs in mica-slate, granite, trap, basalt, and volcanic rocks. In Greenland it is found in mica-slate, together with felspar, hornblende and eudialyte.

SODAMIDE. *Olive-coloured Sodium-compound.*—When a quantity of sodium which evolves from water 100 measures of hydrogen gas, is heated in ammoniacal gas, it absorbs tranquilly between 142 and 163 measures, setting 100 measures of hydrogen free, and assuming first a blue and afterwards a green colour. The compound is olive-green and fusible, and manifests the same relations as the corresponding potassium-compound (iv. 695). (Gay-Lussac and Thénard, *Recherches*, i. 354; H. Davy, *Phil. Trans.* 1810, p. 24.)

Sodamide appears to be capable of uniting with sodic oxide. When a mixture of oxygen and ammonia gases, the latter being in excess, is passed over sodium, sodamide alone is formed, and at a lower temperature than with pure ammonia gas; but if the quantity of oxygen is increased, a fused ruby-coloured mass is obtained, consisting of a compound of sodic amide and oxide. This compound is permanent in ammonia gas, even at 300°, but becomes decolorised when air or oxygen is passed over it, and leaves a white substance, apparently consisting of sodic hydrate.—*Potassium* treated in like manner yields a similar compound, but of a deep blue colour. (Weyl.)

SODAMMONIUM. NH^3Na, or rather $N^2H^6Na^2$? (Weyl, Pogg. Ann. cxxi. 697; Jahresb. 1864, p. 163.)—This compound appears to be formed when lumps of pure bright sodium are placed at one end of a bent tube, a quantity of silver-chloride previously saturated with ammonia gas at the other, the tube then sealed, the end containing the silver-chloride heated in a chloride-of-calcium-bath, and the other end immersed in cold water. The sodium then swells up, and is converted into a liquid, which is copper-red by perpendicularly reflected, greenish-yellow by obliquely reflected light, blue in thin films by transmitted light. As the silver-chloride cools, and the ammonia gas is reabsorbed, the sodammonium decomposes and pure sodium remains behind, having a dull surface and spongy texture. By again heating the silver-chloride the compound may be reproduced any number of times.

A *sodammonium-amalgam* appears to be formed by exposing in like manner to the action of ammonia gas, a pulverulent amalgam of nearly equal parts of sodium and mercury. After two hours' action, the portion of the mass in contact with the surface of the tube exhibits a metallic lustre and bronze-red colour, while the interior is dull and brick-red. This product can likewise exist only in an atmosphere of ammonia, being resolved in a few hours after the cooling of the silver-chloride, into ammonia, free mercury, and a sodium-amalgam containing less mercury than the original amalgam.

---

* Including 0·51 potash.

† By difference.

Potassammonium, $N^2H^6K^2$?, is prepared like sodammonium, and exhibits similar properties.

Other metallammoniums may be produced by the decomposition of sodium- or potassammonium. Thus when a mixture of a metallic chloride or oxide with an equivalent quantity of sodium is exposed in the manner above described to the action of ammonia-gas, the gas is first absorbed by the metallic chloride (or oxide) and afterwards by the sodium, the sodammonium thus formed flowing over the metallic salt, and reacting upon it without much rise of temperature, With a mixture of barium-chloride and sodium the reaction appears to be:

$$\underset{\text{Sodammonium.}}{N^2H^6Na} + 2NH^3 + Ba''Cl^2 = \underset{\text{Barammonium.}}{N^2H^6Ba''} + \underset{\text{Chloride of Sodammonium.}}{2NH^3NaCl.}$$

Barammonium forms a deep blue liquid having a metallic lustre.—*Copper-*, *Mercury-*, and *Silver-ammonium* are obtained in like manner from the respective chlorides, and *zinc-ammonium* from the oxide. These compounds are likewise very unstable, being resolved, even in the sealed tube, into metal (which appears grey, dull and destitute of coherence) and ammonia. If in the arrangement just described the metallic chloride be replaced by an ammonium-salt, *e.g.* NH^4Cl or $(NH^4)^2SO^4$, similar reactions take place, and the tube becomes filled with a blue liquid mixed with excess of ammonia. This blue liquid, which is also formed by the action of potassic hydrate on potassammonium, appears to consist of *ammonium* itself, N^2H^8. It is even more unstable than the metallammoniums, being resolved into ammonia and hydrogen, partly even before the reaction between the ammonium-salt and the sodammonium is completed.

Tetrasodammonium. NNa^4?—Monosulphide of sodium brought in contact, in a sealed tube, with liquid ammonia, is converted (with transient formation of liquid ammonium) into an orange-yellow substance, which soon decomposes, leaving a white substance still containing ammonia. This residue gives off ammonia on exposure to the air, and the odour of ammonium-sulphide when heated. It is perhaps formed in the manner represented by the equation:

$$4Na^2S + 8NH^3 = (NNa^4)^2S + 3(NH^4)^2S.$$

Tetrapotassammonium appears to be formed in a similar manner. (Weyl.)

SODIUM. *Atomic Weight* 23. *Symbol* Na (from *Natrium*). Soda, the alkali containing this element, was formerly confounded with potash, but was proved to be a distinct substance by Duhamel in 1736, and subsequently by Marggraf in 1758. H. Davy first obtained the metal in the year 1807.

Sodium is a very abundant element and very widely diffused. It occurs in large quantities, as chloride, in rock-salt, sea-water, salt-springs, and many other mineral waters; abundantly also as nitrate, forming beds several feet thick on the dry pampas of Peru; more rarely as carbonate, borate, and sulphate, either in springs, lakes, &c., or in the solid state; as sodio-aluminic fluoride in cryolite; and as silicate combined with earthy silicates in chabasite, analcime, natrolite, thomsonite, eudialite, albite, soda-spodumene, labrador, nepheline, hauyne, sodalite, brewicite, cancrinite, and achmite; in very small quantity also in bole, pitchstone, pumice-stone, obsidian, ittnerite, and pinite. Traces of sodium-salts are found in coal, in all kinds of limestone and dolomite, and in talc, asbestos, and other minerals. In the vegetable kingdom it occurs as sulphate, iodide, and chloride, and combined with vegetable acids, especially in plants growing in or near the sea; in the animal kingdom, combined with carbonic, phosphoric, sulphuric, hydrochloric, and various organic acids.

Preparation of the Metal. The preparation of sodium is similar to that of potassium. Davy first obtained it by the electrolysis of the hydrate; Gay-Lussac and Thénard afterwards prepared it by decomposing that compound with metallic iron at a white heat; and Brunner showed that it may be prepared with much greater facility by distilling a mixture of sodic carbonate and charcoal.

The preparation of sodium by this last-mentioned process is much easier than that of potassium, not being complicated, or only to a slight extent, by the formation of secondary products. Within the last few years it has been considerably improved by Deville and others, and carried out on the manufacturing scale, sodium being now employed in considerable quantity as a reducing agent, especially in the manufacture of aluminium and magnesium and in the silver amalgamation process (p. 285).

The sodic carbonate used for the preparation is prepared by calcining the crystallised neutral carbonate. It must be thoroughly dried, then pounded, and mixed with a slight excess of pounded charcoal or coal. An inactive substance, viz. pounded chalk, is also added to keep the mixture in a pasty condition during the operation, and prevent the fused sodic carbonate from separating from the charcoal. The following are the proportions recommended by Deville:

For Laboratory Operations.		*For Manufacturing Operations.*	
Dry sodic carbonate	717 parts	Dry sodic carbonate	30 kilogr.
Charcoal	175 „	Coal	13 „
Chalk	108 „	Chalk	3 „

These materials must be very intimately mixed by pounding and sifting, and it is advantageous to calcine the mixture before introducing it into the distilling apparatus, provided the calcination can be effected by the waste heat of a furnace; the mixture is thereby rendered more compact, so that a much larger quantity can be introduced into a vessel of given size.

The distillation is performed, on the laboratory scale, in a mercury bottle heated exactly in the manner described for the preparation of potassium.

For manufacturing operations, the mixture is introduced into iron cylinders, which are heated in a reverberatory furnace, and so arranged that, at the end of the distillation, the exhausted charge may be withdrawn and a fresh charge introduced without displacing the cylinders or putting out the fire. The receivers used in either case are exactly the same in form and dimensions as those employed in the preparation of potassium (iv. 693).

When the process goes on well, the sodium collected in the receivers is for the most part perfectly pure, the carbonised products which give so much trouble in the preparation of potassium being produced in very small quantity only, if at all. Nevertheless a small quantity of somewhat impure sodium always remains attached to the inner surface of the receivers; hence when a receiver has been used, the plates should be separated and scraped before they are used again; and the matter scraped off, being received under naphtha, may be collected after a while and will yield by distillation a considerable quantity of sodium. Lastly, the pure metal obtained by this and by the first distillation is melted under a thin layer of naphtha, which is decanted as soon as the sodium becomes perfectly fluid, and the metal is then run into moulds like those used for casting lead or zinc.

The degree of heat absolutely required for the reduction of sodium is not much higher than for the reduction of zinc; but the distillation goes on better and a larger product is obtained when the temperature is raised considerably higher. The quantity of sodium obtained in a well conducted operation, is about one-third of the weight of the calcined mixture.

[For a detailed description of the manufacture of sodium, with figures of the apparatus, see *Chemical Technology*, i. [4], 5 and [5], 125.]

Properties.—Sodium has a high lustre, and usually a silver-white colour; according to Long however (Chem. Soc. Q. J. xiii. 123), its surface when perfectly clean and metallic, is of a beautiful rose colour, which is best seen when a ray of light falling on a surface of the metal is reflected back from a second surface and again reflected from the first.

The specific gravity of sodium is 0·9348 (Davy); 0·97223 at 15° (Gay-Lussac and Thénard); 0·985, reduced to a vacuum and compared with that of water at 3·9 (Schröder, Jahresb. 1859, p. 12). It is rather hard at − 20°, very ductile at 0°, of the consistence of wax at common temperatures, semifluid at 50°: melts completely at 97·6° (Regnault, Jahresb. 1856, p. 43), at 95·6° (Bunsen, *ibid.* 1863, p. 178). When a few grammes of sodium are melted in a sealed tube filled with coal gas, then left to cool till a few solid points appear on the surface, and the remaining liquid suddenly poured off by inclining the tube, the solidified portion remains in shining octahedral crystals belonging to the dimetric system and having the plane angles at the apex = 50° (Long). Sodium is less volatile than potassium (Davy; Gay-Lussac and Thénard); rather more so (Mitscherlich). Its vapour is colourless. Sodium is an excellent conductor of heat and electricity.

Sodium when exposed to the air oxidises like potassium, but not quite so rapidly. When heated in the air it burns with a yellowish flame, forming protoxide and dioxide of sodium. When heated in oxygen gas till it no longer increases in weight, it is wholly converted into dioxide. When dropt upon cold water, it decomposes a portion of the water, liberating hydrogen and running about on the surface with a hissing noise, but the gas does not take fire unless the water be previously heated.

Sodium is a monatomic metal belonging to the group which includes the other alkali-metals and silver. With chlorine, bromine, iodine and fluorine, it forms the compounds KCl. KBr, &c.; with oxygen it forms a protoxide Na_2O, the corresponding hydrate

NaHO, and a dioxide Na^2O^2; with sulphur, a protosulphide Na^2S, a sulphydrate NaHS, and several polysulphides.

SODIUM, ALLOYS OF. These alloys closely resemble those of potassium, and are prepared in like manner by fusing sodium with the respective metals. The *amalgam of sodium* (iii. 889) is much used as a reducing or hydrogenating agent. M. Scholz (J. pr. Chem. lxxix. 441), by adding sodium to mercury in such quantity that the product solidifies completely on cooling, then pressing out the excess of mercury, fusing the remaining amalgam, and leaving it to cool slowly, obtains a sodium-amalgam, crystallised in fine prisms, often an inch long, which may be kept in well closed vessels without sensible oxidisation, and are easily pulverised. By further addition of mercury, this amalgam may be brought to a more or less fluid state.—F. Muhlhäuser (Zeitschr. Ch. Pharm. 1864, p. 720) heats sodium under naphtha to 90°, and allows mercury to flow into it in a fine stream. The sodium then swells up and ultimately forms a solid mass, which may be left to cool under naphtha.

Respecting the alloys of potassium and sodium, see POTASSIUM (iv. 695).

SODIUM, ANTIMONIDE OF. Prepared by direct combination of its elements. Resembles antimonide of potassium (i. 317).

SODIUM, ARSENIDE OF. This alloy, which is used for the preparation of the arsenides of ethyl, methyl, &c., is prepared by gently heating finely pulverised metallic arsenic in a furnace having a good draught till it begins to fume, and then introducing small pieces of sodium from time to time till the mixture begins to assume a fluid consistence, which effect takes place when a quantity of sodium has been introduced about equal to that of the arsenic. As the product is highly combustible it is necessary to exclude the air, for which purpose the arsenic is placed in a porcelain crucible enclosed within a hessian crucible, both being provided with closely fitting covers, which must only be removed to introduce the sodium, or to stir the mixture with an iron rod. The action is very violent and attended with vivid incandescence. The alloy, which has a crystalline fracture and silver-white colour, must be kept in closely stoppered bottles filled up with sand. It decomposes water with evolution of arsenetted hydrogen, an effect which takes place even in damp air: hence it must be handled with caution. (Landolt, Ann. Ch. Pharm. lxxxix. 201.)

SODIUM, BROMIDE OF. NaBr. This salt, produced by saturating hydrobromic acid with soda, or by decomposing ferrous bromide with sodic carbonate, crystallises by evaporation at temperatures above 30°, in anhydrous cubes, at lower temperatures in oblique rhombic prisms containing $NaBr.2H^2O$ (Mitscherlich). The specific gravity of the anhydrous salt referred to water at 17·5° as unity is 3·079 (Kremers, Jahresb. 1857, p. 69). It dissolves easily in water and in alcohol. The following table exhibits the specific gravities and expansions by heat of solutions of various strengths. (Kremers, Jahresb. 1858, 41.)

Volumes of Aqueous Bromide of Sodium at different temperatures (vol. at 19·5° = 1).

Quantity of salt in 100 parts of water	20·4	42·6	62·3	88·1

100	1·04347	1·04421	1·04453	1·04477

A saturated aqueous solution boils at 121°. (Kremers.)

SODIUM, CHLORIDE OF. NaCl. *Common salt, Culinary salt, Rock-salt, Sea-salt*, formerly called *Muriate of Soda*. This compound is formed by the direct union of its elements, sodium taking fire in chlorine gas. It may likewise be obtained pure by neutralising hydrochloric acid with soda or sodic carbonate and evaporating. It occurs very abundantly in nature, both in the solid state, as rock-salt, forming extensive beds in rocks of various ages,—and in solution in sea-water, salt-lakes, and brine-springs; in smaller proportion also in river water.

In Europe common salt usually occurs in the new red sandstone, or associated with red marl, but it is not confined to those rocks. In Durham, Northumberland, and Leicestershire, salt-springs arise from the carboniferous series; in the Alps, some saltworks are supplied from oolitic rocks: the extensive mines of Cardona in Spain are referred to the greensand formation, those of Wieliczka in Poland to tertiary rocks. Salt-springs occur also in volcanic regions. In the United States the brine comes mostly from Silurian sandstones. Salt occurs also as efflorescences over the dry prairies of the Rocky mountains and California; and in most desert and semi-desert regions there are numerous salt lakes.

The principal salt mines of Europe are at Wieliczka in Poland; at Hall in the Tyrol, and along the range through Reichenthal in Bavaria, Hallein in Salzburg, Halstadt, Ischl and Ebensee in Upper Austria, and Aussee in Styria; at Stassfürth near Magdeburg; in Hungary at Marmoros and elsewhere; in Transylvania, Wallachia, Gallicia and Upper Silesia; at Vic and Dreuze in France; in the valley of Cardona and elsewhere in Spain; at Bex in Switzerland; at Northwich and elsewhere in Cheshire; and near Belfast in the north of Ireland. At Wieliczka the salt deposit is 500 miles long, 20 miles broad, and not less than 1200 feet thick; at Cardona, the salt forms hills 300 and 400 feet high. Near Northwich, the principal deposit of rock-salt in England, the mineral occurs in magnesian limestone, in two beds situated one above the other, separated by about 30 feet of clay and marl, intersected by small veins of salt, the two beds together being about 60 feet thick, 300 yards broad, and a mile and a half long.

Rock-salt occurs also near lake Oroomiah, the Caspian, &c., forming hills and extended plains; in Algeria abundantly; in Abyssinia; in India, in the province of Lahore, and the valley of Cashmere; in Scinde, where there is said to be an immense bed of it, 20 miles long, 15 miles broad, and averaging three feet in thickness; in China and Asiatic Russia; in Peru and other countries of South America. In the United States salt has been found forming beds with gypsum in Washington county, Virginia, and in the mountains of Oregon. (Dana, ii. 9).

The mode in which salt is obtained from these deposits depends very much on the locality, the depth of the deposit, the price of fuel, &c. In some places, as at Wieliczka and in Cheshire, it is a mining operation and is carried on by means of shafts and horizontal galleries. At Cardona in Spain, where the great body of the salt forms a rugged precipice 400 to 500 feet high, there is no excavation, but the salt is procured by working down perpendicularly as in an open quarry.

Rock-salt is sometimes so pure and white that it requires no preparation but grinding to convert it into snow-white culinary salt; this is the case with the salt of Cardona, and with some of that occurring in Cheshire and other localities. More frequently, however, it is coloured red or brown from the admixture of clay or bitumen, and particularly of the kind of infusoria that are now found inhabiting salt lakes: it then requires to be purified by solution and recrystallisation. Frequently also, instead of sinking a shaft to the bed of salt and mining it, the superior strata are pierced by a bore only a few inches in diameter, by which water is admitted to the bed, and the brine formed is drawn off by a pump.

Salt wells or springs, which may be artificially constructed in the manner above described, are also frequently found ready formed in nature wherever a spring during its course has come in contact with a bed of rock-salt. These however are rarely so highly saturated as the artificial wells, although this is actually the case with that of Luneburg, which contains 25 per cent. of saline matter; but they are for the most part, only slightly impregnated, or have become weakened by subsequent addition of fresh water. This difference in the strength and the composition of the saline constituents of salt springs may be seen from the following table (p. 334).

The water of the stronger springs is at once evaporated by heat to procure the salt, and in England and other countries where cheap fuel can be obtained, the same plan is adopted with the weaker springs; but in Germany, where fuel is scarce and dear, the more dilute saline waters cannot be profitably worked in this way. The water is therefore first concentrated by a process called *graduation*, which consists in exposing the brine, diffused over a large surface, to the air. This is effected by pumping it to a height, and then allowing it to trickle slowly over large stacks of faggots, piled in suitable buildings, screened from rain, but freely exposed to the prevailing wind. After this process has been repeated eight or ten times, the solution acquires a density of about 1·40, and is sufficiently concentrated to allow the evaporation to be finished by heat. In the first evaporating pan an insoluble double sulphate of calcium and sodium is deposited, partly in the form of mud or *schlot*, as it is called in Germany, partly as a hard scale, which adheres to the bottom of the pans (*Pfannenstein*). A specimen of this panstone from Schönebeck gave by analysis:

$NaCl$.	Na^2SO^4.	K^2SO^4.	$CaSO^4$.	$MgSO^4$.	$MgCO^3$.	Al^2O^3 and Fe^2O^3.	SiO^2.	H^2O.
44·28	20·67	2·13	27·38	1·64	0·41	0·03	0·02	3·44 = 100

When the liquor reaches a density of 1·236 it is decanted into another pan and evaporated, the crusts of salts being removed as they form.

The appearance of the salt varies according to the rate at which the evaporation is conducted. When the brine is boiled down rapidly, it furnishes the mealy fine-grained salt used for the table; slower evaporation yields the hard crystallised salt, generally used for salting fish.

Separation of Salt from Sea-water.—It is seldom that artificial evaporation is employed for separating the salt from sea-water; where it is practised, the same mode is adopted as with the brine springs; sometimes, as in Siberia, frost is made subservient to this object—for salt water separates on freezing into ice (containing no salt), and a strong saline ley. Dr. Kane states that if the cold is sufficiently intense, the water which is obtained on melting the ice is fit for drinking. This plan is pursued in Prussia, Sweden, and other northern countries, where the sea-water is frozen in reservoirs, and the concentrated brine liquor is boiled down to salt. The salt obtained by this plan, however, is not pure, as the following analyses by Hess will prove.

The evaporation of sea-water is effected wholly or partly by the influence of the air and sun, in what are termed in some localities *Salterns* or *Brine-pans*. Hayling Island, near Portsmouth, has been celebrated for many centuries for its manufacture of salt, carried on in this way during the summer months. The brine-pans vary in size up to a quarter of an acre, in which, in favourable weather, the sea-water becomes brine in about seven days. It is then pumped by windmills into reservoirs or pits, whence it is run into sheet-iron pans, and is boiled for twelve hours, during which

it is skimmed to remove impurities. The crystals of salt begin to appear towards the end of the day, and are shovelled out, hot and wet, into wooden troughs with holes in the bottom to allow the *Litters* to run off.

A somewhat similar plan is pursued at Lymington in Hampshire, but the brine is there run through a series of salterns before it is pumped into the boiling-pans. The drainings from the troughs drop on upright stakes of wood, on which stalactitic masses accumulate in ten or twelve days, weighing from 60 to 80 lbs.; these masses are called *Salt cats*. The residual liquor called *Bitters*, *Bittern*, or *Bittern liquor*, is employed in the manufacture of the carbonate or sulphate of magnesium.

For many centuries salt was also obtained from sea-water in the Firth of Forth and other places on the east coast of this country, by evaporating it in large shallow iron pans, salt works of this kind in former days being given as donations to abbeys.

In warmer latitudes, as on the shores of the Mediterranean, the evaporation is carried on entirely under the influence of the sun and air in a series of shallow ponds, called *salt-gardens*, in which the water is spread over a very large surface. As the evaporation goes on, salt is deposited in the pools farthest from the sea, while the nearer ones are constantly receiving fresh supplies of salt water.

In the salt works of the Mediterranean, the greater part of the surface is about a foot below the main level of the sea. The ponds are divided by small banks of earth two feet high and from one to two feet thick. The salt water is admitted by a small flood-gate and circulates by means of openings in the banks. It enters with a density of 1·025, and continues to increase in density by evaporation under the influence of the dry winds, until it attains a density of 1·143. Its volume is then reduced to one-sixth of its first proportions. It now begins to deposit sulphate of calcium, till the density reaches 1·210. It is then conveyed by means of pumps, worked by horse or steam power, to reservoirs slightly more elevated, the bottoms of which are generally composed of hard clay well beaten in, where the precipitation of the salt takes place. The volume is by this time reduced to one-tenth of its original bulk. From the density of 1·210, representing 25° on Beaumé's hydrometer, up to 1·286, equal to 32° on the same scale, the evaporation takes place in the open air, the liquid constantly depositing chloride of sodium almost pure, which goes into the market without further preparation. In order to obtain it care is taken to run off the liquor marking 32° B., which covers the bed of salt about two inches thick. It is then collected by means of shovels, and thrown into heaps called in the south of France *Caniells*, and in Italy *Cumuli*. It is then allowed to drain, after which it is ready for sale. The salt thus obtained is called bay-salt.

The mother-liquor or bittern is used as a source of bromine. It also contains considerable quantities of sulphate of sodium, and of the sulphates and chlorides of magnesium and potassium. The mode of treating it so as to obtain these salts, especially the chloride of potassium, has been brought to great perfection by Balard. (See POTASSIUM-SALTS, iv. 717, also SULPHATES.)

The following table shows the nature and amount of the impurities in several kinds of commercial salt.

Properties.—Pure chloride of sodium has an agreeable saline taste. It crystallises from aqueous solution by evaporation at ordinary or higher temperatures, in colourless transparent cubes, which are anhydrous. Rock-salt is often found crystallised in cubes, octahedrons, and intermediate forms, and occasionally in tetrakis-hexahedrons (ii. 127); it exhibits perfect cubic cleavage. Specific gravity 2·1—2·57. Hardness = 2·5. It often occurs in large crystalline, transparent, and colourless masses, possessing perfect diathermancy, that is to say, it is equally pervious to heat-rays of every degree of refrangibility (p. 61). An aqueous solution of sodic chloride exposed to a temperature of about −10° deposits the salt in hexagonal plates containing $NaCl.2H^2O$; but as the temperature rises, the water of crystallisation is expelled, and the crystals fall to pieces, being converted into a heap of minute cubes. The anhydrous salt, when rapidly crystallised, contains mechanically enclosed water, and consequently decrepitates in the fire. Some specimens of rock-salt from Wieliczka decrepitate when thrown into water, owing to the escape of condensed gas, consisting, according to H. Rose, of CH^4.

Chloride of sodium melts at a red heat, and forms a crystalline mass on cooling. It is somewhat less volatile than chloride of potassium, but like that salt, volatilises at a low red heat in open, but not in covered, vessels (**H. Rose**); at a white heat it volatilises, even in closed vessels. Heated with potassium, it yields chloride of potassium, and metallic sodium (**Davy**). When heated to redness with silica, it yields silicate of sodium and hydrochloric acid gas, the decomposition taking place rapidly in presence of aqueous vapour. With oil of vitriol it gives sulphate of sodium and hydrochloric acid gas. According to Berthollet, it also evolves a small quantity of hydrochloric acid gas by distillation with oxalic acid, but not with acetic acid. In solution it is decomposed by excess of lead-oxide, into soda and subchloride of lead, Pb^2Cl^2 (**Scheele**), also by nitrate of ammonia. (**Karsten.**)

Anhydrous chloride of sodium dissolves in about 3 pts. of cold water, and is scarcely more soluble in boiling water. Fuchs states that 100 pts. of water dissolve 37 pts. of it at all temperatures; but, according to Gay-Lussac and Poggiale, the solubility increases slightly with rise of temperature, as shown by the following table:

			Poggiale.	Gay-Lussac.	
100 parts of water at	0°	dissolve of NaCl	35·52		parts
„ „	14	„	35·87		„
„ „	$14\frac{4}{5}$	„	. .	36	„
„ „	60	„	. .	37	„
„ „	100	„	36·61		
„ „	$107\frac{3}{5}$	„	. .	40·38	„
„ „	110	„	40·35		

The specific gravity of the solution increases with its strength as follows (**Gerlach**, Jahresb. 1859, p. 43):

Quantity of NaCl in 100 pts. of solution.	5	10	15	20	25	26·395
Specific gravity of solution at 15°.	1·0362	1·0734	1·1115	1·1511	1·1923	1·2043

The number 26·395 represents the quantity of anhydrous sodium-chloride in a saturated solution at 15°. For an extended table by Gerlach of the specific gravities of salt-solutions of various strengths and at various temperatures from 0° to 100°, see *Chemical Technology*, vol. i. part 5. See also **Schiff** (Jahresb. 1858, p. 39); and **W. Schmidt** (*ibid.* 1859, p. 128).

The following determinations of the variations in volume of salt-solutions at different temperatures are by **Kremers** (Jahresb. 1857, p. 68):

Volumes of Aqueous Chloride of Sodium at different temperatures (vol. at 19·5° = 1).

Quantity of salt in 100 p.s. water.	4·7	10·0	15·4	20·5	25·8	31·4

100	1·04179	1·04209	1·04217	1·04214	1·04211	1·04190

The freezing and boiling-points of the solution rise with the degree of concentration in the manner shown in the following table (Karsten):—

Per cent. of salt	1	5	10	15	20	25	29
Freezing-point .	0·76°	3·78°	7·44°	10·99°	14·42°	17·77°	
Boiling-point .	100·21°	101·10°	102·38°	103·99°	105·46°	107·27°	108·83

For more extended tables see *Chemical Technology*, vol. i. part 5.

Chloride of sodium is precipitated from its aqueous solution by passing hydrochloric acid into the liquid till it is saturated; this reaction is recommended by Margueritte for separating the salt from brine-liquors. Chloride of sodium is insoluble in pure alcohol, but is taken up in considerable quantity by dilute spirit.

Chloride of sodium unites with other metallic chlorides, forming crystallisable double salts; these are described with the chlorides of the several metals.

SODIUM, DETECTION AND ESTIMATION OF. 1. *Blowpipe Reactions.*—Sodium-compounds impart an intense yellow colour to the outer blowpipe-flame, which quite conceals the coloration produced by any other metal. Alcoholic solutions of sodium-salts burn with a yellow flame. The spectrum of sodium is distinguished by a single bright-yellow line, coinciding with the dark solar line D.

2. *Reactions in Solution.*—Sodium-salts are even more generally soluble than potassium-salts. They give no precipitate with *platinum-chloride, tartaric acid*, or *perchloric acid*, and no crystals of alum with *sulphate of aluminium*. *Silicofluoric acid* gives a gelatinous precipitate in concentrated solutions.

Acid metantimonate of potassium (i. 326) gives a white precipitate of metantimonate of sodium, flocculent at first if the solution is not very dilute, but soon becoming crystalline. It is produced immediately, in solutions containing not less than 1 pt. of sodium-salt in 300 pts. of liquid. In more dilute solutions the precipitation is gradual, and the metantimonate of sodium is deposited in crystals on the sides of the vessel, the effect being apparent after 12 hours, even in solutions containing not more than $\frac{1}{1000}$ pt. of sodium-salt. The solution of sodium to be tested should be neutral or slightly alkaline, for free acid would separate antimonic acid from the reagent. It must also be free from salts of lithium, ammonium, and the earth-metals, all of which, when diluted to a certain extent, yield precipitates of similar character.

3. *Estimation and Separation.*—Sodium is estimated as sulphate or chloride, in the manner already described for potassium (iv. 699).

Sodium is separated from all the metals of Groups i. and ii. (Analysis, i. 217), by sulphydric acid and sulphide of ammonium; from the alkaline earth-metals by carbonate of ammonium; from magnesium by baryta-water; from potassium by platinic chloride and alcohol; from lithium by the solubility of lithium-chloride in alcohol and ether.

The separation of sodium from potassium is best effected when the metals are in the form of chlorides. The amount of potassium being determined from the weight of the chloroplatinate, that of sodium may frequently be estimated by difference. To estimate the sodium directly, the filtrate from the potassium-salt must be evaporated to dryness at a very gentle heat, and the residue ignited in a platinum crucible till the sodic chloroplatinate and the excess of platinic chloride are entirely decomposed; this decomposition is facilitated by adding a few crystals of oxalic acid during the ignition. The chloride of sodium thus formed is dissolved out by water, evaporated to dryness, ignited, and weighed. Removing the platinum by sulphydric acid does not give good results (H. Rose). The indirect method of analysis (i. 224) may also be advantageously applied, in many cases, to the estimation of potassium and sodium when they occur together.

4. *Atomic Weight of Sodium.*—Berzelius found that 100 pts. of sodium-chloride, NaCl, gave by precipitation 244·6 pts. silver-chloride; the atomic weight of sodium thence deduced is 23·17. Penny (Phil. Trans. 1839, p. 13), by determining the quantity of sodic nitrate produced by decomposing a given weight of sodic chloride with nitric acid, obtained, as a mean of seven closely-agreeing experiments, Na = 23·0. Pelouze (Ann. Ch. Pharm. lvi. 202) found, as a mean of three experiments, that 100 pts. of silver required for precipitation 54·144 pts. sodium-chloride: whence Na = 22·97. Dumas (*ibid.* cxiii. 31), as a mean of seven experiments of a similar kind, found Na = 23·01; and Stas found Na = 23·05. The atomic weight of sodium may therefore be taken as 23.

SODIUM, FLUORIDE OF. NaF. Obtained by saturating hydrofluoric acid with carbonate of sodium. It crystallises in white anhydrous cubes or octahedrons, soluble in 25 pts. of cold, and not much more soluble in hot water; the solution attacks glass. The fluoride is insoluble in alcohol.

Sodio-hydric fluoride, NaF.HF, crystallises by spontaneous evaporation from a solution of sodic fluoride supersaturated with hydrofluoric acid, in small rhombohedrons, having the angle of the terminal edges = 74° 36′, and often united in twins, having oP for the face of junction. (Marignac, Jahresb. 1857, p. 128.)

A *sulphato-fluoride of sodium*, $NaF.Na^2SO^4$, was found by Marignac (*ibid.* 1859, p. 106) to separate from the mother-liquor obtained in the preparation of sodium-fluoride with hydrofluoric acid containing a little sulphuric acid, in small hexagonal plates, which could be recrystallised from water without decomposition.

Fluoride of Sodium and Aluminium. Cryolite, $3NaF.AlF^3$ (i. 159).—This mineral is now used for the preparation of soda.

SODIUM, HYDRATE OF. $NaHO$ or $Na^2O.H^2O$. *Caustic Soda, Hydrated Oxide of Sodium, Mineral Alkali, Natronhydrat.*—This compound is formed when the protoxide or the dioxide of sodium is brought in contact with water, the action being attended with rise of temperature, and, in the latter case, with evolution of oxygen. It is prepared, like caustic potash, by decomposing sodic carbonate with lime; 3 pts. of crystallised sodic carbonate are dissolved in 15 pts. of boiling water, and a quantity of cream of lime, prepared by slaking 1 pt. of lime with 3 pts. of water, is added by small portions, the whole being boiled for some time, and treated as for potash (iv. 700). The hydrate thus obtained may be purified by alcohol. To obtain pure caustic soda without the use of alcohol, Gräger (J. pr. Chem. xcvi. 165) treats the carbonate, previously purified so far as to retain only a trace of chloride, with carbonate of silver, then boils it with calcined marble, and, lastly, filters the solution through a funnel, the throat of which is stopped with lumps of marble and pulverised marble, previously washed with distilled water.

In preparing caustic soda from the carbonate on the large scale, it is of importance to recover all the soda which remains diffused through the lime-mud. In some manufactories the mud is washed repeatedly, and the weak liquors are used either for dissolving fresh portions of carbonate, or for diluting the black ash-liquor; in other works the lime-mud is filtered in the following manner:—A shallow tank of stone or flags is so built that the bottom inclines towards one part, from which a pipe leads away the filtrate: rows of porous firebricks are set lengthways, three inches apart in the bottom of the tank, and upon these are laid in cement porous quarls, which form the filtering-bed. The lime-mud is run on to this bed and allowed to filter for some time, after which a few inches of water are gently run on to the pasty mass, so as not to disturb the particles. When this is properly managed, the water forces a strong ley out of the precipitate, without much diminution of its strength. The filtering-bed may also be constructed of large stones, gravel, and fine sand.

Caustic soda is now made in large quantity from black ash-liquors. For this purpose the liquors are concentrated in a fishing or boat-pan 30 feet long, 8 feet wide, and 2½ feet deep at the greatest depth, up to a specific gravity of 1·40, at a temperature of 260° or 270° F., whilst a little nitrate of sodium is added to oxidise the sulphate of sodium in the black ash. The separating salts are fished out, and the liquor is run into settlers, where more salts deposit during the cooling. The liquor is now run into a hemispherical cast-iron pot (about 5 feet diameter at the top, and 5½ feet deep, including a cast-iron ring about 2½ feet high), and more nitrate of sodium is added. It is boiled in this pot from 12 to 24 hours, during which a further deposit of salts takes place, which are fished out. The liquor is then transferred into another similar pot, called the "finisher," and boiled until it contains 60 per cent. of soda, during which more nitrate of sodium is added, while a thick scum which forms on the surface is skimmed off. When the concentration is complete, the fire is withdrawn, and the melted mass allowed to settle, after which it is run off into iron casks, or on to plates, to solidify.

Arrott proposes to produce a caustic soda from sulphide of sodium, with the aid of the oxides of iron or manganese. Hunt recommends the boiling of the solution of sulphide of sodium with oxide of zinc or black oxide of copper. Gossage has patented the manufacture of caustic soda from silicate of sodium by decomposition with lime, and proposes to employ the resulting calcic silicate as manure. Any of the other methods described for the preparation of caustic potash may also be applied to soda. F. O. Ward proposes to prepare it from albite, in the same manner as potash from orthoclase, by calcining the mineral with lime and fluor-spar. According to another method, patented by Newton, felspar is heated with calcic phosphate and lime, all in powder, at a low red heat, whereby calcic silicate and alkaline phosphate are produced; and when the mass is lixiviated with water, the lime decomposes the alkaline phosphate, reproducing calcic phosphate, while the alkali remains in solution.

Cryolite is now employed as a source of soda on the manufacturing scale in several places on the Continent (Copenhagen, Harburg, &c); the old process was to treat the finely-ground cryolite with sulphuric acid, but this plan is now entirely abandoned. The cryolite is ground to powder and mixed with lime, and either calcined or boiled with as much water as will form a milk. The boiling must be continued for several hours. When the mixture has been calcined, the mass must be exhausted with water. The hydrofluoric acid, alumina, and lime form an insoluble compound, while the caustic soda remains in solution. The following equation shows the change:—

$$AlF^3.3NaF + 3Ca''H^2O^2 = 3NaHO + Al'''H^3O^3 + 3Ca''F^2.$$

Hydrate of sodium is a white, opaque, brittle substance, having a fibrous texture, and specific gravity = 2·00 (Dalton). It melts below redness, but is less volatile at a red heat than hydrate of potassium. It colours the blowpipe-flame intensely yellow.

Crystallised Sodic Hydrate.—Soda-ley of specific gravity 1·385, cooled to 0°, yields large glassy crystals of a hydrate containing $2NaHO.7H^2O$, or $Na^2O.8H^2O$. It melts at 6°, forming a liquid of specific gravity 1·405; absorbs carbonic acid rapidly from the air, water more slowly; gives off half its water in a vacuum over oil of vitriol. It crystallises also very pure from a solution of caustic soda containing sulphate or chloride of sodium (Hermes, Pogg. Ann. cxix. 170). According to G. Rose (Jahresb. 1863, p. 179), the crystals are monoclinic, exhibiting the combination $oP \,.\, \infty P \,.\, +P \,.\, -P \,.\, +2P\infty \,.\, [\infty P\infty]$; tabular by predominance of oP. Angle $\infty P : \infty P$ (clinod.) = 98°; oP: the clinodiagonal prismatic edge = 104°; $2P\infty$: the same = 137°; $oP : \infty P$ = 98° (approximately).

Soda-ley.—Prepared as above from the carbonate, or by dissolving the solid hydrate or anhydrous sodic oxide in water. It is a colourless caustic liquid. A saturated solution at common temperatures has a specific gravity of 1·500 (Dalton); boils at 130°, and contains 36·8 per cent. of soda. 100 pts. of water dissolve, at 18°, 60·53 pts. of hydrate, or 41·43 pts. of dry soda; at 32°, 72·91 hydrate or 45·72 dry soda; at 55°, 100 hydrate or 63·53 dry soda; at 70°, 116·75 hydrate or 71·98 dry soda; and at 80°, 127·02 hydrate or 78·3 dry soda (Osann):—

Amount of Anhydrous Soda (Na^2O) *in a Solution of Caustic Soda, according to* Tünnermann.

(See also Richter's Tables, *Stöchiometrie*, iii. 332; Dalton's Elements, ii. 315).

The reactions of caustic soda are the same as those of potash, excepting that it gives no precipitate with platinic chloride, tartaric acid, or perchloric acid. It is very extensively used for making soap, and indeed for all purposes for which a caustic alkali is required, as it is cheaper than potash, weight for weight, and, moreover, as its combining number is less, a smaller quantity suffices to do a given amount of work.

SODIUM, IODIDE OF. NaI.—This salt is contained in the mother-liquors of kelp. It may be prepared by dissolving iodine in a strong solution of soda, evaporating, and slightly calcining the residue to decompose the iodate formed at the same time. It crystallises from aqueous solution, at 20° and upwards, in anhydrous cubes; at lower temperatures in hexagonal plates containing $NaI.2H^2O$. The anhydrous salt melts when heated, and volatilises at a higher temperature, giving off part of its iodine. It is deliquescent, easily soluble in water and in alcohol; 100 pts. water at 14° dissolve 173 pts. of it. The following relations between the specific gravity and strength of the aqueous solution have been determined by Kremers (Jahresb. 1858, p. 40), the specific gravities being referred to water at 19·5° as unity:—

Quantity of NaI in 100 parts of water	24·5	50·2	79·4	115·6	149·7
Specific gravity of solution	1·1752	1·3362	1·4962	1·6659	1·8047

The following table exhibits the expansion of solutions of sodium-iodide at different temperatures (Kremers, Jahresb. 1859, p. 49):—

Volumes of Aqueous Sodium-Iodide at different temperatures (vol. at 19·5° = 1).

Quantity of Salt in 100 pts. of Water.	31·8	64·5	99·9	138·0
Specific gravity at 19·5°	1·2234	1·4155	1·5942	1·7603
0°	0·99272	0·09030	0·98934	0·98918
19·5	1·00000	1·00000	1·00000	1·00000
40	1·00942	1·01104	1·01169	1·01179
60	1·02021	1·02264	1·02366	1·02382
80	1·03257	1·03514	1·03614	1·03621
100	1·04612	1·04840	1·04917	1·04887

A saturated aqueous solution of sodium-iodide boils at 141° (Kremers).

A compound of *sodic iodide* and *iodate*, $3NaI.2NaIO^3.20H^2O$, crystallises in hexagonal tables, oR . ∞R with + R, $-\frac{1}{2}$ R, &c. Angle, oR : + R = 115° 7′; oR : $-\frac{1}{2}$ R = 133° 10′. (Marignac, Jahresb. 1857, p. 124.)

SODIUM, OXIDES OF. Sodium forms a protoxide and a dioxide.

The *protoxide*, Na^2O, or *anhydrous soda*, is produced, together with the dioxide, when sodium burns in the air, and may be obtained pure by exposing the dioxide to a very high temperature, or by heating sodic hydrate with an equivalent quantity of sodium: $NaHO + Na = Na^2O + H$. It is a grey mass, having a conchoïdal fracture, melts at a red heat, volatilises with difficulty, is a non-conductor of electricity. Specific gravity = 2·805 (Karsten).

Dioxide or *Peroxide of Sodium*, Na^2O^2, is obtained by igniting sodium in oxygen-gas till its weight becomes constant. It is of a pure white colour, but becomes yellow when heated, and white again on cooling. When exposed to the air, it slowly deliquesces, and after a while resolidifies as carbonate. On mixing it with water, great heat is produced, and a small quantity of gas is evolved (arising from the local heating of the peroxide). A small heap of it, when moistened, becomes yellow with heat, and gives off a considerable quantity of oxygen. If, on the contrary, it be thrown into water in the state of powder by small portions at a time, it dissolves with very little evolution of gas, and forms a solution of dioxide.

A solution of the dioxide evaporated over a water-bath, gives off oxygen slowly at first, but rapidly as the solid residue begins to separate; but if evaporated slowly over oil of vitriol at common temperatures, it yields, without evolution of oxygen, large hexagonal tabular crystals of a hydrate, containing $Na^2O^2.8H^2O$.

These crystals, when left to effloresce over oil of vitriol for nine days, lost three-fourths of their water, and yielded another hydrate containing $Na^2O^2.2H^2O$.

Iodine decomposes sodic dioxide, forming an oxyiodide and liberating oxygen:

$$Na^2O^2 + I^2 = Na^2I^2O + O.$$

The dioxide absorbs *carbonic oxide*, forming sodic carbonate:

$$Na^2O^2 + CO = Na^2CO^3.$$

With *carbonic anhydride*, the same compound is formed, and 1 at. oxygen set free. With *nitric oxide* it forms sodic nitrite:

$$Na^2O^2 + 2NO = 2NaNO^2.$$

With *nitrous oxide* the same salt is formed, and 2 at. nitrogen given off:

$$Na^2O^2 + 2N^2O = 2NaNO^2 + N^2.$$

(A. Vernon Harcourt, Chem. Soc. J. xv. 267.)

SODIUM, OXYIODIDE OF. Na^2I^2O, or $NaI.NaIO$?—Produced, as above mentioned, by the action of iodine on sodic dioxide. It dissolves in acidulated water with separation of iodine:

$$Na^2I^2O + HCl = NaHO + NaCl + I^2.$$

SODIUM, SULPHIDES OF. Sodium forms with sulphur a number of compounds corresponding exactly with the sulphides of potassium (iv. 707), and prepared in the same manner. The protosulphide, Na^2S, crystallises in large octahedrons, and forms a large number of sulphosalts, most of which are crystallisable. Hydrate and carbonate of sodium react with sulphur, both in the wet and in the dry way, in the same manner as hydrate and carbonate of potassium.

SODIUM, TELLURIDE OF. Analogous to telluride of potassium.

SOILS. The term "soil" is applied to the upper stratum of the earth's crust,—that which is available for the growth of plants. A soil consists of mineral substances resulting from the decomposition or weathering of rocks, mixed with organic matter—the so-called *humous substances*—produced by the decay or putrefaction of plants which have grown upon it, and in cultivated soils, with the various substances, organic and inorganic, added in the form of manure. The stratum immediately below the cultivable soil, consisting of disintegrated rock, not touched by the spade or plough, and reached only by the deeper-rooting plants, is called the "subsoil."

The soil is the source whence plants derive the whole of their mineral food. All plants require for their nutrition phosphoric acid, sulphuric acid, alkalis, lime, magnesia, and iron: many species require silica; those which grow on the seashore require sodium-salts and metallic iodides. All the compounds required for the nutrition of plants are, in a certain sense, of equal value: if one of them is wanting in the soil, or present only in a form which cannot be taken up by the roots, the plant will not flourish.

The organic constituents of the soil serve as sources of carbonic acid and ammonia. The ammonia is produced by the putrefaction of nitrogenous matters—the carbonic acid by the oxidating action of air penetrating the soil on the carbon of the humous substances. The carbonic acid thus produced not only serves as a source of carbon to the growing plant, but likewise assists in the disintegration of the mineral constituents of the soil, by dissolving the earthy phosphates and decomposing the felspathic minerals. Chloride and nitrate of sodium and ammoniacal salts likewise dissolve the phosphates of calcium and magnesium, and thus contribute to diffuse them through the soil.

It was formerly supposed that the constituents of a soil could not be taken up by the roots of plants, unless they were in the state of solution; but later researches have shown that this is not the case, but that soils, especially those which contain abundance of decayed vegetable matter or humus, have the power of absorbing the acids, alkalis, and salts which filter through them in the state of solution, and retaining these substances in a state of loose combination, in which they are ready to be taken up by the roots of plants.

In 1845 H. S. Thomson (Agr. Soc. J. xi. 68) observed that when solutions of sulphate or carbonate of ammonium are filtered through soils, the first portions of the filtrate contain only traces of ammonia, but, in the case of the sulphate, a considerable quantity of gypsum. Huxtable, about the same time, found that dunghill water filtered through a loamy soil loses its colour and odour.

These observations were further extended by Way (Agr. Soc. J. xi. 313), who showed that certain constituents of farmyard manure, when brought in contact, in the state of solution, with arable soil, lose their solubility, and unite in a peculiar manner with the soil. Caustic ammonia, and sulphate, nitrate, and chloride of ammonium, treated in aqueous solution, with excess of soil, give up their ammonia to it completely; while the sulphuric, nitric, or hydrochloric acid unites with other bases (generally lime) contained in the soil, forming soluble salts which filter through. A similar absorptive power is exerted by the particles of a soil on potash, whether in the caustic state, or in the form of potassic sulphate, nitrate, or chloride. Solutions of sodium and magnesium-salts likewise give up their bases to the soil. Phosphates, however, are not affected by the soil in the same manner as sulphates, nitrates, and chlorides, inasmuch as from solutions of sodic phosphate, or from a solution of guano-ash in dilute sulphuric acid, the phosphoric acid, as well as the base, is withdrawn by the particles of the soil. Way likewise found that putrid urine, the retting water of flax, and sewage-water, are deprived by contact with soil, of their ammonia, potash, and phosphoric acid.

The absorptive power of a soil for potash, ammonia, and phosphoric acid can scarcely be regarded as a definite chemical action, inasmuch as it is exerted in an equal degree by soils of the most various composition: a soil abounding in clay, with a small proportion of lime, possesses it in the same degree as a lime-soil containing a small free portion of clay; it is, however, considerably affected by the quantity of humus present in the soil.

The absorptive power of arable soil depends very much on its degree of porosity; a dense heavy clay-soil and a loose sandy soil possess it in the least degree, and it is most strongly exhibited by those soils which have a light porous structure, like wood or charcoal; in fact, it is similar to the surface-attraction exerted by charcoal on colouring-matters, the attracted particles not entering into a new chemical combination, but retaining their original properties. When a salt, such as sulphate of ammonium or potassium, gives up its base to the soil, the acid separated therefrom enters into combination with lime or magnesia contained in the soil. The attractive force of the earthy particles for the alkali would probably not be sufficient in itself to separate it from the sulphuric or nitric acid, but the decomposition takes place when assisted by the additional attraction of the lime or magnesia for the sulphuric or nitric acid.

Absorption of nutriment from the soil is effected by the extremities of the roots, which must therefore be in immediate contact with the nutritive particles, and hence the necessity of sufficient porosity in the soil to enable the roots to spread and ramify in all directions through it. "The effect produced by breaking up the ground with the plough, spade, hoe, harrow, and roller, depends upon the fact that the roots of plants go in search of their food, that the nutritive substances have no locomotion of their own, and cannot of themselves leave the places in which they are. The root, as if it had eyes to see, bends and stretches in the direction of the nutriment; so that the number, thickness, and direction of its filaments indicate the precise spots where they have obtained food." (Liebig, *The Natural Laws of Husbandry*, London 1853, chapter ii.)

Analysis of Soils.*—The method at present adopted for the analysis of soils is essentially the same as that described by Sprengel and Otto in Sprengel's "Bodenkunde;" depending on the principle, that in order to judge of the fertility of a soil, it is necessary to determine not only what are its elementary constituents, but likewise the manner in which they are combined. With this view, Sprengel and Otto treated a sample of the soil successively with water, dilute hydrochloric acid, strong sulphuric acid, and by fusion with an alkaline carbonate. The constituents of the soil soluble in water were supposed to be actually available as plant-food; those which were soluble in dilute acids as available for that purpose after being subjected to the action of carbonic acid and the humous acids of the soil; the rest as available only after the soil had been subjected for a considerable time to atmospheric influences, assisted by the mechanical operations of tillage. This mode of proceeding was originally based upon the supposition that the constituents of the soil which are to nourish the plant must be presented to it in the state of solution, a view which, as already observed, can no longer be regarded as correct. Still, as the several constituents must be brought into the state of solution before they can be distributed through the soil, and be taken up by its particles in the state of physical aggregation above described, the separation of the soil into portions soluble in water and acids, and an insoluble portion, is still capable of affording useful information as to its nutritive properties.

a. Constituents soluble in Water.—An average sample of the soil having been obtained, and freed from stones and the coarsest particles by sifting, the original plan was to heat a considerable quantity of it (1000 to 2000 grms.) with water nearly to the boiling-point, then filter; wash the residue as completely as possible with hot water; evaporate the entire liquid to about the volume of the water first employed; filter again to separate any deposit that may have formed; then determine the volume of the filtrate; and employ measured quantities of it for estimating the several constituents.

The total amount of the constituents soluble in water is obtained by evaporating a measured quantity of the solution to dryness, and weighing the residue when it no longer loses weight at 100°. The dry residue is then gently ignited for some time in contact with the air, and weighed after drying over oil of vitriol, the loss of weight thus determined being reckoned as organic matter, nitric acid, and ammonia, supposing the presence of the two latter substances to have been previously ascertained by qualitative analysis. The ignited residue is then treated with hydrochloric acid, and evaporated to dryness; the remaining substance is exhausted with dilute hydrochloric acid, and the undissolved silica separated by filtration.

The filtrate is next treated with chlorine-water, and ammonia is added, whereby a precipitate is formed containing alumina, ferric oxide, manganic oxide, and phosphoric acid, together with a portion of the lime and magnesia, in case the quantity of phosphoric acid is considerable. This precipitate is collected and weighed, and its several constituents are separated and estimated in the manner already described with reference to the ash of organic bodies (i. 419). If its quantity is too small for the estimation of all the constituents, the phosphoric acid should at least be determined.

The filtrate from the last-mentioned precipitate is mixed with oxalate of ammonium to separate lime. If this base is present, the solution cannot contain any more phosphoric acid; it is then to be filtered and evaporated, the residue ignited to expel ammoniacal salts, then dissolved in water, and treated by the usual methods for separating the **magnesia, potash,** and **soda.** If, on the other hand, the alkaline earths have been wholly precipitated, together with phosphoric acid, in the liquid filtered from the silica, phosphoric acid may still be present in the filtrate containing the alkalis. In that case the phosphoric acid may be separated by methods already described (iv. 549).

Chem.*, 2te Aufl. ii, [2] 246.

Separate quantities of the aqueous extract of the soil are used for estimating **sulphuric acid** by chloride of barium, and **chlorine** by nitrate of silver. **Carbonic acid,** if present, is estimated in a portion of the extract evaporated to a small bulk, by the method given under ALKALIMETRY (i. 119).

It is evident, however, that an aqueous extract prepared as above, by boiling with distilled water, cannot afford an exact representation of that solution which is actually formed in the soil by rain-water, under the varying atmospheric conditions to which the soil is exposed in the course of a season. To obtain such a solution, an instrument called a "lysimeter" is employed, consisting of a square box, usually made of zinc, open at top, closed at bottom, and having an internal area of exactly one square foot. At the depth of six inches from the upper edge is placed a perforated bottom; the space above this is filled with earth, and the box is sunk in the ground to the level of the upper edge. All rain-water which falls on this square foot of surface must, therefore, either evaporate or filter through the six-inch layer of soil and collect in the box below. The instrument is taken up and emptied every three months, or oftener if the amount of rain is greater than usual.

The following table contains the results of several analyses by Zöller of drainage-water collected in the lysimeter:—1. From manured lime-soil with vegetation.—2. Rough clay-soil with vegetation.—3. Rough clay-soil without vegetation.—4. Manured clay-soil without vegetation.—5. Manured clay-soil with vegetation:—

β. *Estimation of the constituents soluble in dilute Hydrochloric Acid.*—This is the most important part of a soil-analysis, inasmuch as it shows the total amount of those constituents of the soil which are readily available as plant-food. It was formerly made on the residue left after exhausting the soil with boiling water; but as this mode of extraction is no longer regarded as of much importance, it is now more generally made upon the soil in its original state, after mechanical separation of the stones and coarser particles.

A quantity of the soil (50 to 100 grms.) is mixed with water to a thin paste in a flask, and hydrochloric acid is gradually added, as long as any effervescence is thereby produced; the whole is then warmed for a time, with frequent agitation, then filtered, and the insoluble residue thoroughly washed. The filtered solution is evaporated to dryness, after addition of a little nitric acid; the silica is separated by filtration and weighed; and the filtrate is divided into several portions, which are measured or weighed, and used for the estimation (1) of **sulphuric acid**; (2), of **phosphoric acid, alumina, ferric oxide, manganous oxide, lime,** and **magnesia**; (3), of the **alkalis.** A separate portion serves for the estimation of **carbonic acid,** and another for that of **ferrous oxide,** supposing this oxide to be present in the soil together with ferric oxide. For this latter purpose, Fresenius adopts Margueritte's method with potassic permanganate (i. 263; iv. 384), which, however, is not applicable when organic matter is present. In this case it is best to digest the soil with hydrochloric acid in an atmosphere of carbonic anhydride, then nearly neutralise the free acid with sodium-carbonate, and add levigated barium-carbonate in excess, which will throw down the whole of the ferric oxide, leaving the ferrous oxide in solution. The liquid is then filtered in an atmosphere of carbonic anhydride; and the iron in the filtrate is brought to the state of ferric oxide by chlorine-water or nitric acid, and precipitated in that form by ammonia.

γ. *Portion insoluble in dilute Hydrochloric Acid.*—This portion of the soil generally consists of clay and sand, mixed with other minerals. By heating a portion of it (5 to 10 grms.) with several times its weight of strong sulphuric acid, till the greater part of that acid is volatilised, the clay is decomposed, the other constituents remaining for the most part unaltered. The whole is left to cool, the nearly dry residue is treated with dilute hydrochloric acid, and the bases are determined in the filtered solution in the way already indicated (β). From the undissolved residue, the pulverulent silica separated from the clay may be dissolved out, though with considerable difficulty, by repeated boiling with strong solutions of sodic carbonate. There then remains a mixture of sand and other minerals not decomposible by oil of vitriol, the nature of which may generally be determined with sufficient accuracy by the microscope.

δ. *Estimation of Organic Matter.*—The total quantity of organic matter in a soil, consisting of remains of plants and products of decay (the so-called humous substances), may be roughly estimated from the loss of weight which the dried soil undergoes when exposed to a low red heat not strong enough to decompose the earthy carbonates. Many soils, however, especially those containing clay, give up a certain portion of water only at a red heat; moreover, ammonia and nitric acid may be included in the loss of weight obtained on ignition. Hence it is better to determine the amount of carbon in the soil by combustion with oxide of copper, deducting from the amount of carbonic anhydride thus obtained that which exists in the soil in the form of carbonates, or making the combustion on a portion previously freed from carbonates by treatment with dilute acid. Another method is to digest 5 grms. of the soil with 10 c. c. water and 15 c. c. oil of vitriol, allow the disengaged carbonic anhydride to escape, then add 5 grms. of acid potassic chromate, heat the liquid, and collect the carbonic anhydride thereby evolved. (Wolff.)

ε. *Estimation of Nitrogen.*—The entire quantity of nitrogen existing in a soil, in the form of ammonia, of nitric acid, and of organic compounds, may be estimated by combustion with oxide of copper, as in Dumas's method (i. 242). To determine the nitric acid, Wolff exhausts 500 grms. of the soil with cold water; evaporates the filtrate to 30 c. c.; mixes it with a little potash-ley, and boils till ammonia is no longer evolved; then reduces the nitric acid in the residual solution with zinc; and estimates it in the form of ammonia (iv. 88, 89).

No exact method has yet been discovered of determining the quantity of ammonia existing in a soil. W. Mayer found that even when ammonia was added to a soil, it could not be recovered with certainty by boiling with soda-ley.

The following tables exhibit the proportions of carbon and nitrogen found in several soils:—

SOIMONITE. Syn. with CORUNDUM.

SOLANICINE. $C^{50}H^{78}N^{2}O$ (?).—A base produced by the action of hydrochloric acid on solanine. A solution of solanine in cold concentrated hydrochloric acid assumes at first a reddish or violet, then a yellow colour, and afterwards yields a red-brown precipitate containing the hydrochlorates of two new bases sparingly soluble in alcohol. From the alcoholic solution of the precipitate, ammonia throws down a yellow gelatinous mass, which, after treatment with hot alcohol (to remove solanine and solanidine), is resolved, by repeated digestion with ether, into a base soluble with yellow colour, and another nearly insoluble in ether.

The soluble base appears to be impure solanidine. The other, solanicine, which dissolves only in 2,000 pts. of ether, and is very slightly soluble also in water and in alcohol, may be obtained by slow evaporation of its ethereal solution, in slender needles or crystalline flocks. It melts, with decomposition, above 250°; is coloured red by concentrated acids; and forms amorphous, yellow, nearly neutral salts, easily soluble in water and in alcohol, but insoluble in ether. The deep yellow solutions have an astringent bitter taste, and are precipitated by concentrated hydrochloric acid. The *hydrochlorate* has the composition $C^{50}H^{78}N^2O.2HCl$; the *chloroplatinate* is $C^{50}H^{78}N^2O.2HCl.Pt^{iv}Cl^4$. (Zwenger and Kind, Ann. Ch. Pharm. cxxiii. 341.)

Solanicine gives by analysis (mean) 83·01 per cent. C, 10·83 H, 3·87 N, and 2·29 O, agreeing nearly with the formula $C^{50}H^{78}N^2O$, which requires 83·10 C, 10·80 H, 3·88 N, and 2·22 O. If it contained 2 at. hydrogen more, or if solanidine contained 2 at. hydrogen less, it might be supposed to be formed from solanidine by abstraction of H^2O; but neither of these suppositions agrees well with the analytical results. The formulæ of solanine and all its derivatives require further investigation.

SOLANIDINE. $C^{25}H^{41}NO$ (?).—A base produced, together with glucose, by the action of acids on solanine. It was discovered about the same time by Zwenger and Kind (Ann. Ch. Pharm. cix. 244), and by O. Gmelin (*ibid.* cx. 167), the latter of whom regards it as non-nitrogenous (p. 346). It is best prepared by boiling solanine with dilute hydrochloric acid, washing the precipitated hydrochlorate of solanidine with water, recrystallising it from alcohol mixed with ether, precipitating the alcoholic solution by ammonia, and recrystallising the precipitated base, first from alcohol, then from ether. (Zwenger and Kind.)

Solanidine dissolves easily in alcohol and in ether, but is nearly insoluble in water. It crystallises from alcohol in long colourless silky needles, from ether in thicker crystals, exhibiting, when magnified, the form of four-sided prisms. The solutions have a bitter somewhat astringent taste (Zwenger and Kind). The alcoholic solution gives a yellowish-brown precipitate with iodine (Kromayer). When quickly heated it melts above 200°, and sublimes almost without decomposition; when slowly heated, it decomposes more easily. From the solutions of its salts it is precipitated by ammonia, or the fixed alkalis, in the amorphous state. It is not decomposed by boiling potash-ley, and does not reduce chloride of gold, nitrate of silver, or an alkaline cupric solution. With moderately strong sulphuric acid, it gradually forms a dark-red solution, containing two new bases precipitable by water. With more dilute sulphuric acid, especially on addition of alcohol, it exhibits (like solanine) a transient bluish-red colouring, by which small quantities of it may be recognised.

Zwenger and Kind found in solanidine (mean of three analyses), 80·92 per cent. carbon, 11·15 hydrogen, 3·79 nitrogen, and 4·10 oxygen. The formula $C^{25}H^{41}NO$ requires 80·87 carbon, 11·05 hydrogen, 3·77 nitrogen, and 4·31 oxygen.

Salts of Solanidine.—Solanidine has a somewhat stronger alkaline reaction than solanine, and forms both neutral and acid salts, mostly crystallisable, bitter, sparingly soluble in water and in acids.—The *hydrochlorate*, $C^{25}H^{41}NO.HCl$, deposited from the solution of the base in alcohol containing hydrochloric acid, and recrystallised by slow evaporation from alcohol, forms rhombic prisms with end-faces; slightly soluble in water and in hydrochloric acid, easily in alcohol, and volatilising without decomposition when heated.—The *chloroplatinate*, $2C^{25}H^{41}NO.2HCl.Pt^{iv}Cl^4$, separates in yellowish flocks, when a solution of solanidine in alcohol containing hydrochloric acid, is mixed with platinic chloride and poured into cold water.—The *nitrate*, prepared like the hydrochlorate, crystallises in tufts of needles.—The *sulphate* is easily soluble in alcohol, less easily in water, and separates partly in slender needles, partly as an amorphous powder, apparently a mixture of the neutral and acid sulphates. (Zwenger and Kind.)

SOLANINE. $C^{43}H^{71}NO^{16}$ (?).—An organic base discovered in 1820 by Desfosses (J. Pharm. vi. 374), in the berries of the black nightshade (*Solanum nigrum*), and subsequently obtained from several other species of solanum; *e. g.*, from the berries of *Solanum verbascifolium*, from the berries and (in small quantity) from the tubers and green parts of the potato (*S. tuberosum*), but especially in the flowers, stalks, and berries of the woody nightshade (*S. Dulcamara*), and in the shoots or germs which potatoes throw out when kept in cellars during winter (0·068 per cent. according to J. Wolff and Blanchet). Solanine has been investigated by Desfosses (*loc. cit.*), by Payen and Chevallier (J. chim. méd. i. 517), O. Henry (J. Pharm. xviii. 661; xx. 54), Otto (Ann. Ch. Pharm. vii. 150, xxvi. 232), and others, and more recently by

Moitissier (*ibid.* i. 368), **Zwenger** and **Kind** (*ibid.* cix. 244; cxviii. 129), and **O. Gmelin** (*ibid.* cx. 167). The results of these several investigations exhibit many points of difference, possibly because the crystallisable bases obtained from different species of solanum are not really identical, or because many of the products examined were impure.

Preparation.—1. From *Potato-shoots.*—The fresh shoots are boiled in water slightly acidulated with sulphuric acid; the rapidly expressed liquid is precipitated, while still warm, by ammonia; the dried precipitate is exhausted with boiling alcohol; and the solanine, which separates almost completely on cooling, is several times crystallised from alcohol, till it dissolves in hydrochloric acid without turbidity. Fresh rather short potato-shoots, not too much developed, yield the largest quantity (**Reuberg**, Ann. Ch. Pharm. xxx. 225.—**Zwenger** and **Kind**).—As solanine is easily resolved, by heating with acids, into solanidine and sugar, care must be taken not to use the acid too strong or in too large quantity. Acetic acid, which does not decompose solanine, would perhaps be better adapted for the preparation than sulphuric or hydrochloric acid. According to **Kromayer** (Arch. Pharm. [2], cxvi. 214; Jahresb. 1863, p. 450), solanine is most easily obtained by precipitating the expressed juice of the potato-germs with lime, without using acid, and exhausting the precipitate with alcohol.

2. From *Potato-tubers.*—The potatoes rubbed to a pulp are digested in water containing sulphuric acid; the filtrate is boiled to separate albumin; the liquid again filtered, and precipitated with milk of lime; and the precipitate treated with alcohol.

3. From the berries of *Solanum nigrum*, &c.—The ripe berries are pressed; the juice is precipitated by ammonia, and the grey pulverulent precipitate is purified by recrystallisation from alcohol, with aid of animal charcoal.—Peschier dissolves the impure precipitate in acetic acid, precipitates the filtrate with ammonia, and then treats it with boiling alcohol.—Payen and Chevallier exhausted the dried berries of *Solanum verbascifolium* with alcohol, treated the extract which remained on evaporation with water, and precipitated the aqueous solution with magnesia, whereby impure solanine was obtained.

Properties.—Solanine (from potato-shoots) is slightly soluble in cold, easily in hot alcohol, and crystallises therefrom in slender silky needles, which under the microscope present the appearance right-angled four-sided prisms. It is nearly insoluble in water and in ether. From its solution in acids, it is completely separated by alkalis as a white gelatinous precipitate. It has a slightly bitter and somewhat burning taste, and faint alkaline reaction. It is very poisonous, two or three grains being sufficient to kill a rabbit in a few hours,—first, however, producing paralysis of the hinder extremities. The same symptom has been observed in oxen after eating potato-shoots. It melts at about 235° to a yellowish liquid, solidifying to an amorphous mass. At a stronger heat, it emits the odour of burnt sugar (**Zwenger** and **Kind**). When a very small quantity of it, in the state of fine powder, is heated on a piece of platinum-foil having in the middle a hemispherical depression covered with a small watch-glass, it sublimes in a network of slender needles. (**Helwig**, Anal. Zeitschr. iii. 43.)

The analyses of solanine by different chemists exhibit great diversity, as the following table will show:—

	From Solanum Dulcamara.		*From Potato-shoots.*		
	Henry.	Moitissier.	Blanchet.	O. Gmelin.	Zwenger u. Kind.
Carbon . .	75·0	60·9	62·0	62·2	60·01
Hydrogen .	9·1	8·7	8·9	8·7	8·40
Nitrogen .	3·1	3·6	1·6		1·37
Oxygen .	12·8	26·8	27·5	29·1	30·22
	100·0	100·0	100·0	100·0	100·00

Henry's analysis, which differs widely from all the rest, may be represented by the formula $C^{112}H^{82}N^{2}O^{15}$; Blanchet's by $C^{90}H^{77}NO^{30}$ or $C^{45}H^{77}NO^{15}$. Moitissier deduces from his own analysis the formula $C^{42}H^{35}NO^{14}$ or $C^{21}H^{25}NO^{7}$. Zwenger and Kind's results may be represented by the formula $C^{43}H^{71}NO^{16}$, requiring 60·21 per cent. carbon, 8·28 hydrogen, 1·63 nitrogen, and 29·88 oxygen.* O. Gmelin found variable quantities of nitrogen in solanine, and is of opinion that the pure substance is free from nitrogen: he deduces from his analyses the formula $C^{44}H^{72}O^{15}$. But the basic character of solanine renders it most probable that it contains nitrogen.

Decompositions.—1. Solanine, subjected to dry distillation, yields solanidine together with acid empyreumatic products.—2. It is not decomposed by boiling *potash-ley*.—3. It reduces, when heated, a solution of *argentic nitrate* or *auric chloride*, but not an alkaline cupric solution.

---

* [illegible] solanine the formula $C^{86}H^{70}NO^{32}$, for solanidine $C^{50}H^{40}NO^{2}$, and for two of which are inadmissible, because the sum of the hydrogen- and uneven. Moreover, they do not represent the numbers obtained by so closely as the formulæ $C^{43}H^{71}NO^{16}$ and $C^{25}H^{41}NO$.

4. Solanine, warmed or boiled with *dilute sulphuric* or *hydrochloric acid*, easily splits up into solanidine and glucose, the sulphate or hydrochlorate of solanidine separating in the crystalline form, while the sugar remains dissolved. The decomposition is likewise produced by oxalic, but not by acetic acid. According to Zwenger and Kind, the reaction is:

$$\underset{\text{Solanine.}}{C^{43}H^{71}NO^{16}} + 3H^2O = \underset{\text{Solanidine.}}{C^{25}H^{41}NO} + 3C^6H^{12}O^6.$$

According to O. Gmelin it is:

$$\underset{\text{Solanine.}}{C^{44}H^{72}O^{15}} + 3H^2O + O^2 = \underset{\text{Solanidine.}}{C^{26}H^{42}O^2} + 3C^6H^{12}O^6.$$

The absorption of oxygen here supposed is, however, contrary to the analogy of all reactions of this kind. W. Delffs (Chem. Centr. 1859, p. 800) remarks that Gmelin's analysis of solanine may represented by the formula $C^{20}H^{32}O^7$, and his analysis of solanidine (81·9 and 82·0 per cent. C, and 10·6 to 10·8 H), by the formula $C^{14}H^{20}O$, according to which the reaction would be:

$$C^{20}H^{32}O^7 = C^{14}H^{20}O + C^6H^{12}O^6.$$

If this formula were correct, solanine (or rather solanin) would be a glucoside homologous with æsculin, $C^{11}H^{14}O^7$, arbutin, $C^{12}H^{16}O^7$, salicin, $C^{13}H^{18}O^7$, senegin, $C^{14}H^{20}O^2$, and perhaps smilacin, $C^{21}H^{34}O^7$. But, as already observed, it is more probable that solanine and solanidine contain nitrogen.

5. A cold-prepared solution of solanine in more concentrated *sulphuric* or *hydrochloric acid*, deposits on standing a bulky yellowish precipitate containing the salts of solanicine and another base (p. 345), formed from solanidine by the action of the strong acid. (Zwenger and Kind.)

6. With strong *nitric acid*, solanine forms a colourless solution, which exhibits after a while a transient red colour, and ultimately deposits a brown resin. (Zwenger and Kind.)

7. Solanine quickly absorbs vapour of *iodine*, forming iodosolanine, which is brown, permanent in the air, and dissolves with brown colour in water. An aqueous solution of sulphate of solanine likewise assumes a dark-brown colour on addition of aqueous iodine. According to Kromayer, an alcoholic solution of solanine mixed with a large quantity of iodine-water, turns red-brown but remains clear, whereas a solution of solanidine similarly treated yields a yellow-brown precipitate.

8. According to Moitissier, solanine (from *Solanum Dulcamara*), heated in a sealed tube with *ethylic iodide*, yields hydriodate of ethylsolanine, from which the base [$C^{21}H^{34}(C^2H^5)NO^7$, according to Moitissier's formula of solanine] is separated by ammonia as a mass of interlaced microscopic needles soluble in alcohol. Its salts are easily soluble, gummy, and poisonous. In like manner *amylic iodide* converts solanine into amylsolanine, and ethylsolanine into ethyl-amylsolanine. According to O. Gmelin, on the other hand, solanine (from potato-shoots) does not form any substitution-compound with ethylic iodide, even when the two are heated together for a long time, the resulting resinous mass, when dissolved in water and treated with ammonia, yielding nothing but solanine. Moitissier found, in his ethylsolanine, 62·2 per cent. carbon and 8·8 hydrogen, which agrees exactly with Gmelin's analysis of solanine itself.

Salts of Solanine.—Solanine forms both acid and neutral salts, all of which are easily soluble in water. The neutral salts have a faint acid reaction, and bitter, strongly burning taste; they dissolve easily in alcohol, remaining as gelatinous masses on evaporation, and are nearly insoluble in ether. The dilute aqueous solutions of solanine-salts, excepting the acid sulphate, gradually decompose, more quickly when heated, and deposit solanine. (Baumann, Arch. Pharm. xxxiv. 23.—Zwenger and Kind.)

Acetate of solanine cannot be obtained in the solid state without decomposition (Zwenger and Kind).—The *chromate* crystallises in dark-yellow needles.—The *gallate* is a soluble amorphous mass.—The *gallotannate* crystallises in needles, slightly soluble in cold, easily in hot water. (Baumann.)

The *hydrochlorate*, $C^{43}H^{71}NO^{16}.HCl$, is obtained by dissolving the base in alcohol and hydrochloric acid, and repeated precipitation with ether, as a gelatinous precipitate, which dries up to a gummy mass. The alcoholic solution of this salt mixed with platinic chloride, and then with ether, deposits the *chloroplatinate*, $2C^{43}H^{71}NO^{16}.2HCl.Pt^{iv}Cl^4$, as a yellow flocculent precipitate, which may be purified by repeated solution in alcohol and precipitation with ether. It is soluble in hot water, still more soluble in alcohol. (Zwenger and Kind.)

The *hydroferrocyanate* is precipitated in white flocks on mixing a solution of any solanine-salt with ferrocyanide of potassium.—The *mellitate* is soluble in water, the neutral solution depositing solanine when evaporated.—The *mucate* crystallises in slender easily soluble needles. (Baumann, Arch. Pharm. xxxiii. 23.)

The *oxalate*, $2C^{43}H^{71}NO^{16}.C^2H^2O^4.H^2O$, is obtained by evaporating a solution of solanine in aqueous oxalic acid, in white crystalline crusts mixed with amorphous salt: its aqueous solution deposits solanine when boiled. It gives off its water at 100°. (Zwenger and Kind.)

The *phosphate* is obtained by precipitation as a white crystalline powder.—The *succinate* crystallises in easily soluble slender needles.

SOLANOLEIC and **SOLANOSTEARIC ACIDS.** See POTATO-FAT (iv. 723).

SOLANUM. The most important plant belonging to this genus is the potato (*Solanum tuberosum*, iv. 720).

Solanum Dulcamara.—The stalks of this plant, which are used in medicine under the name of bitter-sweet, or *Stipites Dulcamaræ*, contain picroglycion or dulcamarin (iv. 642), together with solanine and other substances.

Solanum Lycopersicon.—The leaves of this plant are said to contain an alkaloïd soluble in water. The deep red somewhat acid fruits, called love-apples or tomatoes, contain a free acid—malic acid according to former statements, citric acid according to Bertagnini (Jahresb. 1860, p. 562); probably also solanine, together with volatile oil, uncrystallisable sugar, &c. (See Enz, Jahresb. 1862, p. 514.)

Various other species of solanum, especially the fruits, are said to contain solanine together with malic acid (?): e.g., *S. mammosum*, *S. nigrum*, and *S. verbascifolium*.

SOLAR OIL. A name applied in commerce chiefly to the heavier portions of petroleum and shale-oil, the lighter portions being called *photogen*, *hydrocarbon*, *&c.* (See PARAFFIN, iv. 346.)

SOLFATARAS. Craters of extinct volcanos, which give indications of their former activity by still emitting vapours and gases of various kinds, sometimes depositing sulphur, sal-ammoniac, and other solid minerals, on the walls of cavities in the craters.

SOLFATARITE. The name given by Shepard (Sill. Am. J. xvi. 203) to soda-alum, on account of its occurrence in the solfatara near Naples.

SOLUTION. The liquefaction of a solid or gaseous body by contact with a liquid, the solid or gas being diffused uniformly through the liquid, and not separating when left at rest. The liquid, which thus takes up or absorbs a solid or gas, is called the solvent or menstruum; and the product of the action, as well as the action itself, is called a solution.

The product formed by the union of liquids one with the other is usually called a mixture, if the two liquids are capable of uniting in any proportions whatever, as is the case with water and alcohol, or alcohol and ether; and a solution, when each of the liquids is capable of taking up only a limited quantity of the other. When two such liquids are brought together in such proportion that neither can dissolve completely in the other, two layers are generally formed, each containing an excess of one of the liquids. Thus, when water and ether are mixed in equal volumes, two layers are formed after a while, the upper consisting of ether holding water in solution, the lower of a solution of ether in water.

The solution of gases in liquids has already been considered under GASES, ABSORPTION OF, ii. 790; the present article relates to the solution of solids.

Respecting the difference between solution and definite chemical combination, see CHEMICAL AFFINITY (i. 851).

The solution of a solid in a liquid is usually attended with a fall of temperature, arising from the conversion of sensible into latent heat, which always accompanies the passage of a body from the solid to the liquid state (HEAT, iii. 79). In some cases, however, the actual solution of a solid is preceded by the formation of a definite chemical compound, and is then attended with rise of temperature: thus, anhydrous baryta or lime, and many anhydrous salts, when brought in contact with a certain quantity of water, are first converted into definite hydrates, and become very hot; but the subsequent solution of these hydrates in a larger quantity of water is attended with reduction of temperature. The solution of one liquid in another takes place without change of temperature, excepting when a definite compound is first formed, as on mixing oil of vitriol with water, in which case heat is evolved. (See HEAT, iii. 79, 109; also *Gmelin's Handbook*, ii. 69.—Favre and Silbermann, Compt. rend. xxiv. 1081; Jahresb. 1847-48, p. 53.—Favre, Compt. rend. l. 1150; lii. 316; Jahresb. 1860, p. 33.—Pohl, J. pr. Chem. lxxxii. 254; Jahresb. 1860, p. 36.—Hausmann, Jahresb. 1864, p. 97).—On the depression of temperature consequent on the dilution of saline solutions, see J. Regnauld (Instit. 1864, p. 158; Jahresb. 1864, p. 99).

The manner in which the solubility of a solid in a liquid is related to the chemical composition of the two, has not yet been reduced to any definite laws. As a general rule, it may perhaps be stated that solids dissolve with the greatest facility in those liquids which they most resemble in composition. Thus, metallic salts are for the most part more soluble in water than in alcohol or ether; whereas fats, resins, and many other organic bodies, dissolve more easily in alcohol, ether, benzene, oils, &c. than in water. But solids of strictly analogous constitution dissolve in the same liquid with very different degrees of facility. Thus, sulphuric acid forms a great number of salts which are soluble in water, and, on the other hand, baryta, lime, and magnesia form soluble salts with many acids; but barytic sulphate is one of the least soluble salts known, and calcic sulphate is but slightly soluble in water, whereas magnesic sulphate is very soluble.

The facility with which a solid dissolves in a liquid is not always proportional to the amount which the liquid is ultimately capable of dissolving, for it depends in a great measure on the physical condition of the solid, and on the manner in which it is brought in contact with the liquid. Pulverisation, by increasing the number of points of contact, of course facilitates solution. If the solid is placed at the bottom of the liquid, it dissolves with comparative slowness, because the solution formed immediately around the solid, being heavier than the supernatant liquid, remains at the bottom, and protects the solid from the further action of the liquid: the solution will therefore be facilitated by stirring the liquid, or by heating it at the bottom, so as to produce upward and downward currents. In many cases it is best to suspend the solid in the upper part of the liquid in a basket, or perforated box, so that the solution as it forms may fall to the bottom, and enable fresh liquid to come in contact with the solid. This plan is adopted in many manufacturing operations, as in lixiviating ball-soda, crude nitre, borax, &c.

Many substances, when immersed in a solvent, absorb a certain quantity of it, and are converted into tenacious lumps very difficult to dissolve; this is especially the case with resinous bodies. In such cases, it is often advantageous to mix the body with an insoluble substance, such as sand or pounded glass, to prevent the caking together, and enable the solvent to penetrate more easily to all parts of the solid.

The solubility of a solid in a liquid increases, for the most part, with rise of temperature; and for each particular temperature there is a certain limit, called the **point of saturation**, beyond which the liquid is incapable of taking up any more of the solid. The rate of increase is very different for different substances, and does not appear to be reducible to any regular law. Even the general law of increased solubility with rise of temperature admits of many exceptions: thus, lime-water saturated at 0° contains nearly twice as much lime as can be dissolved by the same quantity of water at 100°. Calcic sulphate also is more soluble in cold than in boiling water, and quite insoluble in water at 120°; sodic sulphate is more soluble in water at 33° than at other temperatures, either above or below, and has about the same degree of solubility at 0° as at 100°. Many other salts also exhibit a point of maximum solubility at some particular temperature, generally above the boiling-point of water. (HEAT, iii. 79.)

A saturated solution of a salt at any particular temperature may be obtained, either by heating an excess of the salt with water to a higher degree, and leaving the solution to cool to the required temperature, or by immersing an excess of the salt in cold water and slowly heating the liquid to the same point.

In the case of salts which, like saltpetre, do not contain water of crystallisation, and of many hydrated salts, the saturated solution contains the same quantity of salt, by whichever method it is prepared. But when certain hydrated salts—especially those which, like sodic sulphate and neutral sodic carbonate, are capable of crystallising with more than one proportion of water—are dissolved to saturation in hot water, and the solutions are left to cool slowly and quietly in a closed vessel, they often retain, after cooling to a certain temperature, a much larger quantity of the salt than the same quantity of water would be capable of taking up if originally placed in contact with the salt at that temperature. Such solutions are said to be **supersaturated**. They retain their excess of salt so long as they are left at perfect rest, and not cooled too low; but if stirred or agitated, or brought in contact with air containing particles of dust, or with a crystal of the same salt, or cooled down to a certain temperature, they suddenly deposit the excess of salt in crystals, exhibiting at the same time a considerable rise of temperature. This sudden crystallisation, if not produced by cold, appears to depend essentially on contact of the solution with small solid, perhaps crystalline particles; for it is not produced by passing air previously purified by oil of vitriol through the solution, or by agitation with a glass rod previously purified from dust by ignition (Löwel, Ann. Ch. Pharm. lxxvi. 227; Jahresb. 1850, p. 294; 1851, p. 331; 1852, p. 358.—Lieben, *ibid.* 1854, p. 322). According to Violette (Compt.

rend. lx. 831, 973; Jahresb. 1865, p. 74) and De Gernez (Compt. rend. lx. 833; lxi. 847; Jahresb. 1865, pp. 74, 78), the sudden crystallisation is in all cases induced only by contact with a crystal of the same salt, possessing the same form and degree of hydration as the crystals which separate out; and in the case of those supersaturated solutions which crystallise suddenly on exposure to the air, it is due to the presence of minute particles of that salt floating in the air. From an experiment of De Gernez, it appears that microscopic crystals of sodic sulphate may be obtained by passing air, even in the open country, through pure water, and evaporating the water on a glass plate. Jeannel (Compt. rend. lxi. 412; lxii. 37; Jahresb. 1865, pp. 77, 79), however, denies the necessity of contact with the salt actually contained in the solution. He finds, indeed, that a supersaturated solution of sodic acetate may be made to crystallise by contact with any solid substance (a piece of paper, for example), and a solution of sodic tartrate by contact with a clean dry glass rod. He attributes the phenomenon of supersaturated solutions chiefly to the fact, that the salts in question are capable of forming in hot water peculiar hydrates, which under certain circumstances remain permanent after the solution has cooled to a certain point, but are, for the most part, broken up by contact with a solid body, and especially with a particle of the dissolved salt. (Respecting supersaturated solutions of sodic carbonate and sulphate, see CARBONATES, i. 795, and SULPHATES.)

When two or more salts are dissolved in water, and no new salt separates out by double decomposition, the quantity of each held in solution by a given quantity of water is generally, but not always, less than if either salt were dissolved separately. In this case the quantities contained in a saturated solution are the same, whether the two salts are dissolved simultaneously in the water, or the water is first saturated with the one salt, and then brought in contact with an excess of the other, a portion of the first salt then crystallising out. A saturated solution of common salt shaken up with sal-ammoniac takes up a large quantity of the latter, and deposits some of the sodic chloride in cubes; a saturated solution of sal-ammoniac also takes up common salt, and deposits sal-ammoniac in dendritic forms. When a solution of common salt saturated at ordinary temperatures is mixed with a saturated solution of sal-ammoniac, a mixture is formed, without change of temperature, which is capable of taking up a certain quantity both of common salt and of sal-ammoniac. On warming the saturated mixture with common salt, a small quantity is also taken up, and separates out again on cooling. If, on the other hand, sal-ammoniac be added during the warming of the mixture, it at first dissolves, forming a clear solution; if a larger quantity be added, this also dissolves, but separates a considerable quantity of common salt; and as the liquid cools, the common salt redissolves, and the sal-ammoniac which had been taken up by the hot liquid crystallises out. Similar relations are exhibited by mixtures of sal-ammoniac and chloride of potassium, of the latter with chloride of sodium or barium, and apparently also by nitrate of ammonium and nitrate of sodium.

Many salts dissolve in water to the same amount, whether the water is shaken up with an excess of either of them alone, or simultaneously with a second salt; but the quantity of this second salt dissolved, is smaller than if the first were not present. Thus a saturated solution of potassic chloride, or nitrate, dissolves only a small quantity of potassic sulphate; and if a saturated solution of the latter be shaken up with either of the preceding salts, a large quantity of potassic sulphate separates out.

Lastly, a given quantity of water can in some cases dissolve a larger quantity of a salt (*A*), if previously saturated with another salt (*B*), and at the same time take up an additional quantity of the second. In this case the quantities taken up are different according as:

α. A quantity of water saturated with a salt *A* are shaken up with an excess of *B*.
β. Water previously saturated with *B* is saturated with *A*.
γ. The water is shaken up with an excess of the two salts simultaneously.

For example, with sal-ammoniac (*A*) and saltpetre (*B*), dissolved in water at 18¾°, the following quantities are taken up in the three cases by 100 pts. of water:

	α.	β.	γ.
Sal-ammoniac . .	37·98	44·33	39·84
Saltpetre . . .	37·68	30·56	38·62

In solutions containing three salts, still more complicated relations are observed, and in all cases, the effects produced are such as indicate the formation of double salts, and the division of the acids among the several bases. (CHEMICAL AFFINITY, i. 863; *Handw. d. Chem.* ii. 2^{te} Aufl. ii. [1], 554.—*Gmelin's Handbook*, ii. 71.)

SOMERVILLITE. A variety of mellilite from Vesuvius (iii. 870).

SOMBRERITE. An earthy mineral, consisting mainly of calcic and aluminic phosphates, occurring on some of the small islands of the Antilles, chiefly on Sombrero. It contains, according to Phipson (Chem. Soc. J. xv. 277; Chem. News, ix. 28), 65 per cent. tricalcic phosphate, 17 aluminic phosphate, and 9 water, besides calcic sulphate, carbonate, &c.—a composition which may be approximately represented by the formula $8(3Ca''O.P^2O^5).(2Al^2O^3.3P^2O^5).20H^2O$. According to Julien, however, (Chem. News, ix. 16), it is not of constant composition.

SOMMITE. Syn. with NEPHELIN, from Somma (iv. 30).

SONCHUS. *Sow-thistle.*—A genus of cichoraceous plants. *Sonchus arvensis*, gathered during flowering-time, yields 86·0 per cent. water, and 1·19 ash; the plant also contains a bitter principle, wax, resin, a small quantity of free acid, &c. *S. oleraceus* yields, at flowering-time, 90·0 per cent. water, and 1·48 ash. The ashes of the two species were found by C. Sprengel (J. techn. Chem. ix. 17; x. 36) to contain, besides alumina and ferric oxide:

	K^2O.	Na^2O.	CaO.	MgO.	SiO^2.	SO^3.	P^2O^5.	Cl.	
S. arvensis .	21·9	13·7	27·0	4·6	3·0	15·1	8·6	6·0	= 99·9
S. oleraceus .	29·3	18·6	18·8	1·6	2·8	6·1	15·3	7·4	= 99·9

SONORA GUM. A kind of lac produced by the puncture of a coccus in *Mimosa cerifera*, a tree growing in Mexico. It appears to have been long used in Mexico as an irritant.

SOORANJEE. The root of *Morinda citrifolia* (iii. 1048).

SORBAMIDE. $C^6H^9NO = \left.\begin{matrix}C^6H^7O\\H^2\end{matrix}\right\}N$.—An amide produced by the action of dry ammonium-carbonate on crude sorbic chloride, or of aqueous ammonia on sorbic ether at 120°. It forms white easily fusible needles, soluble in water and in alcohol. (Hofmann.)

SORBANILIDE or *Phenyl-sorbamide*, $C^6H^8(C^6H^5)NO$, is produced by the action of aniline on sorbic chloride, as an oil which solidifies in the crystalline form. (Hofmann.)

SORBIC ACID. $C^6H^8O^2 = \left.\begin{matrix}C^6H^7O\\H\end{matrix}\right\}O$. (A. W. Hofmann, Chem. Soc. Qu. J. xii. 43.)—A monobasic acid, produced by isomeric transformation of parasorbic acid, a volatile oily acid obtained from mountain-ash berries. When the liquid which remains after partially saturating the juice of the unripe berries with milk of lime, is left to stand till all the neutral calcic malate is deposited from it (iii. 789), and then distilled in a copper vessel, ultimately with addition of a little sulphuric acid, an acid distillate is obtained, from which, after saturation with sodic carbonate and evaporation, a brown oil is separated by sulphuric acid; and by dissolving this oil in ether, leaving the ether to evaporate, and rectifying, a transparent colourless oil is obtained, consisting of parasorbic acid, $C^6H^8O^2$, which when gently heated with solid caustic potash, or boiled for some time with strong hydrochloric acid, is transformed into crystallisable sorbic acid, having the same composition.

Sorbic acid is easily purified by recrystallisation from hot water; it dissolves easily also in alcohol and ether, and crystallises from a boiling mixture of 1 vol. alcohol and 2 vols. water, in white needles an inch long. It is inodorous, melts at 134·5°, volatilises without decomposition, and decomposes carbonates. With *phosphoric chloride* it yields sorbic chloride, C^6H^7OCl. Heated with hydrate of barium, it yields a volatile aromatic hydrocarbon, together with carbonate of barium.

Sorbate of Ammonium crystallises in long needles: its concentrated solution is precipitated by chloride of calcium and by most salts of the heavy metals, but not by chloride of barium, strontium, or magnesium.—The *potassium-* and *sodium-salts* crystallise with difficulty.—The *barium-salt*, $C^{12}H^{14}Ba''O^4$, and the *calcium-salt*, $C^{12}H^{14}Ca''O^4$, crystallise in silvery scales.—The *silver-salt*, $C^6H^7AgO^2$, is a white crystalline precipitate.

Ethylic Sorbate or *Sorbic ether*, $C^6H^7(C^2H^5)O^2$, produced by passing hydrochloric acid gas into an alcoholic solution of the acid, or by the action of alcohol on sorbic chloride, is a liquid having an aromatic odour, like that of benzoic ether, and boiling at 195·5°.

Parasorbic Acid, $C^6H^8O^2$.—This acid, prepared as above, is when freshly distilled, a transparent colourless liquid, of specific gravity 1·068 at 15°. Its vapour, in the concentrated state, has a repulsive almost intoxicating odour: it is, in fact, the source of the peculiar pungent odour which the juice of mountain-ash berries evolves when partially saturated with lime. It boils constantly at 221°, but a portion of it is always converted during distillation, even in a stream of hydrogen, into a yellow resinous substance. It is faintly acid, dissolves in moderate quantity in water, forming an acid solution, and in all proportions of alcohol and ether. Its solutions in ammonia, potash, soda, baryta-water, and lime-water, dry up to amorphous residues; it dissolves in alkaline carbonates, but without expelling the carbonic acid.—*Nitrate of silver* added to the ammoniacal solution forms a white gelatinous precipitate, $C^6H^7AgO^2$, which blackens on exposure to light.

SORBIC CHLORIDE. *Chloride of Sorbyl*, C^6H^7OCl.—Produced by the action of phosphoric chloride on sorbic acid or its potassium-salt. It is converted by water into the acid, by alcohol into ethylic sorbate, by ammonia into sorbamide, by aniline into phenyl-sorbamide.

SORBIC ETHER. Ethylic sorbate.

SORBITARTARIC ACID. An acid produced by heating sorbite with tartaric acid to 100°. (Berthelot.)

SORBITE. *Sorbin*. $C^6H^{12}O^6$. (Pelouze, Ann. Ch. Phys. [3], xxxv. 292.)—An unfermentable sugar, isomeric with grape- and milk-sugar, existing in the ripe juice of mountain-ash berries. The expressed juice of the berries, gathered towards the end of September, produces deposits and vegetations when left to itself for 13 or 14 months, and at last becomes clear again; and the clear liquid, decanted and evaporated to a thick syrup, yields repeated crops of crystals, which are obtained pure by two crystallisations with help of animal charcoal.

Sorbite forms very fine, regular, transparent crystals, which, according to Berthelot, belong to the trimetric system, and are for the most part rhombic octahedrons:

$\breve{P}\infty$. $P\infty$. with oP ; over oP the angle $\breve{P}\infty : \breve{P}\infty = 38° 49'$; $\bar{P}\infty : \bar{P}\infty = 37° 7'$. The faces between oP and $P\infty$ are truncated by m$\bar{P}\infty$ (m$\bar{P}\infty : \bar{P}\infty = 164° 20'$). The crystals have a specific gravity of 1·654 at 15° ; they grate between the teeth, and are as sweet as cane-sugar. Optical rotatory power, for the transition-tint = 46·9° at 7°, only slightly variable with the temperature, and just as great in a recently prepared solution as in one that has been kept. (Berthelot, *Chim. organ.* ii. 252.)

Sorbite dissolves in about ½ pt. cold water; the saturated solution has a specific gravity of 1·372 at 15°. It is insoluble in cold, slightly soluble in boiling alcohol.

Sorbite forms with *chloride of sodium*, a compound crystallising in cubes.—Aqueous sorbite dissolves *hydrate of calcium* and *hydrate of barium*. The solution of the former deposits flocks when heated, decomposition occurring at the same time.—Aqueous sorbite dissolves *oxide of lead*; it does not precipitate basic acetate of lead, but on addition of ammonia throws down a white precipitate, which, while being dried, smells of caramel, and contains 79·4 per cent. lead (Pelouze).—Aqueous sorbite also dissolves *cupric hydrate*.

Sorbite when heated gives off acid water, and is converted after some time, at 150°—180°, into a dark-red mass consisting of sorbitic acid (Pelouze's sorbic acid). When quickly heated on platinum-foil, it melts and burns away with a smell of caramel. Hot *nitric acid* converts it into oxalic acid (Pelouze). Oxidising agents also produce racemic acid from sorbite (Dessaignes, Bull. Soc. Chim. 1861, p. 32). It is not altered when heated with *dilute acids*; it is coloured reddish-yellow by *oil of vitriol*, charred on heating. When heated for several hours with fuming *hydrochloric acid*, it is converted into humous substances in the same way as glucose (p. 315). (Berthelot, *Chim. organ.* ii. 252.) Sorbite, heated to 100° with *tartaric acid*, yields a small quantity of a substance belonging to the class of saccharides (p. 316), whose calcium-salt reduces potassio-cupric tartrate (Berthelot). It turns brown when heated with *potash-ley*, and evolves a smell of caramel. Heated with *lime*, *hydrate of barium*, or *oxide of lead*, it behaves in the same way. The solution of *cupric hydrate* in aqueous sorbite, and aqueous solution of sorbite mixed with *potassio-cupric tartrate*, deposit cuprous oxide when warmed or left to stand. Sorbite is not fermentable with *yeast* (Pelouze), not even after being heated with acids; but when left to stand in contact with *cheese* and *chalk*, at 40°, it suffers a decomposition, which gives rise to a large quantity of lactic acid, alcohol, and butyric acid, without previous formation of a fermentable sugar. (Berthelot.)

SORBITIC ACID. Pelouze's *Sorbic Acid.*—An acid obtained by heating sorbite for some time to 150°—180°. On dissolving the residue (which is insoluble in water, aqueous acids, or alcohol), in aqueous ammonia or potash, a dark-brown solution is obtained, from which hydrochloric acid throws down amorphous dark-red flakes; these contain, after drying between 120° and 150°, 57·96 per cent. C, 5·51 H, and 36·53 O, corresponding, according to Pelouze, with the formula $C^{32}H^{18}O^{15}$. Their solution in ammonia-water gives coloured precipitates with metallic salts; with lead-salts one containing 51·35 per cent. lead-oxide, $C^{32}H^{18}O^{15}.3PbO$, according to Pelouze.

SORBUS AUCUPARIA. *Pyrus Aucuparia. Mountain-ash. Rowan-tree. Sorbier. Vogelbeerbaum.*—A pomaceous tree, the unripe berries of which contain large quantities of free vegetable acids—viz. citric, tartaric, and malic acids; the last is most abundant when the berries have a rose-red colour; previously to this, the tartaric acid predominates, and later in the season the malic acid likewise disappears. The juice of the berries contains also a non-fermentable sugar, viz. sorbite, together with fermentable sugar; for the juice even of unripe berries has been found to pass into spontaneous fermentation, and to yield, from 100 vols., 4 vols. of spirit containing 50 per cent. alcohol. After the spirit there distils a milky liquid, which, after a few days, deposits a small quantity of a stearoptene in small shining crystals (Liebig). Brandy is prepared from the juice of the ripe berries in the Tyrol, in North Germany, and other places.

The juice likewise contains a pungent-smelling oily acid (*parasorbic acid*, p. 352), which may be separated by distillation after the malic acid has been precipitated by lime.

The flowers of the mountain-ash, and the bark of the stem and root, are said to yield, by distillation with water, products containing hydrocyanic acid; the bark also tannin and a bitter principle. (Gössmann.)

SORBYL. C^6H^7O. The hypothetical radicle of sorbic acid.

SORDAWALLITE. A mineral resembling pit-coal in appearance, forming three layers in trap near Sordawala in Finland, and associated with magnetic pyrites, at Bodenmais in Bavaria. Hardness = 2·5. Specific gravity = 2·53—2·58.

Gives off water when heated, and melts to a black bead before the blowpipe. Partially decomposed by acids. Analysed—*a.* by Nordenskiold (Schw. J. xxxi. 148);—*b.* by Wandesleben (N. Jahrb. Pharm. i. 32):

	P^2O^5.	SiO^2.	Al^2O^3.	Fe^2O^3.	FeO.	MgO.	H^2O.		
a.	2·68	49·40	13·80	. .	18·17	10·67	4·38	=	99·10
b.	2·26	47·70	16·65	24·32	. .	10·21	. .	=	98·14

The presence of phosphoric acid, and the uncertainty as to the state of oxidation of the iron, render it impossible to reduce these results to a definite formula.

SORGHO. *Sorghum saccharatum. Holcus saccharatus.* Sugar-sorgho. Chinese sugarcane. Imphee. Kao-lien.*—A sugar-producing grass, resembling maize in external appearance. It appears to have been first obtained by the Jesuit missionary Du Halde, from the Chinese province Le Chuen; the seed was sent to France in 1851, where the plant was cultivated, chiefly by Vilmorin and Beauregard, and exported in 1854 to the United States, where numerous experiments were made with reference to its utility for the manufacture of sugar, and in agriculture as a substitute for the ordinary green-crops. Its chemical composition has been investigated by Gössmann and other chemists; but it does not appear certain that all the experiments have been made on the same species of plant.

The stem or cane freed from leaves contains, according to Gössmann, 78·9 per cent. water, 10·2 soluble constituents, 8·2 cellulose, 0·4 to 0·5 insoluble salts and cerasin. This last is a waxy substance distributed unequally over the surface of the plant, but most thickly on those parts which are covered by the sheaths of the leaves; when mixed with tallow it is said to make excellent candles. By charring the defoliated cane, Gössmann obtained 0·71 per cent. inorganic constituents. The residue, which was alkaline, consisted of calcic and magnesic phosphates, calcic, magnesic, potassic, and sodic carbonates and chlorides, and silica; the potash was in larger proportion than the soda.

The leaves, which contain no sugar, leave when burnt, 2·07 per cent. inorganic constituents, chiefly consisting of silica, lime, and magnesia, and contain 27 per cent. moisture.

The ash-constituents of the entire plant have been determined by J. Elwert. The plants used in this investigation belonged to a species of sorgho, called *broom-corn*, cultivated in America, and distinguished from the Chinese sugar-cane by its longer and much-divided panicle. 100 kilogrames of the green plant, equivalent to 15·5 kilogrammes of the dry plant, yield 1·379 kilogrammes ash, consisting of—

K^2O.	Na^2O.	CaO.	Cl.	SO^3.	P^2O^5.	CO^2.	Si^2O.	X.†		
20·3	4·7	21·4	2·2	1·9	8·0	14·1	16·5	10·5	=	99·6

Of these there are soluble in water—

K^2O.	Na^2O.	Cl.	SO^3.	P^2O^5.	SiO^2.
20·3	4·7	2·2	1·9	3·4	3 3

soluble in hydrochloric acid: 21·4 CaO, 14·1 CO^2, 4·6 P^2O^5; insoluble: 13·2 silica, and 10·5 sand.

The juice obtained by pressing the plant tastes very sweet, has a greenish-yellow colour, turbid appearance, faint acid reaction, and a specific gravity of about 1·07 (9° to 9½° B.) at 19°. It boils at 101°—101·5°, and between 60° and 70° begins to deposit an albuminous coagulum, without however clarifying completely, an effect which takes place only after prolonged boiling. When left to itself, at 20° to 25°, it soon begins to ferment. When evaporated, it leaves—after the albuminous constituents have been skimmed off—a transparent, viscid, sweet residue, which exhibits no trace of crystals, and, if somewhat unripe plants have been used, gives the reactions of starch. From perfectly ripe canes Gössmann obtained nothing but cane-sugar, and that to the amount of 9 to 9·56 per cent. According to Reihlen and Fehling, the juice of broom-corn, not quite ripe, contains 4 per cent. cane-sugar, and 10 per cent. uncrystallisable sugar. Lüdersdorff found in the juice of the Chinese sugar-cane, 7·5 per cent. sugar, consisting of equal parts of cane-sugar and fruit-sugar; and Bergemann found in it no cane-sugar, but 11·3 per cent. fruit-sugar. Hence, and from the elaborate experiments of Dr. Jackson (Polyt. Centralbl. neue Folge, xii. 1649), it appears that the plant, in its earlier stages of development, contains only grape-sugar, together with starch; but when it ripens, all the starch disappears, and nothing but cane-sugar is present. Of indifferent substances, the juice contains mucous nitrogenous matters, chlorophyll, gum, and albuminous compounds. The quantity of the latter, though not very great, is sufficient to convert the whole of the cane-sugar into glucose, and to resolve the latter into alcohol and carbonic anhydride. According to Löffler, the juice also contains two peculiar vegetable acids.

---

* Henry S. Olcott, *Sorgho and Imphee, the new Chinese and African Sugarcanes*, New York, 1857.—Vilmorin, *Recherches de sorgho sucré*, 1854.—Stansbury, *The Chinese Sugar-cane*, New York. 1857.—James F. C. Hyde, *The Chinese Sugarcane*, Boston, 1857.—J. Lovring, *The Chinese Sugarcanes*, Philadelphia, 1858.—A. Gössmann. *Journ. f. Landwirthschaft*, von Henneberg, neue Folge, i 294 (1868).—Habich, *Polyt. Centralbl.* 1858, p. 1647.—Löffler, *Das Chinesische Zuckerrohr*, Braunschweig, 1859.—*Handw. d. Chem.* viii. 68.

† Sand with traces of iron.

Olcott found in the juice 15·2 per cent. sugar, 1·0 salts and organic constituents (albumin, vegetable fibre, gum, chlorophyll, &c.), and 83·8 water. The salts were found to consist of 0·750 potassic carbonate, acetate, chloride, and sulphate, 0·218 acid calcic and magnesic phosphates, and 0·012 silicic hydrate, mixed with ferric and manganic oxides.

The ash of the juice contains, according to Gössmann, 0·0015 per cent. silica, together with the following constituents soluble in water:—0·219 calcic and magnesic phosphates, with traces of iron; 0·310 alkali, chiefly potash; 0·69 sulphuric anhydride, 0·065 chlorine, and 0·079 phosphoric anhydride (= 0·742). The juice probably also contains small quantities of oxalic and tartaric acids.

The expressed plants (*begasse*), which may be used for paper-making, contain, according to Olcott, 1·6 per cent. ash, consisting of—

K^2SO^4.	Na^2SO^4.	CaO.	MgO.	SO^3.	P^2O^5.	Cl.	SiO^2.	X.*	
8·10	9·60	11·80	9·30	28·70	14·42	3·70	14·40	0·68	= 100

The seed of sorgho is yellowish, and yields a white flour, used in Marseilles and Lyons for the finer sorts of bread and biscuits. It is rich in starch and fat, and contains, according to Olcott, from 10 to 12 per cent. nitrogenous substances, and 60 to 66 per cent. starch. The seeds boiled with 12 to 15 pts. water form a glutinous paste; when exhausted with ether, they yield a not inconsiderable quantity of fat. From 50 to 60 grammes of the ground seeds Gössmann obtained several grammes of solid fatty acid.

When animals are fed on the seed, their bones gradually acquire a red colour.

The glumes (floral leaves) and stems of sorgho contain red colouring-matters, which may be used for dyeing silk and wool.

SPADAITE. A hydrated magnesic silicate occurring, together with wollastonite, at Capo di Bove, near Rome. It is amorphous, has a conchoïdal to splintery fracture, bluish-red colour, and slightly waxy micaceous lustre. Hardness = 2·5. Gives off water when heated, and melts before the blowpipe to a glassy enamel. Dissolves in strong hydrochloric acid, the silica easily gelatinising. Contains, according to v. Kobell (J. pr. Chem. xxx. 467), 56·00 per cent. silica, 0·66 alumina, 30·67 magnesia, 0·66 ferrous oxide, and 11·34 water (= 99·33), which may be represented, approximately, either by $5Mg''O.6SiO^2.4H^2O = Mg''Si^2O^5.4Mg''SiO^3.4H^2O$, or by $6Mg''O.7SiO^2.4H^2O = Mg''Si^2O^5.5Mg''SiO^3.5H^2O$.

SPÄNKÅDA. *Tuggkåda.*—A resin much used in Northern Sweden for chewing, and said to keep the teeth clean and the mouth cool. It collects in lumps on the stems of pine-trees, and is difficult to separate from the pine-resin, which it resembles. It is separated from adhering bark by kneading under warm water.

This resin is brownish without, with a rose-red tinge, yellowish-brown within, becomes darker and reddish on exposure to the air. It is brittle at ordinary temperatures, and when chewed softens at first, exhibiting a sour and balsamic taste; by continued chewing it becomes rose-red and brittle. It contains a small quantity of a viscid volatile oil, quite distinct from oil of turpentine, which may be separated by distillation with water; also several resins, and a crystallisable easily alterable acid, which may be extracted by water. This acid is soluble in alcohol, forms soluble salts with the alkalis and alkaline earths; precipitates ferric chloride completely; forms a dingy-green precipitate with cupric acetate, sulphur-yellow with basic acetate of lead, even in dilute solution; with the neutral acetate also in concentrated solution; white with nitrate of silver.

The resin, after exhaustion with water, dissolves completely in alcohol of specific gravity 0·84, but not completely in ether; water added to the alcoholic solution throws down a powder, which can no longer be masticated. Potash unites with the resin, forming with one portion of it, a compound insoluble in excess, with the remainder a soluble compound; the latter resin is also soluble in ammonia. (Berlin, Ann. Ch. Pharm. lii. 404.)

SPANIOLITE. Von Kobell's name for certain varieties of tetrahedrite containing mercury.

SPANIOLITMIN. A non-azotised colouring-matter, occurring, according to Kane, in small quantity in litmus (iii. 731).

---

* Ferric oxide, carbonic anhydride, and loss.

SPARTAITE. Breithaupt's name for a variety of calcspar from New Jersey, which, according to Jenzsch (Pogg. Ann. xcvi. 145), has a specific gravity 2·81, hardness 3·5, and contains 80 per cent. calcic carbonate, together with the carbonates of magnesium, manganese, iron, and zinc, and 5·3 per cent. calcic fluoride.

SPARTALITE. Native oxide of zinc, usually coloured red by admixture of manganic oxide. (See ZINC.)

SPARTEINE. $C^{15}H^{26}N^2$. (Stenhouse, Ann. Ch. Pharm. lxxviii. 15; Pharm. Centr. 1851, p. 439; Chem. Gaz. ix. 117.—Gerhardt, *Traité*, iv. 236.—E. J. Mills, Chem. Soc. J. xv. 1; Gm. xiii. 151.)

History.—Sparteine was discovered in 1851 by Dr. Stenhouse, while investigating the *Spartium Scoparium*, or Common Broom. The formula proposed by Stenhouse was subsequently modified on theoretical grounds by Gerhardt, but a re-examination by Mills showed that Stenhouse's formula doubled represents the true composition of sparteine.

Preparation.—1. An aqueous decoction of broom is concentrated to about a tenth of its bulk, and set aside in a cool place for twelve hours; and the gelatinous mass which forms is thrown on a filter, and washed with cold water. The solutions contain the sparteine, while scoparin in an impure state remains on the filter. The filtrate is distilled with excess of soda, when a colourless basic oil slowly collects at the bottom of the aqueous liquid in the receiver. (Stenhouse.)

2. The plant is exhausted with water faintly acidulated with sulphuric acid; the extract, concentrated by evaporation, is distilled with soda until the distillate has no longer a bitter taste or alkaline reaction; the distillate, acidified by hydrochloric acid, is evaporated to dryness on a water-bath; and the mass, slightly moistened, is then distilled with solid hydrate of potassium. Ammonia is then given off, followed by the base in the form of a thick oil. The base is dehydrated by gentle heating with sodium in a current of dry hydrogen. When completely dry, the sodium remaining is removed, and the base is finally purified by rectification. (Mills.)

Properties.—Sparteine is a colourless, transparent, viscid oil. Its specific gravity does not appear to have been determined, but it is heavier than water. It has a peculiar odour, which is more unpleasant after rectification. It has a very bitter taste. It boils at 288°. (The high boiling-point suggests the idea of its being a diamine). It neutralises acids, but the salts formed crystallise with difficulty. It is a narcotic poison of the nicotine character, but inferior in energy. One drop dissolved in acetic acid, and administered to a rabbit, first produces excitement; but this is followed by stupor, lasting for five or six hours. Four grains are sufficient to kill a large rabbit. It readily forms double salts with the chlorides of the heavy metals.

Sparteine dissolves sparingly in water, but may be separated by adding chloride of sodium to the solution. Most of its physical properties, including its vapour-density, have yet to be determined.

Decompositions.—1. Sparteine becomes brown on exposure to the air for a few days at ordinary temperatures, and more rapidly while boiling.—2. Boiled with *hydrochloric acid*, it is decomposed, yielding a solution having an odour of mice (Stenhouse). On the other hand, Mills concentrates weak solutions of sparteine by saturating with *hydrochloric acid*, and evaporating to dryness on the water-bath.—3. *Nitric acid* decomposes sparteine, yielding a substance which, when treated with *chloride of lime*, affords chloropicrin.—4. *Bromine* converts sparteine into a brown resinous substance, much heat being developed during the reaction.

Salts of Sparteine.—The *chloride*, *bromide*, and *iodide* are amorphous and unfit for analysis. (Mills.)

The *oxalate* forms acicular crystals, which are difficult to obtain.

Chloroplatinate, $C^{15}H^{26}N^2.2HCl.Pt^{iv}Cl^4.2H^2O$.—This salt precipitates as a yellow crystalline powder when a solution of tetrachloride of platinum is added to a solution of sparteine in hydrochloric acid. It crystallises readily from a solution in hot hydrochloric acid.

Chloroaurate, $C^{15}H^{26}N^2.2HCl.Au'''Cl^3$.—Sparteine also forms double salts with iodide and chloride of zinc.

Substitution-derivatives of Sparteine.

Iodide of Ethylsparteine, $[C^{15}H^{27}(C^2H^5)N^2]'I^2$.—Equal volumes of sparteine, alcohol, and iodide of ethyl are to be heated together in sealed tubes for an hour to 100°. The mixture becomes dark-coloured, and deposits the ethylated compound in crystals. They are sparingly soluble in cold, readily in hot alcohol, and excessively soluble in hot water (Mills). Oxide of silver transforms the iodide of ethylsparteine into the hydrated oxide, $\left.\begin{matrix}[C^{15}H^{27}(C^2H^5)N^2]\\H^2\end{matrix}\right\}O^2$. (Mills.)

Hydrate of ethylsparteine, on treatment with alcohol and iodide of ethyl, in sealed tubes, yields iodide of diethylsparteine, $[C^{15}H^{26}(C^{2}H^{5})^{2}N^{2}]''I^{2}$. (Mills.)

Constitution of Sparteine.—It appears from the above researches that sparteine is a tertiary diamine, having the formula $(C^{15}H^{26})^{vi}N^{2}$, but, as with so many of the natural alkaloïds and also of those formed by destructive, distillation, nothing definite is known of the hydrocarbon group which replaces the hydrogen in the typical ammonia. C. G. W.

SPARTIUM. A genus of plants belong to the papilionaceous group of the leguminous order. *Sp. monospermum* is said, by Lorenzo and Moreno (J. Chim. med. ix. 747), to yield a crystalline substance, spartiin, analogous to salicin.

The common broom (*Spartium scoparium*, L., *Cytisus scoparius*, Link) has been examined by several chemists. Cadet (J. Pharm. x. 432) found in the flowers a volatile oil, fat, a light-yellow colouring-matter, and a peculiar substance soluble in water and alcohol, and having the taste and smell of the plant; Reinsch (Jahrb. pr. Pharm. xii. 141) found, in the flowers and green parts of the plant, a crystallisable bitter principle. Stenhouse (Phil. Trans. 1851, p. 422) obtained from the plant a crystalline colouring-matter, scoparin (p. 208), and a volatile base, sparteine; both these substances are most abundant in plants which have grown in sunny situations. According to C. Sprengel (J. techn. Chem. v. 129), 100 pts. of the green plant yield 0·615 pt. of ash free from carbonic acid, and containing 27·6 per cent. potash, 1·0 soda, 24·1 lime, 4·2 magnesia, 13·0 alumina, 5·7 ferric oxide, 0·7 manganic oxide, 9·7 silica, 1·4 chlorine, 0·1 sulphuric anhydride, and 12·3 phosphoric anhydride.

The root of the common broom has, according to Reinsch, a decided liquorice-taste, with irritating after-taste.

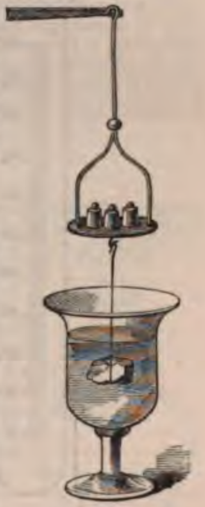
SPEAR PYRITES. Syn. with Marcasite (iii. 402).

SPECIFIC GRAVITY. By this term is understood the weight of a body as compared with that of an equal volume of another body assumed as a standard. It is, of course, necessary that the standard shall be readily obtainable in a pure state; distilled water is therefore employed for solids and liquids, and atmospheric air for gases and vapours. In certain scientific investigations it is not unfrequent to use hydrogen as the unit of density for gases and vapours. In this case it is usual to make the experimental comparison with air, and subsequently reduce it to that of hydrogen by calculation.

As the volumes of solids, liquids, and gases are affected by heat, it is absolutely necessary to perform the operations at known temperatures. It is usual in this country to make the experiment at 60° F. (= 15·5° C.) in the cases of solids and liquids; and with gases, to make the experiment at the temperature of the air at the time, and reduce the observed volume, by calculation, to the temperature of 15·5°. With vapours the experiment must be made at a temperature sufficiently elevated to ensure their obeying, within certain limits, the laws of permanent gases. The standard temperature in France is usually 0° for gases, and 4° (the point of maximum density of water) for solids and liquids.

We shall consider the methods of determining the specific gravities of solids, liquids, vapours and gases under separate heads:—

Fig. 750.



Specific Gravities of Solids.

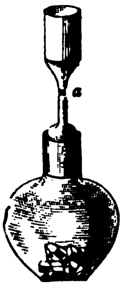
To determine the specific gravity of a solid, it is only necessary, in addition to its weight, to know that of an equal bulk of water. The method to be selected will depend upon the chemical and physical characters of the substance. We shall consider the following instances, which include all those which are likely to occur even in the investigation of the most troublesome organic substances:—

1. *The substance is solid, heavier than water, and insoluble in that liquid.*
2. *The substance is solid, and insoluble in, but lighter than water.*
3. *The substance is solid, heavier than water, but in fragments.*
4. *The substance is solid, heavier than water, but soluble in it.*
5. *The substance is solid, but soluble in and lighter in water.*

1. *The substance is solid, heavier than water. and insoluble in that liquid.*

a. By the Hydrostatic Balance.—The most usual and generally applicable method is by the use of a hydrostatic balance. The substance is first to be weighed accurately, in the usual manner. It is then to be attached by a slip-knot to a horsehair, and suspended from the short pan of a balance, as in *fig.* 750. A vessel of distilled water being so placed that the substance will hang freely in it, the substance will appear to be lighter than before, the loss of weight being exactly the same as the weight of a volume of water equal to that of the substance. In other words, a body immersed in water not only displaces its own volume, but also loses a portion of its weight exactly equal to that of the water displaced. If the arms of the balance are equal in length, it will only be necessary to place weights in the short pan until the equilibrium is restored, to get all the data necessary to enable the specific gravity to be computed. If the arms are unequal in length, it will be necessary to adjust the weights in the other pan until the substance is counterpoised. To calculate the density, it is only necessary to divide the weight in air by the loss of weight in water. Great care must be taken during the operation that the substance is always surrounded by water, that it does not touch the sides of the vessel, and that no air-bubbles adhere to it.

Fig. 751.

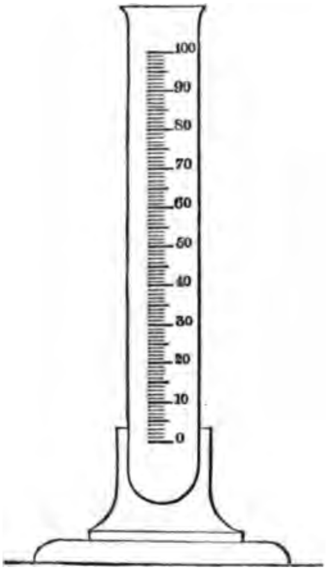


b. By Nicholson's Hydrometer. See HYDROMETER (iii. 211).

c. By the Flask.—A flask with a wide mouth and hollow stopper, enlarged at its upper extremity, and having a mark at *a* (*fig.* 751), is to be filled to the mark with water, and its weight is to be ascertained. The level of the liquid can easily be regulated by the aid of a small roll of filtering-paper. The stopper having been removed, the substance, the weight of which is known, is to be dropped in. The stopper is then to be replaced, care being taken that no air-bubbles either adhere to the substance, or lie between the stopper and the water; the level of the water having been again adjusted to the mark, the weight is to be ascertained. To calculate the result, we must add the weight of the substance to the weight of the flask of water, and from the number so obtained deduct the weight of the flask, &c., as obtained after inserting the substance. The difference will be the weight of a quantity of water equal in bulk to the substance. It is then only necessary to divide the original weight of the substance by the number so obtained.

d. Process by measuring the volume of the substance.—The substance is to be weighed in air, and then dropped into a graduated tube (*fig.* 752), filled to the zero of the scale with water. The graduations indicate grains (or grammes) of water. It is evident, therefore, that when the substance is inserted, the liquid will rise in the tube, and indicate at once the weight of a bulk of water equal to that of the substance. It is, therefore, only necessary to divide the weight in air by the weight of an equal volume of water, as indicated by the instrument, to obtain an approximation to the specific gravity.

Fig. 752.



2. *The substance is solid, and insoluble in, but lighter than water.*

a. The solution of this problem is excessively simple. Only three data are required, namely: the weight in air of the light substance $= P$; the weight *in water* of a piece of lead, or other heavy substance sufficient to sink it, $= P'$; and the weight *in water* of the light substance, and the lead attached to each other, $= P''$. We have then the density D by the following expression:

$$D = \frac{P}{P' - P'' + P}$$

Or, in words, deduct from the weight of the heavy substance, in water, the weight, in water, of the light and heavy substance attached; add to the remainder the weight of the light substance in air; and divide the weight of the light substance in air by the number so obtained: the result is the density.

b. The process by the flask is also applicable to this case. A vessel capable of being closed by a stopper being taken and weighed full of water, the light substance, if its physical condition permit, may be inserted after weighing; a quantity of water, equal in bulk to the substance, will then overflow; on replacing the stopper, and re-weighing, all the necessary data will be obtained, the calculation being made as in 1 c.

3. *The substance is solid, heavier than water, but in fragments.*

The process by the flask is especially applicable to this case. The operation and calculation are precisely as in 1 *c.*

4. *The substance is solid, heavier than water, but soluble in it.*

It is sometimes possible to varnish it very thinly, so as to prevent the access of the water, and to determine the specific gravity by the process 1 *a.* A serious error may, however, creep in if the varnish should penetrate any interstices in the substance. It is, therefore, in every way preferable to use the method 1 *a*, substituting for the water a liquid in which the substance is insoluble, making in the calculation a correction for the density of the liquid. Oil of turpentine, or benzene, will answer for most cases of this kind.

The calculation, which is extremely simple, is as follows:—From the weight of the substance in air, deduct the weight in the liquid; this gives the weight of a volume of the *liquid* equal to that of the substance. Then, to obtain the weight of a bulk of *water* equal to that of the substance, we say: As the specific gravity of the liquid, is to the specific gravity of water, so is the weight of a bulk of the *liquid* equal to that of the substance, to the weight of a bulk of water equal to that of the substance. The weight in air of the substance is then to be divided by the latter number. Or, more simply, calling the weight of the substance in air P, and the weight in the liquid P′, the weight of a bulk of the liquid equal to that of the substance will be $P - P' = P''$; and calling the density of the liquid S, and that of the water S′, we obtain the weight P‴ of a volume of water equal to that of the substance by the expression:

$$\frac{P'' S'}{S} = P'''$$

The density D of the substance therefore becomes:

$$D = \frac{P}{P'''}$$

The operation may also be made by the flask, a correction for the density of the liquid used being introduced into the calculation.

5. *The substance is solid, but soluble in and lighter than water.*

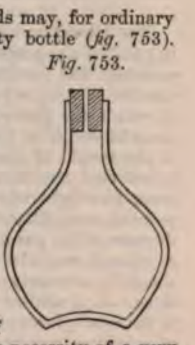
The process by the flask is specially adapted to this comparatively rare case. Benzene or turpentine is to be substituted for water, and the experiment is to be conducted as in 1 *c.* To obtain the weight of a bulk of water equal to that of the substance, we say: As the specific gravity of the liquid is to the weight of the liquid displaced, so is the specific gravity of water to the weight of a bulk of water equal to that of the substance. The weight of the substance in air divided by the latter number, of course gives the density required.

SPECIFIC GRAVITIES OF LIQUIDS.

a. By the Hydrometer. See HYDROMETER (iii. 205).

b. By the Specific Gravity bottle.—The specific gravities of liquids may, for ordinary purposes, be determined by means of the common specific gravity bottle (*fig.* 753). As ordinarily constructed by instrument-makers, it consists of a very thin glass flask, having a hollow stopper made from thermometer tube, carefully fitted by grinding. It is so constructed that, with the stopper in its place before adjustment, it holds a little less than 1000 grains of water. Enough of the under-surface of the stopper is then removed by grinding to allow of the bottle holding exactly that quantity at a temperature of 15·5° = 60° F. A counterpoise is also supplied having exactly the weight of the bottle. By this arrangement specific gravities may be readily obtained without calculation. If the bottle holds 1000 grains of water, it will hold 1850 grains of monohydrated sulphuric acid, 850 grains of benzene, &c., these numbers at once expressing the ratios of the densities.

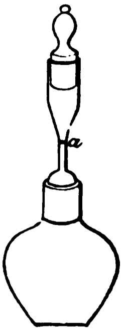
Fig. 753.



It is evident that the adjustment of the bottle to a capacity of 1000 grains of water has no advantage except that of saving the necessity of a very short calculation. Such a piece of apparatus has disadvantages which far more than counterbalance so slight a convenience. In the first place, it requires a quantity of liquid, which is often more than is at the disposal of the operator. In the next place, it has the serious drawback that, if the temperature of the balance-case be higher than that of the liquid, expansion of the latter takes place, and it rises in the tube and escapes down the sides of the flask. If, on the other hand, the temperature of the balance-case be lower, contraction ensues, and a void space is formed below the stopper, which cannot always be easily filled up. Moreover, volatile liquids escape by the aperture, rendering exact weighing excessively difficult. It would also be impossible, in such an apparatus, to determine the density of a liquid at a standard temperature either above or below that of the air at the time of making the experiment.

All the above objections are obviated by the use of the flask shown in *fig.* 754. It is essentially the same as that described in treating of the method of determining the specific gravities of solids by the flask, but furnished with a light well-fitting stopper having no aperture.

Fig. 754.



If it be required to determine the density of a very volatile liquid at (say) 4°, it is only necessary to fill the flask, a little above the mark *a*, first with pure distilled water, and subsequently with the liquid to be examined. After filling, it will be necessary, both with water and with the liquid, to keep the flask in a bath cooled to 4°, until the required temperature is obtained; the level at *a* may then be adjusted by the aid of a piece of filtering-paper. The stopper having been inserted, the apparatus is to be allowed to acquire the temperature of the laboratory, so as to prevent errors in weighing, which might arise from the deposition of moisture. The only effect, as regards the liquid, will be its rise in the tube, its escape being impossible owing to the enlargement. Volatilisation is also provided against by the stopper.

If, on the other hand, the determination is to be effected at a temperature above that of the atmosphere, the level is to be adjusted at the proper moment, and the apparatus may then be allowed to cool. The liquid will then descend in the tube at *a*; but no source of error is introduced if the stopper be removed for an instant to allow of the ingress of a proportional volume of air, and even this precaution is unnecessary save in refined experiments.

When the quantity of liquid to be operated upon is very small, a vessel of the above form, but of sufficiently small size, may easily be constructed at the blowpipe-lamp. Of course the flask will then be only in one piece; and if the liquid under examination be volatile, a small cork can be inserted, because, as the fluid is only allowed to rise to the mark on the neck, there will be no fear of errors arising from contact, and consequent absorption or chemical action.

Another method of determining the specific gravities of liquids, consists in weighing a piece of glass or platinum, first in water, and then in the liquid; the weights of equal volumes of the two liquids can thus be obtained with accuracy, even when working upon comparatively small quantities. It is not often, however, that this method possesses any great advantages over the others previously described.

For general considerations on specific gravity, as connected with atomic volume, see the article Atomic Volume (i. 440).

Specific Gravities of Gases.

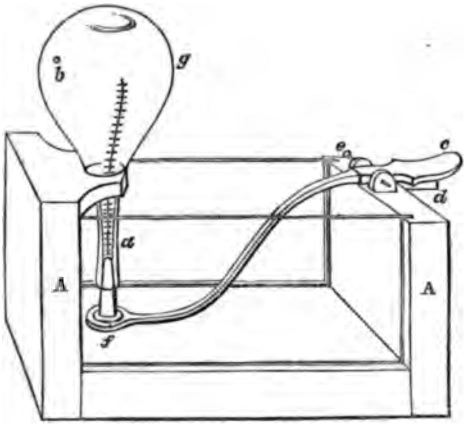
The determination of the specific gravity of a gas, so eminently simple in theory, is in practice an operation of the greatest delicacy. It is easy enough to obtain moderate accuracy, but results worthy to be depended on can only be procured by taking a number of minute precautions:—1. In the first place, it is important that the balloons in which the gases are to be weighed should be of such capacity that any minute error in weighing (such as a deci-milligramme) shall bear but a very small proportion to the weight of the gas, even if the latter be hydrogen itself.—2. Great care must be taken that the film of moisture which deposits upon the glass of the balloon is the same in weight when weighing the gas that it was when weighing the air. This is a point of great difficulty, and its neglect may give rise to serious errors.—3. The absolute dryness of the gas and the air, with the weight of an equal volume of which it is to be compared, must also be ensured.—4. The temperature must be most carefully noted, and should be as nearly as possible the same during all the weighings, so as to avoid corrections.—5. A similar remark applies to the pressure of the atmosphere, and consequently to the elastic force of the gas.—6. The balance should be of such delicacy that the errors of weighing have no appreciable influence upon the result.—7. Every possible care must be taken that the air and gas are absolutely pure.

There are three principal cases, which occur in laboratory practice, in which it becomes necessary to determine gaseous densities:—1. In the first, it is merely necessary to ascertain the specific gravity of a gas produced in a reaction, with a view to controlling or ascertaining its atomic weight.—2. It is often required to determine the specific gravity of coal-gas for technical purposes.—3. It is sometimes required to determine the specific gravity of a gas with every precaution, so as, in fact, to obtain a standard result. In the first and second cases, the process of Bunsen is unquestionably the best to be employed; in the third, it would be proper to use that of Regnault. We shall consider both of these methods, premising that for minute details it will be proper to consult the original works. (Bunsen's *Gasometry*, translated by Roscoe. Walton and Maberly.—Regnault, *Relation des expériences entreprises par ordre de M. le Ministre des travaux publics, et sur la proposition de la Commission Centrale des Machines à vapeur, pour déterminer les principales lois et les données numériques qui entrent dans le calcul des Machines à vapeur. Mémoires de l'Académie Royale des Sciences de l'Institut de France.*—Also Jamin, *Cours de Physique*, ii. 165.)

Bunsen's Method.

For the purpose of determining the specific gravity of a gas, Bunsen employs a light glass flask (*fig.* 755), of 200 or 300 cubic centimetres capacity, with a long narrow neck, having a millimetre scale etched upon it. It is furnished with an accurately-fitting glass stopper. The aperture of the neck is only about the thickness of a straw. Before filling the flask with gas, a small piece of fused chloride of calcium is dropped in, and made to crystallise on the side of the flask, by allowing a drop of water to come in contact with it, and then warming the glass until it has dissolved. On cooling it will crystallise. This is to enable the gas to be dried in the flask itself. The flask is to be filled with mercury by the aid of a small funnel reaching to the bottom. It is then to be inverted in the mercurial trough, A A. The gas, saturated with moisture, but otherwise in a state of purity, is then to be allowed to enter the flask. It is not, however, to be quite filled, but the entry of gas is to be so regulated, that the mercury in the neck shall remain a few millimetres above that in the trough. The whole is then to be allowed to remain until the gas has acquired the temperature (t) of the laboratory, at the atmospheric pressure P. The volume V of the gas, and the height p of the mercury in the flask above that in the trough, are then to be observed through the telescope of the cathetometer. The actual volume of the gas at t and P is found by consulting a previously prepared table, indicating the capacity of the flask at each of the millimetre marks on the neck. Calling the observed volume so obtained V_1, the volume V_2, at 0° C. and 760 mm. pressure, becomes:—

Fig. 755.

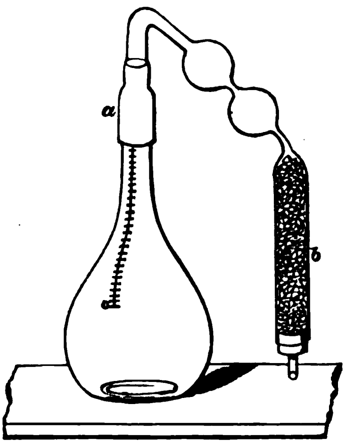


$$V_2 = \frac{V_1 (P - p)}{760 (1 + 0{\cdot}00367\, t)}.$$

The flask is then to be weighed, to obtain the weight G_2 of the corrected volume V_2.

It is necessary, in order to do this without bringing the hands in contact with the flask (which, by warming it, would alter the volume), to make use of the lever apparatus represented in the engraving at *c f*. At the end, *f*, a hollow cork is fastened containing the stopper, but it is so placed that while its superior extremity enters the flask for a short distance, it does not close it, because the wedge *d*, by raising the end *c*, keeps the end *f* depressed. When, therefore, the flask is to be closed, preparatory to the weighing, the wedge *d* is to be taken away, and the finger-plate *c*, being pressed upon the stopper, enters and closes the flask. The pin *c* is then to be withdrawn, and the flask, along with the lever *c f*, removed from the trough. The lever apparatus can then be detached from the stopper, so as to allow of the flask being placed on the pan of the balance. Previous to the weighing, it is necessary to clean the extremity of the flask with the most scrupulous care. It is to be allowed to repose on the balance until it has had time to attain the temperature t_1 of the balance-case at the pressure P_1; it may then be weighed. The number so obtained we shall call G. The glass stopper having been removed, it is to be replaced by the drying-tube *b* (*fig.* 756). It is then necessary to put the apparatus under the bell-glass of an air-pump, and exhaust and readmit the air until all the gas has been replaced by it. The stopper is again to be inserted after removal of the drying-tube, and the flask is to be reweighed. This weight is called G_1. The weight G_2 of the volume of gas V_2 measured in the flask becomes:

Fig. 756.



$$G_2 = G - G_1 + \frac{V_1 P_1}{773 \times 760 \times (1 + 0{\cdot}00367 t_1)}.$$

The number 773 is the volume in cubic centimetres of a gramme of dry air at 0°, and under a pressure of 760 millimetres in the latitude of Berlin.

The specific gravity (D) may then be found from the expression

$$D = 773 \frac{G_2}{V_2}.$$

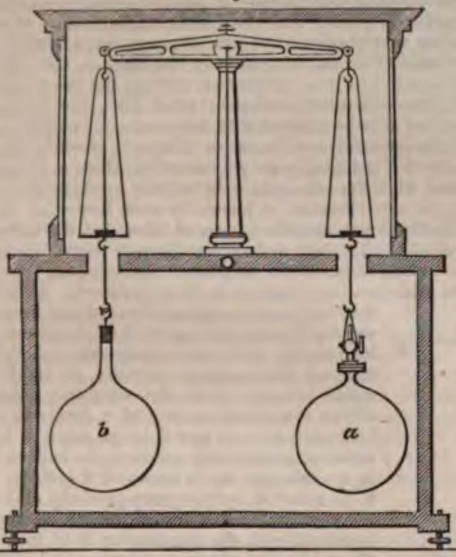
For a method of determining the specific gravity of a gas, by ascertaining the time of its effusion, as compared with the time of effusion of air, the reader is referred to Bunsen's work above cited.

Regnault's Method.

Regnault, in his magnificent work on the steam-engine above cited, gives an elaborate account of the methods employed by him to determine, with the utmost possible accuracy, the specific gravities of the more important gases. These methods are, however, far too complex, and require too elaborate apparatus to be employed in the laboratory, when, as in ninety-nine cases out of a hundred, the object in view is simply to confirm the formula of a gas which is under investigation. The process is nevertheless so perfect, and the results so trustworthy, that it would be highly improper to omit a condensed account of it.

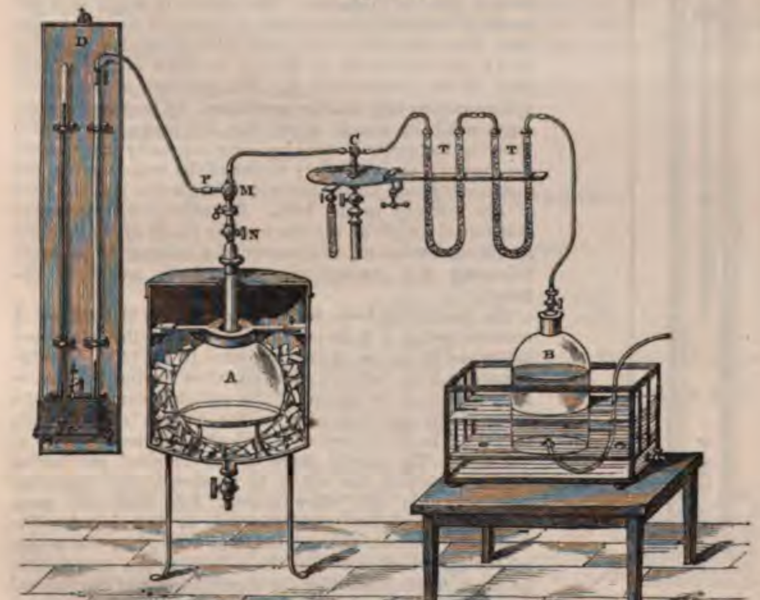
Regnault uses large balloons capable of holding ten litres. The balance, when loaded with a kilogramme in each pan, indicates readily half a milligramme. In order to do away with numerous uncertain corrections, arising from variations in the temperature, pressure, and hygrometric state of the air, the balloon in which the gases are weighed is counterpoised by another balloon of equal bulk, the same kind of glass, and of nearly equal weight. In order to determine the volume of air displaced by the balloon in which the gases are to be weighed, it is to be filled with water, and then weighed in water of the same temperature. The balloon is then to be removed and weighed, after wiping, upon a strong balance. It is plain that the difference between the two weighings is the same as the weight of water displaced by the external volume of the balloon. It is then necessary to obtain a counterpoise of precisely similar external volume, or, in other words, which displaces the same volume of air. For this purpose a balloon is selected a little smaller than the first, including its stopcock. The latter is merely closed with a cap ending in a hook, permitting it to be suspended from the balance-pan. Its volume is then ascertained, and if less than that of the balloon in which the gases are weighed, a tube closed at each end, and of a volume equal to the deficiency, is attached to it. The balloons, when adjusted, are then to be suspended beneath the scale-pans of a balance, in the manner shown in *fig.* 757.

Fig. 757.



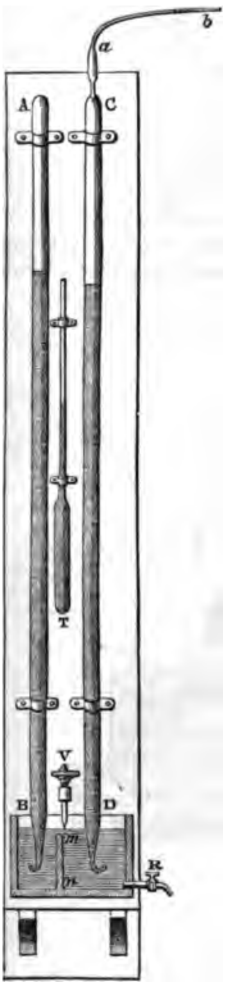
The flask, *a*, has a stopcock connected with a three-way tube, allowing it to be put in communication with a gasholder, an air-pump, and a manometric apparatus, which allows the elastic force of the gas to be ascertained with great precision. The arrangement may be seen by reference to *fig.* 758.

Fig. 758.



The stopcocks are then to be so turned as to place the balloon, A, in communication with the air-pump only, and the latter is to be worked until as perfect a vacuum as possible is obtained. The gas is then allowed to enter from the receiver B but slowly, so as to ensure its complete desiccation on passing through the tubes TT. These tubes may be charged with pumice moistened with sulphuric acid, or with fragments of chloride of calcium, or with pieces of hydrate of potassium, according to the nature of the gas. Lest any trace of air should remain in the balloon, the exhaustion and refilling are to be repeated until it is certain that nothing but the pure gas is contained in it. Before filling the exhausted globe for the last time, the sheet-iron case represented in the engraving is to be charged with fragments of ice; the taps N, M, and C then being turned, the gas is allowed to enter. When the globe is full, the tap N is to be closed. The tube at P not having as yet been slipped on, a momentary communication may be made with the atmosphere by rapidly opening and closing N. The elastic force of the gas may therefore be known by mere inspection of the barometer. The cock N being finally closed, and the system of tubes, &c. disconnected, the balloon is to be carefully wiped with a cloth sufficiently damp to prevent electrical excitation, which would cause serious errors in the weighing. The globe is then to be suspended on the balance, and after two hours' repose is to be weighed. This delay is imperative, because so large a volume of gas does not immediately acquire the temperature of the balance-case. Moreover, as long as the air of the balance-case and the balloon are of different temperatures, currents are liable to form, which would interfere with the weighings; finally, the delay allows the normal amount of moisture to condense on the balloon. As soon as weighings, taken at intervals of a few minutes, are perfectly constant, the balloon is to be replaced in the case, and again surrounded with ice. The gas is then to be removed by the pump precisely as before. In order to ascertain the elastic force of the residual gas, the tube connected with the manometer B is to be attached at P. The tube must, of course, be prevented from collapsing by a spiral of wire contained in it, or it may be made of lead. The barometric manometer is seen in section on a larger scale in *fig.* 759. The tube A B is merely a barometer of 20 mm. interior diameter. The cistern in which it is inverted is divided into two parts by means of the diaphragm *mn*. The tube CD is a glass tube of similar diameter to AB, but contracted at the top to allow of the attachment of the leaden tube *ab*. The pressure of the atmosphere may at any time be ascertained by pouring in mercury until it stands above the diaphragm, and, after lowering the screw V until its lower extremity just touches the mercury, measuring, by means of the cathetometer, the distance between the upper part of the screw and the level of the mercury in the tube. By adding the previously ascertained length of the screw to the result of the cathetometric measurement, the length of a column of mercury balancing the atmospheric pressure is accurately obtained.

Fig. 759.



The gas having been finally removed from the balloon, a communication is to be established between the latter and the tube CD, in the manner indicated in *fig.* 759. The difference in level between the two tubes having been carefully measured by means of the cathetometer, the elastic force of the gas remaining in the balloon is at once obtained. The thermometer T indicates the temperature at the time. The elastic force of the residual gas having been ascertained, the tap is to be closed, the connecting tube removed; and after wiping, &c., with the same precautions as before, the balloon is to be weighed. The difference between the weighings $(P-p)$ gives the weight of the gas which at 0° fills the balloon at the atmospheric pressure H, diminished by the elastic force, h, of the residual gas. The weight of the gas at the normal temperature and pressure then becomes:

$$(P-p)\frac{760}{H-h}$$

SPECIFIC GRAVITIES OF VAPOURS, OR VAPOUR-DENSITIES.

The determination of the vapour-density of a substance being the most severe check that can be obtained on the results of analysis, it necessarily becomes a process of constant occurrence in laboratories of research. All substances that volatilise without decomposition, at temperatures that can be accurately measured, can have their atomic weights determined in this manner, but the process to be employed will depend upon a number of variable conditions.

It is not intended in this article to describe all the processes which have been devised at various times to meet special cases, but it will be proper to consider those which have been found of general applicability and sufficient accuracy.

There are certain precautions which must be observed in *all* cases where the vapour-density of a substance is to be determined; these will be described in the first instance.

General precautions to be observed previous to determining Vapour-densities.—1. It is essential that the substance be entirely volatile without decomposition. It sometimes happens that the substance, although possessing this first and most essential quality, is nevertheless so readily oxidisable, that it cannot be distilled in a vessel containing air or oxygen without forming oxidised products, which are comparatively fixed. It is easy in most cases to overcome this difficulty, by filling the balloon with hydrogen previous to employing the method of Dumas, presently to be described. It even happens, at times, that the substance is (like isoprene), so readily oxidisable at ordinary temperatures, that, even when the vapour-density is determined by a process which does not allow of its coming in contact with air or oxygen at a high temperature, a portion of the substance is unable to assume the gaseous form. This may generally be avoided by preparing the substance only a short time before the operation, or by rectifying it over sodium immediately previous to inserting it into the bulb or tube, presently to be described.

2. It is very important that the substance shall be entirely free from bodies of higher or lower boiling-point. In the first case, the density will generally come out too high, and in the second too low. If, therefore, the substance to be experimented on be one of an homologous series, and be contaminated with any of its congeners, it is absolutely necessary that it be subjected to an elaborate fractional distillation, or other method of purification, before being examined.

3. The substance must be perfectly dry. It is obvious that the presence of comparatively small portions of water will lower the density of most organic vapours to an extent sufficient to destroy all confidence in the result as a means of checking a formula.

There are a few more precautions, of a somewhat less general character, but they will be considered in describing the various processes.

The methods which we shall describe are the following:

1. The process of Gay-Lussac.
2. „ „ Dumas.
3. „ „ H. Ste-Claire Deville and Troost.
4. „ „ Regnault.

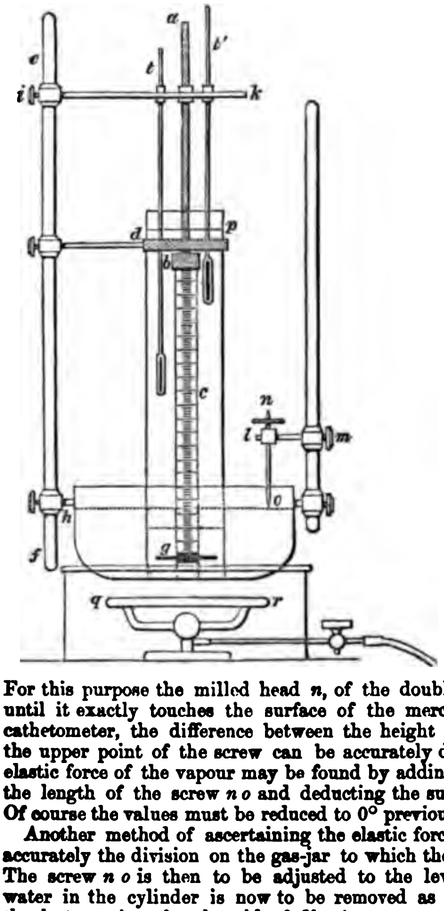
We shall also incidentally consider the following special cases:—

a. The substance is liquid, and boils below 100°.
b. „ „ „ „ above 100°, but below 150°.
c. „ „ „ „ above 150°, but below 300°.
d. „ „ solid, and boils below 300°.
e. „ „ liquid or a fusible solid, and boils above 300°, but below 350°.
f. „ „ boils above 350°, but below 440°.
g. „ „ „ above 440°, but below 860°.
h. „ „ „ above 860°, but below 1040°.

1. *The process of* Gay-Lussac.

a. The substance is liquid, and boils below 100°.—This simple and beautiful process consists in ascertaining the volume (V) occupied by a given weight (W) of a substance when heated to the temperature T, at a known pressure P. For this purpose a small iron pan is to be supported over a charcoal furnace or a powerful gas-lamp. A glass gas-jar (*c*) divided into cubic centimetres is, after drying, to be filled with mercury, and inverted in the trough. A small glass bulb, containing a known weight of the liquid, is then to be passed up into the gas-jar. It is of great importance that this bulb should be as thin as possible, so that it may not fail to burst by the mere expansion of the liquid. For this purpose it is also necessary that the bulb be perfectly filled. A large glass cylinder open at both ends is then to be lowered over the gas-jar. The gas-jar may be kept in the axis of the cylinder by means of the metal piece *g* having three projections, and also by means of the rod *a b*, carrying a cap *b*. The rod *a b* passes through one of three apertures in the arm *i k*, which slides on the upright rod *e f*, attached to the iron pot at *h*. The arm *i k* also allows two thermometers, *t* and *t′*, to be supported by means of pierced corks at different heights in the cylinder. The arm *l m* supports a double-pointed screw of known length, the use of which will be described presently. The cylinder is now to be filled with water up to the line *d p*, and heat is to be applied by means of the circular burner, *q r*. The liquid in the cylinder will now gradually increase in temperature, and at a certain point the bulb will burst, and the mercury will begin slowly to descend in the gas-jar. Soon after the water enters into ebullition, it will be found that the vapour will cease to expand any further. The volume *V* may then be noted, as also the temperature *T*, and the height of the barometer. But to obtain the true elastic force, *P*, of the vapour, it will be necessary to ascertain the height of the mercury in the jar above that in the trough, and to deduct this value from the height of the barometer. For this purpose the milled head *n*, of the double pointed screw *n o*, is to be turned until it exactly touches the surface of the mercury in the trough. By means of a cathetometer, the difference between the height of the mercury in the gas-jar and the upper point of the screw can be accurately determined. It is obvious that the elastic force of the vapour may be found by adding to the reading of the cathetometer the length of the screw *n o* and deducting the sum from the height of the barometer. Of course the values must be reduced to 0° previous to calculating the results.

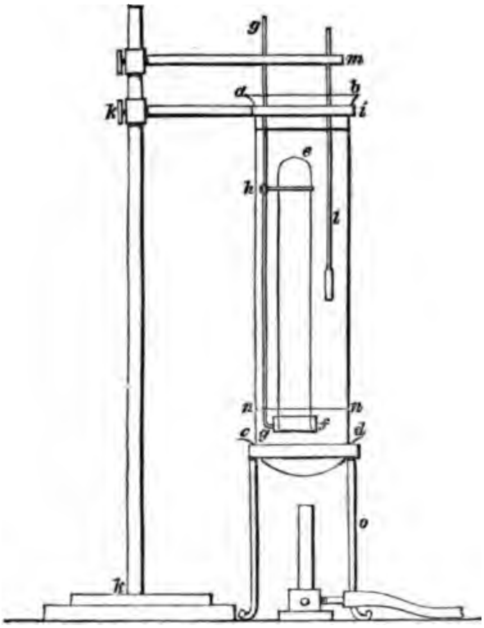
Fig. 760.



Another method of ascertaining the elastic force of the vapour is as follows. Note accurately the division on the gas-jar to which the inner level of the mercury reaches. The screw *n o* is then to be adjusted to the level of the mercury in the pot. The water in the cylinder is now to be removed as far as possible with a siphon, and the last portions by the aid of filtering-paper. The metal will then, of course, be found to have receded from the point of the screw. More metal is now to be added, until it exactly touches the point of the screw again. The exact point to which this level reaches on the gas-jar is to be noted. The distance between these two points, being deducted from the height of the barometer, gives the elastic force *P* of the vapour at the temperature *T*.

A more generally convenient form of apparatus for determining vapour-densities by Gay-Lussac's method, and one which requires a much smaller quantity of mercury, is represented in fig. 761. It consists of a cylinder of rather thin glass, *a b c d*, in shape like a very large test-tube; it may be about 16 or 18 inches long, and 5 or 6 in diameter. At the lower and closed end it is rounded, and care must be taken that it is thin enough to stand the application of heat, and yet strong enough to bear the weight of the mercury and the rest of the apparatus which will have to be inserted. A small and rather light gas-jar *e*, divided into half cubic centimetres, is supported at its lower end by an iron cup *f*, attached to a rod *g g* of the same metal. In the engraving it is represented in the act of being lowered into its place. The upper end of the jar is kept steady by the ring *h* which slides on the rod *g g*. The cylinder is retained in its vertical position by the ring *i* sliding on the massive retort-stand *k k*. The rod *g g* and the thermometer *l* are supported by the arm *m*, also attached to the retort-stand. The cylinder being charged up to the line *n n* with mercury, the gas-jar, filled with mercury, and having the glass bulb containing the fluid to be examined inserted, is placed in the position seen in the figure. The cylinder is then to be filled with water, or neat's-foot oil, until the gas-jar is covered for at least an inch. The cylinder may be supported on wire-gauze over the tripod *o*, or in any other convenient manner. Heat may be applied by means of a Bunsen's burner.

Fig. 761.



Great care must be taken, in passing the bulb up into the gas-jar, to prevent fracture. The most convenient way of accomplishing this, is to place the lower end of the jar in a mercurial trough, and to incline it to an angle of about 45°. The bulb is then to be held between the thumb and two first fingers, the tail towards the palm of the hand; it is then to be presented to the opening of the gas-jar, and when inserted is to be let go; it will then ascend to the top.

The elastic force of the gas can be very readily determined, owing to the transparency of the cylinder. With this apparatus the height of the column of oil or water must be ascertained, and reduced by calculation to a corresponding value in millimetres of mercury. The elastic force of the vapour is then found by adding this number to the height of the barometer, and deducting the height of the mercury in the gas-jar above the level of the mercury in the outer cylinder.

By proceeding according to either of the methods described, we ascertain the volume which a known weight of substance occupies at a given temperature and pressure, and it only remains to determine the weight *W* of the same volume *V* of air at the same temperature *T* and pressure *P*. This may be ascertained by means of the following formula:

$$W = 0{\cdot}0012932 \text{ grm} . V . \frac{1}{1 + 0{\cdot}00367\,T} . \frac{P}{760}$$

The expression $1 + 0{\cdot}00367\,T$ for the temperatures at which the specific gravities of *gases* are usually determined, has been calculated by several physicists, and may be found in works on physics; and an especially elaborate table of this description, for every tenth of a degree between − 2° and + 40°, may be found in Roscoe's translation of Bunsen's *Gasometry*. But it is evident that vapour-densities are almost always determined at temperatures more elevated than this: the author of this article has, therefore, calculated the more comprehensive expression $\frac{1}{1 + 0{\cdot}00367\,T}$ for all the temperatures at which a vapour-density is likely to be determined by Gay-Lussac's process—viz., from 1° to 150°. This table will, from the time which it will save in calculating, be found invaluable to those who have many determinations of this class to make.

b. The substance is liquid, and boils above 100°, *but below* 150°.—The process of Gay-Lussac is quite capable of meeting this case, but, instead of water, it will be necessary to substitute neat's-foot oil, or spermaceti. During the operation the oil must be stirred by the aid of a small stirrer attached to a wire. As oil does not remain colourless if heated for a long time to 150°, it is advisable to make the experiment in such a position, that a good light from a window or lamp may be brought behind it, so as to illuminate the divisions on the gas-jar and thermometer. In other respects the operation may be conducted in the same manner as that last described.

Table for the Calculation of $\frac{1}{1 + 0{\cdot}00367\,T}$

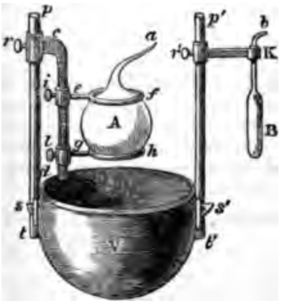
2. *The process of* Dumas.

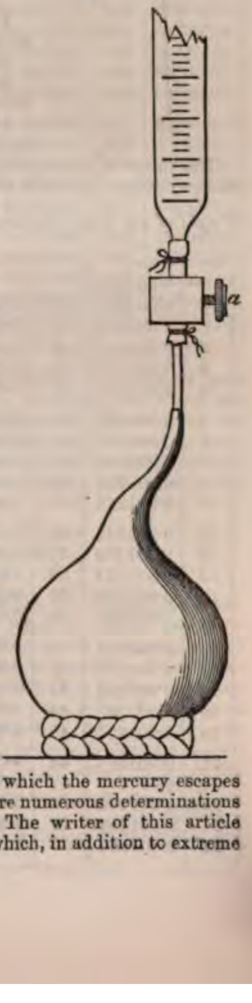
Fig. 762.



c. The substance is liquid, and boils above 150°, *but below* 300°.—The process best adapted for determining the vapour-densities of liquids boiling between the above temperatures is that of Dumas. For this purpose it is proper to employ glass balloons, having a capacity of from 100 to 350 cubic centimetres; the size will depend, to a great extent, upon the quantity of substance at the disposal of the operator. It is, however, absolutely necessary to have more substance than is sufficient to fill the balloon with its vapour. It is also proper to use larger balloons as the density of the vapour is lower; otherwise the difference between the weight of the balloon filled with vapour, and when filled with air, will be so small as to render excessively accurate weighing necessary, in order to prevent error. Dumas' method of determining vapour-densities is quite capable of yielding accurate results in the cases *a* and *b*; but it requires more substance, and does not permit of the density being determined at more than one temperature, without making a separate experiment in each case. The process of Gay-Lussac, on the other hand, permits numerous experiments with one small specimen of substance at any desired temperature within certain ranges, and thus enables the operator, in a very short time, to accumulate information regarding certain physical properties of substances which it is often very desirable to know—such, for example, as the lowest temperature at which the substance under study begins to obey the laws of permanent gases.

The balloons should be selected of a light and readily fusible glass, so as to allow the point to be sealed hermetically without difficulty at the close of the operation. One having been selected, and its neck having been drawn out to a moderately fine point, it is to be thoroughly dried. This may be done by exhausting it repeatedly, and allowing it to fill each time with air dried by passing over a column of chloride of calcium. The balloon is then to be weighed, the same precautions being taken as in the case of gases. As much fluid is then to be inserted as it is judged will be more than enough to fill it with vapour. An iron pot V (*fig.* 762), having been filled with melted tallow or neat's-foot oil, is to be supported in any convenient way over a charcoal furnace, or a powerful gas-burner. For all ordinary experiments, the air-thermometer b B may be replaced by a mercurial one passing through a cork at K. The ears s and s' of the pot V support two rods, $t\,p$ and $t'\,p'$. The former has sliding upon it a bent arm, $c\,d$, capable of being fixed at any height by the screw r. Two rings, $e\,f$ and $g\,h$, serve to support the balloon A; they may be adjusted by the screws $i\,l$. The tallow being heated to nearly the boiling-point of the substance, the balloon is to be lowered gradually, until the point a projects only about half or three-quarters of an inch above the tallow. When the temperature reaches the boiling-point, the vapour begins to escape, rapidly at first, but more and more gently afterwards, and finally ceases. The absolute cessation of the evolution of the vapour may be ascertained by bringing a piece of cold metal near the point a. The liquid which condenses in the neck is to be chased away with a piece of red-hot charcoal. The temperature should be allowed gradually to rise, until it is 20 or 30 degrees above the boiling-point of the substance. The heat must then be so regulated as to allow the bath to remain as nearly as possible at the same temperature, while the point of the balloon is being sealed. This latter operation is most conveniently effected by the aid of a Herapath's blowpipe, attached to a flexible tube of sufficient length to allow of ample freedom of movement. A common mouth-blowpipe and spirit-lamp will suffice when the gas-apparatus is not at hand.

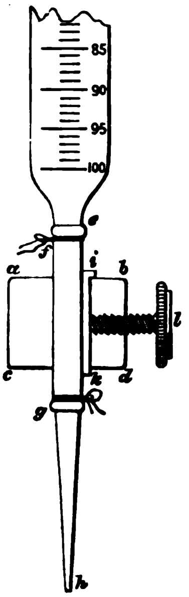
Fig. 763.



As soon as it is deemed that the point is perfectly closed, the temperature of the bath and the height of the barometer are to be noticed; the screw r may then be loosened, and the balloon raised completely from the bath; the point a should then be turned downwards, so that the condensed liquid may flow into it. It should now be carefully watched, to see if any air-bubbles rise through it, indicating incomplete sealing. If no leak be observed, the balloon may, after cooling, be thoroughly cleaned, placed on the balance-pan, and allowed to remain long enough to become constant in weight. The exact weight having been ascertained, the point a is to be inserted below the surface of the metal in the mercurial trough, and a file-mark having been made on it, the point is to be snapped off. The mercury will then rush in, and, if the operation has been completely successful, will, with the condensed liquid, entirely fill the balloon. In most cases, however, a bubble of air will remain, indicating that the whole has not been expelled from the balloon by the vapour. It is absolutely essential that the volume of this residual air should be accurately ascertained. For this purpose the mercury and condensed liquid are to be transferred to a cylinder, divided into cubic centimetres, and placed in a vertical position. A mirror then being held behind the cylinder, and in contact with it, the operator places himself in such a position that the line on the cylinder which coincides with the level of the mercury, or rather that of the condensed liquid, also coincides with the centre of the reflection of the pupil of the eye as seen in the mirror. The balloon is then to be refilled entirely with mercury, and the contents are to be again transferred to the graduated cylinder, and the volume ascertained as before. It is obvious that the second reading will give a greater value than the first, and that the difference between the two readings will indicate the volume of the residual air.

The above process for the determination of the residual air takes a considerable time, owing to the slowness with which the mercury escapes from the small aperture in the neck of the balloon, and, where numerous determinations of vapour-density have to be made, causes great delay. The writer of this article has therefore devised the following method of proceeding, which, in addition to extreme simplicity and accuracy, has the advantage of occupying only a few seconds (Phil. Trans. 1857, p. 460). The point of the balloon having been broken off under mercury, and the metal having entered the globe, the latter is to be placed on a straw ring (as in *fig.* 763, p. 369), beneath a burette divided into cubic centimetres and fractions. The screw *a* of the compression-stopcock is then turned, so as to allow a slow stream of metal to flow into the balloon until the condensed liquid exactly reaches the orifice. The quantity of mercury required for the purpose at once indicates the residual air. The compression-stopcock shown in *fig.* 763 is seen in section in *fig.* 764. It is capable of withstanding a very considerable pressure of mercury, and is so manageable that the smallest portion can be added at will. A block of wood, *a b c d*, has a square hole mortised in it, through which passes the vulcanised tube *e f g k*, attached at *e f* to the lower orifice of the burette. A piece of hard wood, *i k*, also passes through the mortise, and is retained in its place by the flange *i*. To close the orifice it is only necessary to turn the milled head *l* of the screw; the piece *i* will then be pressed against the vulcanised tube, and close it.

Fig. 764.



From the data obtained in an experiment conducted as above, the vapour-density (D) may be calculated in a few minutes with sufficient accuracy for most purposes, by the aid of the following formula:—

$$D = \frac{P + Vn_t}{(V - v)n_t'}$$

P = the difference in weight between the globe filled with air and when filled with vapour.

V = the capacity of the balloon in cubic centimetres.

n_t = the weight of one cubic centimetre of air at the temperature at which the balloon filled with air was weighed.

n_t' = the weight of one cubic centimetre of air at the temperature of sealing the globe.

The values of n_t and n_t' (in grammes) may be obtained at once from the following table, calculated for each degree centigrade from 0° to 300°:—

Weight of one Cubic Centimetre of Atmospheric Air at different Temperatures, from 0° *to* 300° *at* 760 *mm.*

160	0·000815	195	0·000754	230	0·000701	265	0·000655	300	0·000616

But the formula last given does not afford results of sufficient exactness for very delicate experiments, inasmuch as it does not include some necessary corrections, the most important being one for the expansion of glass. Regnault's formula, on the other hand, includes all the corrections required, and possesses also the merit of simplicity. The weight P of the balloon having been ascertained, and the temperature t of the balance-case, and the height (H) of the barometer having been noted, it is evident that the weight, p, of the air in the balloon will be:

$$p = 0{\cdot}0012932\, V \cdot \frac{1}{1 + 0{\cdot}00367\, t} \cdot \frac{H}{760};$$

V being the capacity of the balloon in cubic centimetres.

The point of the balloon having been sealed, and the height, H', of the barometer, and the apparent temperature, T, of the bath having been taken, it will be necessary to find the true temperature, T', which corresponds to it. It must be remembered that only a small portion of the tube of the thermometer is heated in the bath. It is therefore proper to have a small thermometer so placed that its bulb is in contact with the tube of the principal thermometer, and at the height of about one-half of that portion of the mercurial column which projects above the oil or tallow of the bath, and the division θ of the principal thermometer, which should be two or three centimetres above the bath. It may then be admitted that $(T-\theta)$ represents the portion of the mercurial column at the average temperature t. This portion would dilate by $(T-\theta) \cdot \frac{T-t}{6380}$ if heated from t to T. The true temperature T' is therefore found by adding to the apparent temperature, T, the number of degrees indicated by the expression $(T-\theta)\frac{T-t}{6380}$. But the temperature T', as indicated by a mercurial thermometer, must be exchanged for the corresponding temperature T'', as indicated by an air-thermometer; this may be obtained without experiment from the following table, founded on the experiments of Regnault:—

Table for the Conversion of the Degrees (T') of a Mercurial Thermometer into the corresponding Values (T'') of an Air Thermometer.

T'.	T''.	T'.	T''.	T'.	T''.	T'.	T''.
100°	100°	169·68	170	239·90	240	301·08	300
109·98	110	179·63	180	250·05	250	311·45	310
119·95	120	189·65	190	260·20	260	321·80	320
129·91	130	199·70	200	270·38	270	332·40	330
139·85	140	209·75	210	280·52	280	343·00	340
149·80	150	219·80	220	290·80	290	354·00	350
159·74	160	229·85	230				

The balloon having been sealed, and well cleaned, its weight (P') is to be determined; the weight of the vapour will therefore be $P'-(P-p)$.

The residual air, v, having been found in the usual manner, and the temperature t'' and pressure H'' noted, its weight p' may be ascertained by means of the expression:

$$p' = 0{\cdot}0012932 \text{ grm} . v \frac{1}{1 + 0{\cdot}00367t''} . \frac{H''}{760}$$

The weight of the vapour becomes, therefore, $(P'-P + p-p')$.

But it is evident that to obtain the true volume of the vapour we must deduct the volume of the residual air at the temperature of sealing the balloon, which, even as corrected, we shall for simplicity's sake call T. The volume v' of the residual air at T and H' will be:

$$v' = v \frac{1 + 0{\cdot}00367 . T}{1 + 0{\cdot}00367 . t''} . \frac{H''}{H'}.$$

Calling the coefficient of expansion of glass k, we have for the volume of the vapour at T and H' $[V(1 + kT) - v']$. The density of the vapour will therefore be:

$$\frac{P' - P + p - p'}{0{\cdot}0012932[V(1 + kT) - v'] \frac{1}{1 + 0{\cdot}00367 . T} . \frac{H'}{760}}.$$

or, at full length:

$$\frac{P' - P + \left(\frac{0{\cdot}0012932}{760(1 + 0{\cdot}00367t)}(V - v)H\right)}{\left[V(1 + kT) - v\frac{1 + 0{\cdot}00367T}{1 + 0{\cdot}00367t}\right]\frac{0{\cdot}0012932}{760(1 + 0{\cdot}00367T)} . H'}.$$

For very full details regarding the calculations in vapour-density determinations, see Brown (Chem. Soc. J. [2], iv. 72).

As the expression $\frac{1}{1 + 0{\cdot}00367 . T}$ can be taken at once from the table given under section *b*, the calculation is by no means a long one.

If the height (H') of the barometer has been taken in inches, it can be reduced at once to millimetres from the following table, extracted from the writer's *Handbook of Chemical Manipulation*:—

Table for the Conversion of Inches into Millimetres.

Inches.	Millimetres.	Inches.	Millimetres.
1	25·39954	6	152·3972
2	50·79908	7	177·7968
3	76·19862	8	203·1963
4	101·5982	9	228·5959
5	126·9977		

The coefficient of expansion of glass may be ascertained, for temperatures between 0° and 350°, by inspection of the following table (**Regnault**):—

Between 0° and 100°	K = 0·0000276
„ 150	0·0000284
„ 200	0·0000291
„ 250	0·0000298
„ 300	0·0000306
„ 350	0·0000313

In laboratories where vapour-densities are frequently being determined, it will be found of great advantage to keep copies, not only of all the data obtained in such experiments as the above, but also of each step in the calculations; so that, in the event of real or supposed error, the point at which it has occurred can be detected at once.

When the quantity of the residual air is small, and the atmospheric pressure is not far from 760 mm., its weight may be obtained with sufficient accuracy by multiplying the number opposite the temperature in the table on p. 370 by the number of cubic centimetres found.

d. The substance is solid, and boils below 300°.—The last-described method is quite capable of meeting the case, it being only necessary to fuse the substance so as to allow of its being inserted in the balloon.

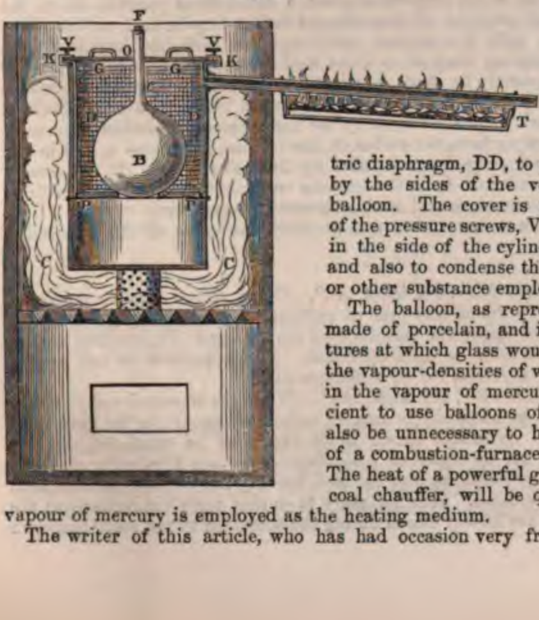
3. *The process of* **Deville** *and* **Troost**.

e. The substance is fluid or a fusible solid, and boils above 300°, *but below* 350°.—The chief difficulty in determining the vapour-densities of substances boiling beyond the range of the mercurial thermometer has been the accurate determination of the temperature. MM. **Deville** and **Troost** (Ann. Chim. Phys. [3], lviii. 257) have most ingeniously and successfully overcome this difficulty, by heating the balloons in the vapour of substances of elevated, but accurately known, boiling-points. It is evident that with homogeneous substances the temperature of their vapours, in contact with the boiling substances, is invariable as long as the pressure remains constant. Thus, under these circumstances, a thermometer surrounded by steam escaping from boiling water, will always indicate 100°. The same phenomena present themselves with bodies requiring much higher temperatures for vaporisation; the substances most convenient for the purpose are mercury boiling at 350°, sulphur at 440°, cadmium at 860°, and zinc at 1040°. In the case now under consideration, it is sufficient to use mercury the boiling-point of which is 350°.

The apparatus required is of the simplest description. It consists of an iron cylinder, CCKK (*fig.* 765), 22 centimetres high and 12 centimetres in diameter. It may very conveniently be constructed out of a mercury-bottle. It is to be closed with an iron cover, GG, pierced in its centre to allow of the passage of the neck of the balloon, B. The latter rests upon a ring of metal, PP, supported on points fixed to the interior of the cylinder. There is also a concentric diaphragm, DD, to prevent the heat radiated by the sides of the vessel from reaching the balloon. The cover is fastened down by means of the pressure screws, VV. The tube, T, inserted in the side of the cylinder, serves to carry away and also to condense the vapour of the mercury or other substance employed.

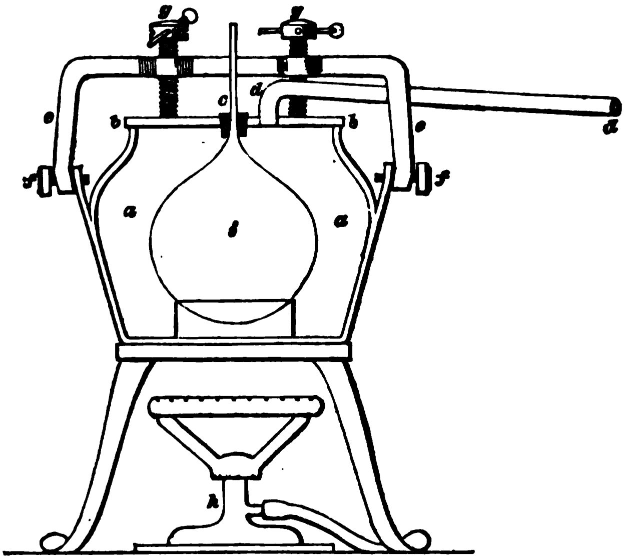
The balloon, as represented in the figure, is made of porcelain, and is used only for temperatures at which glass would soften: for substances the vapour-densities of which can be determined in the vapour of mercury, it will be quite sufficient to use balloons of ordinary glass. It will also be unnecessary to heat the tube T by means of a combustion-furnace, as shown in the figure. The heat of a powerful gas-burner, or small charcoal chauffer, will be quite sufficient when the vapour of mercury is employed as the heating medium.

Fig. 765.



The writer of this article, who has had occasion very frequently to employ this process, makes use of the apparatus shown in *fig.* 766. A small glue-pot, *a a*, is to be ground at its mouth, to fit accurately the iron plate *b b*. The latter is pierced with two holes—one serving to give egress to the neck *c* of the balloon, and the other to admit the bent iron tube *d d*, which serves to carry away and condense the vapour of the mercury. The gland *e e*, bent twice at right angles, has two screws *f f*, which attach it to the ears of the pot. The gland is pierced with three holes, two serving to admit the pressure-screws *g g*, and one to permit the passage of the neck of the balloon. A ring gas-burner (*h*) serves to heat the apparatus. The substance to be examined having been inserted in the balloon, *i*, and a few pounds of mercury having been placed in the pot, the balloon is to be put in its place, the neck passing through a cork, the upper portion of which projects as short a distance as possible above the cover of the pot. A small quantity of linseed-meal luting may be laid on the cover before fastening it down with the screws. Although the cork and luting will be destroyed during the operation, they serve quite well for one experiment. Another iron tube may very conveniently be made to slip over the tube *d d*, so as to conduct the condensed mercury-vapour to a convenient receptacle. The neck of the balloon must be kept very hot during the operation, by the aid of pieces of red-hot charcoal. When no more vapour escapes from the orifice of the balloon, it is to be sealed in the same manner as in vapour-density determinations by Dumas's method. It is scarcely necessary to add that the value of *k*, in the formula on p. 372, is too considerable to be neglected in determinations conducted at this elevated temperature.

Fig. 766.



It will save some trouble to remember that at 350° the value of the expression $\frac{1}{1+0\cdot00367\,T}$ is 0·000566.

f. The substance boils above 350°, *but below* 440°.—Glass globes may be employed for a temperature of 440° without any fear of softening. 500 or 600 grammes of sulphur are to be used in the apparatus described on pp. 373 and 374, and 200 or 300 grammes are to be distilled over in each operation. The apparatus is not injured by the sulphur, and lasts, therefore, for an indefinite time.

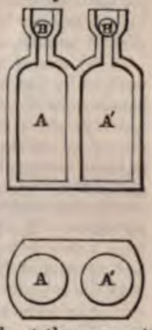
g. The substance boils above 440°, *but below* 860°.—When the vapour-density is to be determined at 860°, it will be necessary to employ cadmium-vapour for the purpose of heating the balloon. The apparatus shown in *fig.* 765 must be employed, and the tube *T* must be kept very hot by means of a combustion-furnace filled with charcoal. Two or three kilogrammes of cadmium may be used, but only 300 or 400 grammes need be distilled over in each operation. It is necessary to employ porcelain balloons at the temperature of 860°; they are loosely closed during the operation by the small porcelain stopper F (*fig.* 765, p. 373), which permits the escape of the vapour of the substance under examination. The opening is closed at the end of the experiment, by directing the flame of the oxyhydrogen-blowpipe over the stopper; the opening then closes without difficulty. For details as to the numerous precautions to be observed and corrections to be made in calculating the results, the reader is referred to the elaborate paper of MM. Deville and Troost, previously alluded to. It may be mentioned, however, that the coefficient of cubic dilatation of porcelain between 0° and 860° was found by the authors to be 0·0000108.

h. The substance boils above 860°, *but below* 1040°.—In this case it will be necessary to employ the vapour of zinc. The general process is similar to that employed in the case of cadmium. The coefficient of dilatation of porcelain between 0° and 1040°, was found to be 0·0000108—that is to say, the same as between 0° and 860°.

In determining precisely the boiling-points of sulphur, cadmium and zinc by means of the air-thermometer, great difficulties arise from the fact that minute errors of weighing seriously affect the results, owing to the extremely small quantities by weight of air which remain in the apparatus at the temperatures employed. Deville and Troost have overcome this difficulty by employing iodine instead of air in the thermometer. The very considerable density of the vapour of iodine (8·7), and the fact that it has, fortunately without sensible error, the same coefficient of dilatation as air, render it invaluable for this purpose.

4. *Regnault's processes.*—The limits of this work will not permit the introduction of a complete account of the numerous processes devised by Regnault for determining the densities of the vapours of substances. The methods already described are capable of meeting every case likely to occur in chemical researches. It is true that instances sometimes present themselves where it is desirable to obtain information as to the physical characters of certain vapours, and their behaviour under various circumstances of temperature and pressure: in such cases it will be necessary to refer to the original memoirs; a list of some of the more important is therefore appended to this article. It would, however, be improper to omit a description of the following simple method, devised by Regnault (Ann. Ch. Phys. [3], lxiii. 53), for determining the densities of vapours at elevated temperatures. It is, however, only adapted for substances which are unacted on by air. The apparatus consists of two flasks, A A′, made of cast-iron, as nearly as possible of the same thickness. They are terminated by tubulures, which are closed by the bullets B B′, resting on the openings. The volumes of the two flasks are to be exactly determined by ascertaining the weight of water required to fill them. Some mercury is to be poured into the flask A; and in A′, the substance the vapour-density of which is to be ascertained. The apparatus is then to be placed on a muffle heated to a temperature somewhat more than sufficient to convert the substance into vapour. The mercury and substance soon enter into ebullition, expelling the air by the apertures, which are only imperfectly closed by the bullets. When the apparatus has been sufficiently heated, it may be removed and allowed to cool. The weights of the mercury remaining in A, and of substance in A′, are then to be determined by analysis.

Fig. 767.



Let P be the weight of the mercury,

P′ that of the substance,

δ the density of mercury compared with that of air under the circumstances of temperature and pressure which existed in the muffle at the moment of removing the apparatus.

The density of the vapour will be under the same conditions, and, assuming the volumes of the two flasks to be identical,

$$x = \delta \frac{P'}{P}.$$

But as, in practice, the capacities of the two flasks will never be exactly the same, we must substitute the following formula for that given by M. Regnault. Representing, therefore, the volume of *A* by *V*, and the volume of *A′* by *V′*, we have:—

$$x = \delta \frac{P'}{P} \cdot \frac{V}{V'}.$$

It is proper to remark that this method ceases to be accurate if there be any great difference between the volumes of *A* and *A′*.

The relations between the atomic weights of substances and their densities in the state of vapour or gas, have been so fully discussed in the article ATOMIC WEIGHTS (i. 466), that we only now have to consider the *method of calculating the theoretical* *vapour-density of a substance.* This may at once be obtained by multiplying the atomic weight of the substance by half the density of hydrogen, 0·034635. If the results of experiment differ from the number so obtained by a very large amount, it will probably arise from the vapour-density being anomalous. (See Atomic Weights.)

SPECTRAL ANALYSIS. The examination of the properties of the light emitted by substances in the state of glowing gas has been termed Spectral Analysis. By this method we not only succeed in obtaining a much more accurate knowledge than we have hitherto possessed concerning the chemical composition of terrestrial matter, but we acquire information respecting the chemical nature of the sun, fixed stars, and distant nebulæ, opening out the new sciences of solar and stellar chemistry.

If, by means of a prism and suitable optical arrangements, we examine the light emitted by *incandescent solid* or *liquid* bodies, we find, first, that all such bodies become luminous at the same temperature; and, secondly, that when they first become luminous red rays alone are emitted, and that as the temperature rises, rays of every higher degree of refrangibility, up to a certain limit, are likewise given off, until, when the highest temperature is reached, all the luminous rays are emitted, and the body is said to be white-hot. Hence the spectrum of every incandescent solid or liquid is *continuous,* and cannot be used as a means of detecting the chemical nature of the substance. The light emitted by *incandescent gases* differs essentially from that radiated from solids or liquids, inasmuch as the spectrum of a glowing gas is *not continuous,* but consists of distinct bands or lines of light; in other words, is made up of different rays of definite degrees of refrangibility. Another difference to be noted is that, except in certain cases to be spoken of hereafter, the *quality* of the light of a glowing gas does not alter with increase of temperature: thus, as soon as sodium-vapour becomes luminous, it emits yellow light, nor can this colour be changed by increasing the temperature; sodium-vapour cannot be made white-hot.

Each elementary substance in the state of gas produces a spectrum consisting of bright lines or bands, which are unalterable in position, and are produced by that particular element alone; hence this property may be made use of for detecting the presence of the substance in question, and it matters not how far distant the source of light may be from the observer, provided the lines can be distinctly seen. Many chemical compounds are not decomposed below the temperature at which their vapours become luminous, and these compounds yield spectra differing from those of their constituent elements; in some cases a further elevation of temperature produces a sudden dissociation of the combined elements, and then the true elemental spectra become for the first time apparent—no further change in the position of the lines occurring with subsequent increase of temperature. In many instances, however, even in the case of the elemental lines, increase of temperature renders new lines visible, which could not be seen before, possibly owing to their not possessing sufficient intensity.

The methods of obtaining the spectra of the elements, or their compounds, differ according to their volatility. The instrument or spectroscope employed varies according to the degree of accuracy which the observations require: thus, for the detection of some of the more commonly-occurring substances, a rough apparatus with one prism will suffice, whereas for exact experiments, and for researches on solar chemistry, a much more powerful and optically perfect instrument is needed.

Examination of the Spectra of Bodies which tint the colourless Gas-flame.

It has long been known that certain substances, especially the salts of the alkalis and alkaline earths, tint the blowpipe-flame, and these tints have long been used as tests for the presence of the substances. Bunsen and Kirchhoff (1860, *Chemical Analysis by Spectrum Observations*: First Memoir, Pogg. Ann. cx. 161; and Phil. Mag. [4] xx. 89: Second Memoir, Pogg. Ann. cxiii. 337; and Phil. Mag. [4] xxii. 329 and 498) were the first successfully to apply the prism to the examination of these tints, whereby the accuracy and delicacy of their indications were infinitely increased, and thus to found the science of Spectral Analysis.

The improved spectroscope employed in these experiments is represented in *fig.* 768. On the upper end of the cast-iron foot, F, a brass plate is screwed, carrying the flint-glass prism P, having a refracting angle of 60°. The collimator-tube, A, is also fixed to the brass plate; in the end of this tube nearest the prism is placed a lens, whilst the other end is closed by a plate, in which a vertical slit has been made. Two arms are also fitted on to the cast-iron foot, so that they are moveable in a horizontal plane about the axis of the foot. One of these carries the telescope B, having a magnifying power of eight, whilst the other carries the tube C; a lens is placed in this tube at the end nearest the prism, and at the other end is a scale, which can be seen through the telescope by reflexion from the front surface of the prism. This scale is a photographic copy of a millimetre-scale, which has been produced in the camera of about $\frac{1}{15}$ the original dimensions. The structure of the slit is seen in *fig.* 769: the upper half only is left free; the lower half is covered by a small equilateral glass prism, which sends by total reflexion the light of the lamp D through the slit, whilst the rays of the lamp E pass freely through the upper and uncovered slit. By help of this arrangement, the observer sees the spectra of the two sources of light immediately one under the other, and can thus easily determine at a glance whether the lines are coincident or not. The instrument is used as follows:—In the first place, the telescope B is drawn out so far that a distant object is plainly seen; it is then screwed into the ring in which it is held, care being taken to loosen the screws α and β beforehand. The tube A is then brought into its place, and the axis of B brought into one straight line with that of A. The slit is then drawn out until it is distinctly seen

Fig. 768.

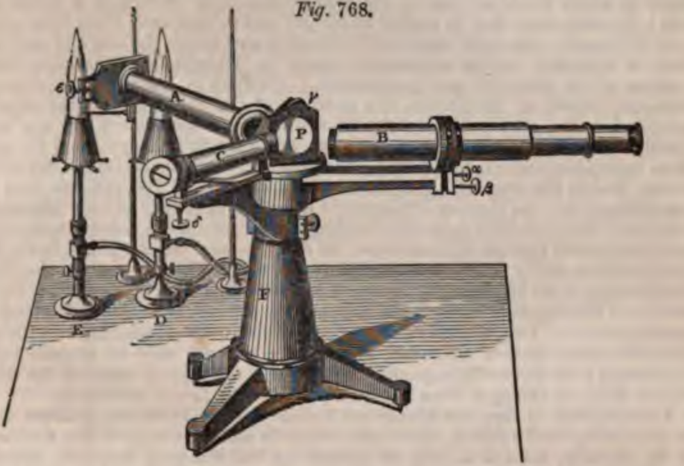

Fig. 769.

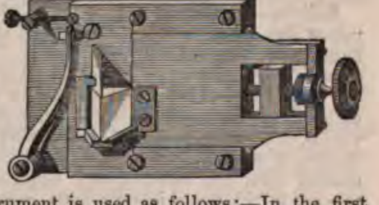

on looking through the telescope, and this latter is then fixed by moving the screws α and β until the middle of the slit is seen in the middle of the field of view. After removing the small spring γ, the prism is next placed on the brass plate, and fastened in the position which is marked for it, and secured by screwing down the spring-clamp γ.

If the axis of the tube A be now directed towards a bright surface, such as the flame of a candle, the spectrum of the flame is seen in the lower half of the field of the telescope, on moving the latter a certain angle round the axis of the foot F. When the telescope has been placed in position, the tube C is fastened on to the arm belonging to it; and this is turned through an angle such that, when light is allowed to fall on the divided scale, the image of the scale is seen through the telescope B, reflected from the nearer face of the prism. The divisions can easily be focussed, and the line on which the divisions lie brought parallel with the line dividing the two spectra by means of the screw (δ); a small gas-flame is then placed opposite the tube C to illuminate the scale. The breadth of the slit can be regulated, by means of the screw ϵ, according to the degree of illumination present, or the purity of the spectrum required. A black cloth, with holes for the tube C, is thrown over the whole apparatus to shade off stray light. In order to bring the two sources of light, D and E, into position, the following method may be employed :—If the lamp E be pushed past the slit, a point is easily found at which the blue lines of the hydrocarbon-flame (Swan, p. 358) are plainly seen; the lamp must then be pushed to the left still farther, until these lines nearly or quite disappear; the right mantle of the flame is now before the slit, and into this the bead of substance under examination must be brought. In the same way the position of the flame (D) may be ascertained (Bunsen). Owing to variations in the refracting power of the prisms, the positions of the lines of the same substances, measured by the photographic scale, on two different instruments will not coincide exactly. Bunsen has, however, given (Pogg. Ann. cxix. 6) an easy method for reducing these variations, rendering comparable the measurements thus made with different instruments. He has also proposed a graphical method (shown in *fig.* 770, opposite page 382) of mapping not only the position of the bright lines, but also their relative intensities and degrees of sharpness: this consists in shading in the lines under a millimetre-scale (representing that seen through the telescope), the starting-point being taken to be the D lines, the position of which is always represented at 50 mm. The height of the shading gives the intensity of the bright band, the extent of the shading gives the breadth of the line or band, and the degree of sharpness is indicated by the sudden or gradual growth of the shaded portions. This method cannot, of course, give to one unfamiliar with the spectra themselves, any idea of their real appearance; this can only be attained (and but imperfectly) by chromo-lithographic tables, which accompany some of the memoirs, and of which an enlarged series has been published by Lenoir of Vienna.

The discovery of four new elementary bodies (cæsium, rubidium, thallium, indium), by help of spectral analysis, since 1860, serves to show the value of this new method; of its delicacy, some idea may be formed by the following numbers, which give, in fractions of a milligramme, the weights of the smallest quantities of the metals in question which can thus be detected with certainty:—

	mgm.		mgm.
Sodium	0·0000003	Thallium	0·00002
Lithium	0·0000009	Rubidium	0·0002
Calcium	0·00001	Potassium	0·001
Cæsium	0·00005	Barium	0·001
Strontium	0·00006		

Spectrum Reactions of the Metals of the Alkalis and Alkaline Earths.

Sodium.—The spectrum-reaction of this metal is the most delicate of all. The yellow line, Na α, is the only one which appears in the sodium-spectrum as seen in the flame with the ordinary spectroscope. Examined at the high temperature of the electric spark with a more powerful set of prisms, this yellow line is seen to be double, and it is found to be exactly coincident with the dark double solar line known as D; under these circumstances, three other pairs of lines and a nebulous band become visible, in addition to the yellow D lines (Huggins, Phil. Trans. 1864, p. 139, on *The Spectra of some of the Chemical Elements*). The line Na α is remarkable for its exactly-defined form and extraordinary brightness. If the quantity of sodium-compound present in the flame is very large, some portion is precipitated in the solid form, and this gives rise to a faint continuous spectrum stretching at each side of the double yellow line; if a small piece of the metallic sodium be volatilised in the flame, the important phenomenon of the *reversal* of the sodium-spectrum is observed—that is, the *bright* sodium-lines on a *dark* background become changed to a *dark* one upon a background of a *bright* continuous spectrum. The explanation of this will be given hereafter. All the sodium-compounds yield the yellow line when heated in the flame; those (such as the oxides, chloride, iodide, bromide, sulphates, and carbonates) which are easily volatilised give the reaction most vividly, but the non-volatile phosphates, silicates, and borates also exhibit the line plainly. Swan in 1857, and indeed Melville in 1752, pointed out the delicacy of this reaction. The $\frac{1}{3000000}$ part of a milligramme of soda can be easily detected, and this reaction shows the constant presence of sodium-compounds floating about as motes in the sunbeam; all bodies, after exposure to the air for a few minutes, exhibit the soda-lines on ignition. This dust of sodium-compounds is derived from the evaporation of the minutely-divided particles of sea-spray, and from the transportation of the infinitely small solid particles by the winds.

Lithium.—The luminous vapour of lithium, obtained by the ignition of the salts of this metal in the flame, yields a spectrum consisting of two bright lines: the one a bright red line, Li α (31 mm. on Bunsen's scale), and the other a very much less distinct orange line, Li β (45 mm. on Bunsen's scale). When lithium-vapour is more strongly heated, as in an oxyhydrogen-flame or in the electric discharge, a blue line or band becomes visible, in addition to the other two lines which do not change their position (Tyndall and Frankland, Phil. Mag. [4], xxii. 472). This new blue lithium-line, when viewed with one prism, appears coincident with the blue strontium-line, Sr δ (see p. 380). On examination with three prisms and a high magnifying power, the blue lithium-line is seen to be somewhat more refrangible than the strontium, δ, the lines being separated by a space about equal to that separating the two sodium-lines. (Roscoe and Clifton, Proc. Manch. Phil. Soc. 1861–62, p. 227.)

All the lithium-compounds give the reaction; indeed, minerals containing lithium (such as triphylline, triphane, and petalite) only require to be held in the flame to exhibit the red line, Li α, most distinctly. Lithium-compounds were formerly supposed to occur most sparingly on the earth's crust, but spectral analysis has shown that this metal is most widely diffused. It has been found in the waters of the Atlantic, in the ashes of marine plants, in all the quartz and orthoclase of the Odenwald, as well as in very many other minerals from different localities; in almost every mineral-water, as well as in almost all well- and river-waters; in the ashes of tobacco, of wood of the vine; in milk, coffee, tea; in human blood, and in muscular tissue. Lithium-salts have been found to occur in large quantities in a spring in Cornwall (W. A. Miller, Brit. Assoc. Report, 1864). Lithium has also been found in meteoric stones. (Bunsen, Ann. Ch. Pharm. cxx. 253.—Engelbach, Pogg. Ann. cxvi. 512.)

Potassium.—Volatile potassium-compounds, when placed in the flame, give a widely-extended continuous spectrum, which consists of two chief lines: one line, K α, situated in the outermost red (from 16·5 to 18·5 on Bunsen's scale), and a second line, K β, situated far in the violet rays towards the other end of the spectrum (152·5 to 153·5 on Bunsen's scale). When the vapour of potassium is heated in the electric spark, several other lines make their appearance (Huggins). All potassium-salts containing volatile acids exhibit the two lines when placed in the flame, but the potash-silicates and some other non-volatile compounds do not show it, and must therefore be ignited with sodium-carbonate. The presence of the sodium-salt does not interfere with the reaction, and scarcely diminishes its delicacy. Orthoclase, sanidine, and adularia may in this way be easily distinguished from albite, oligoclase, labradorite, and anorthite. If only a trace of potash is present, the silicate must be heated with ammonium-fluoride in a platinum-basin, and the residue brought into the flame on a platinum-wire.

The potassium-red line, K α, was at one time supposed to be coincident with Fraunhofer's line A (Kirchhoff, *Researches*, part i.); it has since been shown that the red line is a double one (Roscoe), and that it is not coincident with Fraunhofer's A. (Kirchhoff, *Researches*, &c., part ii.)

Rubidium and Cæsium.—These two new alkali-metals were discovered by Bunsen in the mineral-water of Dürkheim, and in Saxon lepidolite (Berlin. Acad. Ber. 10 Mai 1860, p. 221; Chem. News, iii. 132). Since their discovery they have been found to be widely diffused; indeed, rubidium may be said to be a commonly-occurring substance; for although it exists only in small quantities, it is met with in a large number of mineral waters, and in the ashes of many vegetables, such as tobacco, coffee, and beetroot (Grandeau, Compt. rend. liv. 450, 1057). The chemical properties of the cæsium-compounds, together with the methods employed for the separation of this metal from rubidium, are described in vol. i. p. 1112 of this Dictionary; the rubidium-compounds are noticed in vol. v. pp. 127–131; hence it will here only be necessary to describe their spectra.

The spectra of the new metals exhibit, in the first place (in accordance with their correspondence in other chemical properties), a striking analogy with the potassium-spectrum; all three metals possess spectra which are continuous in the centre, decreasing in intensity towards each end. In the case of potassium, the continuous portion (indicated in the mass by a dark band *above* the division) is most intense, in that of rubidium less intense, and in the cæsium-spectrum this luminosity is least. In all three we observe the most intense and characteristic lines towards both the red and blue ends of the spectrum. Of the *rubidium-lines*, those marked Rb α and Rb β (137 and 135—136 mm.) are the most brilliant, and best suited for the recognition of the metal. Less brilliant, though still characteristic, are the red lines Rb γ and Rb δ (15—16 and 13—14 mm.), from which the metal derives its name; they are remarkable as both being less refrangible than the potassium red lines K α, and the outer one of them lies so far in the dark red as to be only rendered visible by a special arrangement. The other lines, which are found on the continuous portion of the spectrum, cannot so well be used as a means of detection, because they only appear when the substance is very pure, and when the degree of illumination is very great. The nitrate, chloride, chlorate, and perchlorate, on account of their easy volatility, show these lines most distinctly; but even the least volatile rubidium-compounds, such as the silicates, yield spectra in which all these details are plainly seen.

The *spectrum of cæsium* is chiefly characterised by the two lines Cs α and Cs β (109 and 106 mm.), remarkable for their brilliancy and sharpness of definition, as well as by the absence of any line in the red as in the two other spectra. The line Cs γ in the orange (42 mm.) is the next most distinct. The other yellow and green lines marked on the map first appear when the luminosity is great; and though they cannot be used for detecting the presence of small quantities of the cæsium-compounds, they may serve with advantage as tests of the purity of the cæsium-salt under examination, as they are seen only when all foreign matter is got rid of.

The delicacy of the spectrum-test for the pure compounds is, for rubidium 0·0002 mgm., and for cæsium 0·00005 mgm.; if other members of the alkaline group of metals be present, the delicacy of the reaction is of course impaired; but even when mixed with from 300 to 400 times its weight of the chlorides of potassium and sodium, the cæsium-chlorides would be easily detected; whilst the rubidium-salt will bear dilution with from 100 to 150 times its weight of the common alkalis before its spectrum is rendered indistinct. (Bunsen.)

The following is a list of the chief sources in which the new alkaline metals have as yet been found:—

In mineral waters:—Durkheim, Kissingen, Nauheim, Kreuznach, Baden-Baden, Wiesbaden, Soden near Frankfort, all contain both metals: see the Second Memoir by Bunsen and Kirchhoff.

Vichy, Bourbonne. (Grandeau, Compt. rend. liii. 1100.)

Ebensee, Haller, Gastein. (Redtenbacher, J. pr. Chem. lxxxv. 458.)

Aussee. (Schrötter, *ibid.* p. 458.)

Topusco, Lassinga, Karlsbrunn. (Schneider, *ibid.* p. 458.)

Salins (Jura), Contrexéville (Vosges).

Dead Sea water. (Grandeau, Ann. Ch. Phys. [3], lxvii. 175.)

In minerals:—Lepidolite from Roxena, Cs and Rb. (Bunsen and Kirchhoff.)

Lepidolite from Hebron in Maine, Rb and Cs. (O. D. Allen, Phil. Mag. [4], xxv. 189).

Lepidolite from Prague, Petalite from Uto, Rb and Cs. (Grandeau, Ann. Ch. Phys. [3], lxvi. 172, 173.)

Triphylline, Rb and Cs. (Bunsen, Chem. News, iv. 163.)

Lithia-mica from Zinnwald in Bohemia, Rb and Cs. (Bunsen, Chem. News. iv. 286.—Schrötter, J. pr. Chem. lxxxv. 458.)

Gneiss from Freiberg, Rb. (Rube, Berg- und Huttemänn. Zeitung, 1862, No. 8, p. 75.)

Carnallite, Rb and Cs. (Erdman, J. pr. Chem. lxxxvi. 377.)

Orthoclase from Carlsbad, Rb. (Erdman, *ibid.* p. 448.)

Chile saltpetre. (Bunsen, Pogg. Ann. cxiii. 361.—Grandeau, Ann. Ch. Phys. [3], lxvii. 207.)

Pollux from Elba (Pisani, Compt. rend. lviii. 714) contains 34 per cent. of cæsium; in all former analyses of the mineral this had been taken for potassium.

In vegetables and vegetable products, rubidium alone is found.

In beetroot and the saltpetre derived from it:—Grandeau (Compt. rend. liv. 450; Ann. Ch. Phys. [3], lxvii. 201).—Lefebre (Compt. rend. lv. 430).

In tobacco (Havana and Kentucky), in coffee, tea, cream of tartar.

In the ash of the oak-tree, *Quercus pubescens*. (Von Thann, J. pr. Chem. lxxxvi. 254.)

Strontium.—The spectra of the alkaline earths are by no means so simple as those produced by the alkalis; that of strontium is characterised by the absence of green bands. Eight lines in the strontium-spectrum are remarkable—six red, one orange, and one blue line: of these the orange, Sr α (45—47 mm.), two red, Sr β and Sr γ (31·5—33 and 33·5—34·5 mm.), and the blue line, Sr δ (104·5—105·5 mm.).

The chloride and other haloid salts of strontium give the best reaction, whilst it is seen less distinctly with the sulphate and carbonate, and cannot be obtained at all with the non-volatile compounds. On moistening the bead with hydrochloric acid, the lines are seen more vividly; the sulphate must previously be reduced to sulphide by holding the bead in the reducing flame, and the silicates must be fused on a platinum-loop, with carbonate of sodium, and the fused mass powdered, and washed on a plate by decantation. The insoluble carbonate of strontium is thus obtained, of which one or two-tenths of a milligramme, brought on to a platinum-wire and moistened with hydrochloric acid, suffices to give the most distinct reaction. The strontium-lines do not interfere with the indications of potassium and sodium; and lithium can also be detected in presence of strontium when the proportion of the former metal is not very small. The lithium-line appears as an intensely red and sharply-defined line upon a less distinct red ground of the broad strontium-band, Sr β. (Bunsen and Kirchhoff.)

If the temperature of the incandescent strontium-compounds be greatly increased, as when they are volatilised in the intense induction-spark, a sudden change in the spectrum is noticed, especially if a more powerful spectroscope is employed. Not only do new lines thus become visible which were not seen in the flame-spectrum, but the broad *bands*, characteristic of the spectrum at the lower temperature, totally disappear, and a mass of fine bright *lines* supply their place. These are, however, not coincident with any part of the band, being sometimes more and sometimes less refrangible. The lines, Sr α, β, γ disappear in the intense spark, whilst the blue line, Sr δ, does not alter either in intensity or in position with the alteration of temperature, but four new violet lines make their appearance. An explanation of this phenomenon of the disappearance of the broad bands and the production of the bright lines may be given by the supposition that the glowing vapour at the low temperature consists of the oxide or other compound of the difficultly reducible metal, whereas, at the enormously high temperature of the intense spark, these compounds are decomposed, and the true bright lines of the metal-spectrum are obtained (Roscoe and Clifton, Proc. Manch. Society, 1861–62, p. 227). The bright lines of metallic strontium have been carefully mapped by Huggins (*loc. cit.*).

Kirchhoff states in his memoir (Part i. p. 11) his opinion that the position of the bright bands, or maxima of light, is not dependent upon the temperature, upon the presence of other vapours, or upon any other condition except the chemical constitution of the vapour. The appearance of the spectrum may, however, Kirchhoff states, be very different under different circumstances. "Even the alteration of the mass of the incandescent gas is sufficient to effect a change in the character of the spectrum. If the thickness of the film of vapour whose lines are being examined be increased, the luminous intensities of all the lines increase, but in different ratios. The intensity of the bright lines increases more slowly than that of the less visible rays. The impression which a line produces on the eye depends on its breadth as well as its brightness. Hence it may happen that one line being less bright, although broader than a second, is less visible when the mass of incandescent gas is small, but becomes more distinctly seen than the second line when the thickness of the vapour is increased. Indeed, if the luminosity of the whole spectrum be so lowered that only the most striking of the lines are seen, it may happen that the spectrum appears to be totally changed when the mass of the gas is altered. Change of temperature appears to produce an effect similar to this alteration in the mass of the glowing vapour, no deviation in the maxima of light being observed, but the intensities of the lines increasing so differently, that those most visible at a high temperature are not those most readily seen at a low temperature" (Kirchhoff). Although this explanation of the changes observed may certainly apply to many cases, yet there can be no doubt that experiments made since the foregoing opinion was expressed, prove that in most instances the changes which occur are sudden, and are due to an alteration in the chemical constitution of the incandescent vapour.

Calcium.—The spectrum of this metal is immediately distinguished from all the preceding by the characteristic green band, Ca β (57 to 62·5 mm.), and by the orange band, Ca α (39·5 to 44 mm.). The chloride, iodide, and bromide give the reaction best; the non-volatile calcium-compounds must be decomposed either by hydrochloric acid, or by ammonium-fluoride, before the spectrum can be plainly obtained; and then, if the quantity of metal present be very small, the characteristic lines are seen to flash out only for a moment as the salt rapidly becomes basic and non-volatile. In this way, either by heating the substance alone, or after treatment with hydrochloric acid or ammonium-fluoride, the mineralogist and geologist is provided with a simple method of recognising the components of a minute fragment of substances with an ease and certainty attained in the ordinary method only by a large expenditure of time and material. Examples of the application of these tests are given in Bunsen and Kirchhoff's second memoir: these prove that some limestones contain lithium and strontium, as well as sodium and potassium; and it is probable that an exact series of experiments on the amount of these ingredients contained in these various limestones may prove of the highest geological interest, both as regards the order of their deposition and their local distribution. The calcium-spectrum shows the same kind of remarkable change on increase of temperature as the strontium-spectrum (Kirchhoff, *Researches*, i. 12); thus the broad band, Ca β, is replaced in the intense spark-spectrum by five fine green lines, all of which are less refrangible than any part of the band Ca β, whilst in place of the orange band, Ca α, three more refrangible orange lines are seen. The total disappearance in the spark-spectrum of a well-defined yellow band seen in the flame-spectrum at the lower temperature was strikingly evident (Roscoe and Clifton). The spark-spectrum of calcium contains also two bright lines in the violet, which may coincide with the two solar lines known as Fraunhofer's H. (Huggins.)

Barium.—This is the most complicated of all the flame-spectra of the alkalis and alkaline earths. It is at once distinguished from all the others by the green bands, Ba α (69·5 to 73 mm.) and Ba β (75 to 79 mm.); these are by far the most distinct, appearing at the first, and continuing during the whole of the reaction. Ba γ (59 to 63 mm.) is not quite so distinct, but is still a well-marked and peculiar line. The chloride, bromide, iodide, and fluoride, as well as the hydrate, carbonate, and sulphate, yield the reaction; the silicates must be treated previously with hydrochloric acid, or fused with sodium-carbonate, and the resulting barium-carbonate dissolved in acid. If barium and strontium occur in small quantities together with large amounts of calcium, the carbonates obtained by fusion are dissolved in nitric acid, and the dried salt exhausted with alcohol. The residue contains only barium and strontium, both of which can be almost always detected.

Unless one or more of the bodies to be detected is present in very small quantities, the methods of separation just mentioned are quite unnecessary, as a simple inspection of the flame-spectrum generally exhibits the bright lines of the various substances, appearing one after the other in the order of their volatility, and dying gradually out again as the pictures in a dissolving-view. The absence of any one or of several of these bodies is at once indicated by the non-appearance of the corresponding bright lines (Bunsen and Kirchhoff). The same phenomenon of change from broad bands to fine lines on increase of temperature has been observed in the barium as in the two foregoing spectra.

The spectrum of magnesium, as well as the spectra of almost all the other metals, cannot be obtained by means of the flame, owing to their compounds being non-volatile at the temperature of burning coal-gas. In order to obtain the spectra of these substances, recourse must be had to the method with the electric spark, explained hereafter.

Thallium.—The compounds of this new metal, discovered by Mr. Crookes (Chem. News, March 30, 1861) in certain specimens of iron-pyrites, give when brought into the flame, a splendid green coloration, and this yields a spectrum consisting of one green line, Tl α (77·5 to 78 mm.), which coincides with a part of the green barium-band, β. When examined with one prism, the extreme brilliancy of this line renders the detection of traces of thallium in pyrites easy (see the article THALLIUM in this volume; also Crookes, Phil. Trans. 1863, p. 173). When the spark-spectrum of thallium is examined, five lines are observed, in addition to the intense one in the green; first a very faint one in the orange; next two of nearly equal intensity in the green, more refrangible than Tl α, with a third much fainter, these lines being nearly equidistant; whilst fifth in the blue is a bright well-defined line (W. A. Miller, Proc. Roy. Soc., 1863, p. 407). Gassiot (Proc. Roy. Soc. xii. 536) found that the two green thallium- and barium-lines do not coincide when examined with a magnifying power of 80.

Indium.—This metal was discovered by Drs. Reich and Richter in the Freiberg zincblende (Phil. Mag. [4], March 1864, xxvii. 199). Its compounds are recognised by the deep indigo-coloured tint which they impart to flame. The indium-spectrum is characterised by two blue lines, which are best seen when a bead of an indium-compound is held between two electrodes from which a spark passes. The lines In α and In β fall respectively upon divisions 107·5 and 140 mm. of the photographic scale of the spectroscope when Na $\alpha = 50$ and Sr $\delta = 100·5$. The specific gravity of the metal is 7·277, and its atomic weight about 37 = In (monatomic). (Reich and Richter, J. pr. Chem. xcii. 480; see p. 268, vol. iii. of this Dictionary; also Strong, Berg- und Hüttenm. Zeit. 1865, p. 191; A. Winkler, J. pr. Chem. xciv. 1; Weselsky, Wien. Acad. Berichte, li. 286, May 1865.)

Although Bunsen and Kirchhoff have the merit of founding the method of spectral analysis, inasmuch as they placed it on a complete scientific basis, yet previous observations on this subject had not been wanting. Thus, so long ago as 1752, Thomas Melville pointed out the peculiar nature of certain coloured flames, and observed the yellow soda-flame, although unacquainted with its cause. In 1822 Brewster proposed his monochromatic lamp, but the first idea of this is due to Melville. In 1822 Sir John Herschel (Phil. Trans. p. 455) investigated the spectra of many coloured flames (muriates of strontia and lime, nitrate of copper, and boracic acid), and he writes in 1827 about them as follows, in the *Encyclopædia Metropolitana*: "The colours thus communicated by different bases to flame afford in many cases a ready and neat way of detecting extremely minute quantities of them." Fox Talbot, writing in 1826, makes the following valuable suggestions respecting these spectra: "The red fire of the theatres, examined in the same way, gave a most beautiful spectrum, with many light lines or maxima of light; in the red these rays were more numerous, and crowded with dark spaces between, besides an exterior ray greatly separated from the rest, and probably the effect of the nitre in the composition" (really K α). "In the orange was one bright line, one in the yellow, three in the green, a very bright one in the blue, and several that were fainter. . . . If this opinion (about the formation of these lines) should prove correct, and applicable to the other definite rays, a glance at the prismatic spectrum of a flame might show it to contain substances which it would otherwise require a laborious chemical analysis to detect."

These early observers, however, got altogether wrong with respect to the soda-reaction, and hence they cannot be considered in any way to have founded the science of spectrum-analysis. Thus Herschel says that he found "that when sulphur is thrown into a white-hot crucible, a very large quantity of a definite and purely homogeneous yellow light is produced," and that "Dr. Brewster obtained the same yellow light by setting fire to spirits of wine diluted with water and heated." Talbot states: "Hence the yellow rays may indicate the presence of soda, but they nevertheless frequently appear where no soda can be supposed to be present." He then mentions that the yellow light of burning sulphur is identical with the light of a spirit-lamp with a salted wick, and states that he is inclined to believe that the yellow light which occurred when salt was strewed upon a platinum-foil and placed in a flame, "was owing to the water of crystallisation rather than the soda." He is puzzled to know why, if this be the case, the same result is not obtained with salts of potash; he then finds that wood, ivory, paper, &c. give more or less of this yellow light, always the same in its characters. The only principle which these have in common is *water*, and yet he doubts whether water can cause this yellow light, as ignited sulphur produces the same. At one part of his paper he attributes this yellow colour to soda-salts, and in another part he says: "The bright line in the yellow is caused without doubt by the combustion of the sulphur." Talbot further on states that the "mere presence" of the substance, "which suffers no diminution in consequence," as in the case of chloride of calcium, causes a red-and-green line to appear in the spectrum. (See Kirchhoff, on *History of Spectrum Analysis*, Phil. Mag. [4], xxv. 250.)

In February 1834, Talbot writes (Phil. Mag. iv. 114): "Lithia and strontia are two bodies characterised by the fine red tint which they communicate to the flame. Now, it is difficult to distinguish lithia-red from strontia-red by the unassisted eye, but the prism displays between them the most marked distinction that can be imagined. The strontia-flame exhibits a large number of red rays, well separated from each other by dark intervals, not to mention an orange and a bright-blue ray. The lithia exhibits only one single red ray. Hence I hesitate not to say (referring to some experiments of Herschel), that optical analysis can distinguish the minutest portion of these substances from any other with as much certainty if not more than any other method." In 1845, W. Allen Miller (Phil. Mag. [3], xxvii. 81) published an investigation on the spectra of coloured flames, as well as the dark absorption-bands produced when white light passes through certain gases. Coloured diagrams of the spectra accompany the memoir, but, owing to the fact that the flame employed was a luminous one, these spectra are not distinctive enough of the particular substance to enable them to be used as characteristic tests for the metals in question. Amongst the spectra described and drawn are chloride of copper, boracic acid, nitrate of strontia, chloride of calcium, and chloride of barium; also the chlorides of sodium, manganese, and mercury, and of a large number of other metals.

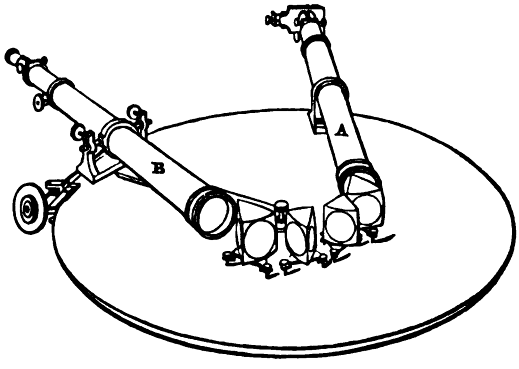
The first to point out the extreme delicacy of the spectrum-test for soda was Swan (Edin. Phil. Trans. xxi. 411), who showed that the reaction could be produced by $\frac{1}{2500000}$ part of a grain of common salt. And he concludes as follows: "When, indeed, we consider the almost universal diffusion of the salts of sodium, and the remarkable energy with which they produce yellow light, it seems highly probable that the yellow line R, which appears in the spectra of almost all flames, is in every case due to the presence of minute quantities of sodium." The following literature, in addition to the memoirs already cited on this part of the subject, may be consulted:—(1) *Lectures on Spectrum Analysis*, by W. A. Miller, Pharm. Journ. Feb. 1862; (2) Ditto by H. E. Roscoe, Chem. News, iii. 153, 170; *ibid.* v. 218, 261, 287.—Grandeau, *Instruction pratique sur l'Analyse Spectrale*, Paris, 1863.—Dibbits, H. C., *De Spectraal Analyse*, Rotterdam, 1863 (containing an able historical summary of the discoveries in the subject).—Mousson, *Résumé de nos Connaissances sur le Spectre*, Arch. Sc. Natur. de Genève. Mars. 1861.

Examination of the Spectra of Bodies volatilised in the Electric Spark.

This method is applicable not only to all those bodies which are non-volatile at the temperature of the colourless gas-flame, but also to those which are gaseous at the ordinary temperature (such as hydrogen), and require to be heated by the electric spark in order to be made incandescent.

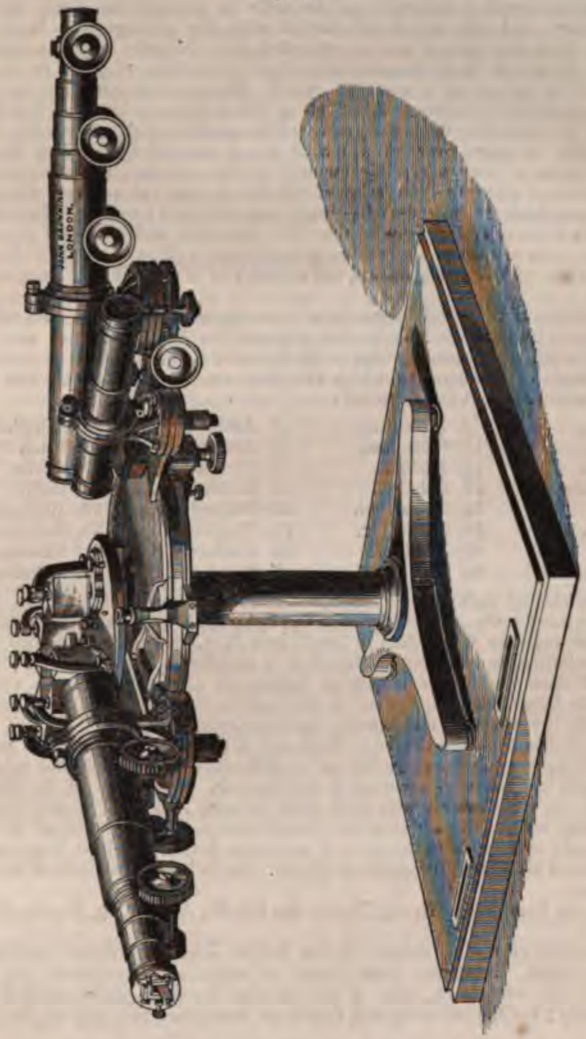
As the number of lines which become visible in the spectrum of the spark is very much larger than is seen in the flame-spectrum, a much more perfect and powerful spectroscope is needed for these observations. *Fig.* 771 represents the arrangement employed by Kirchhoff in his *Researches on the Solar Spectrum and Spectra of the Chemical Elements* (Macmillan, London, 1862 and 1863), and made by Steinheil of Munich. It consists of a collimator, A, screwed on to a planed circular iron table, and carrying the slit, formed of two knife-edges, the breadth of which can be regulated by a micrometer-screw. The slit itself can be brought into the focus of the achromatic object-glass by a rack-and-pinion motion. The telescope B, containing a similar objective, is fastened to a brass arm movable about the centre of the plate, either by the hand or with a micrometer-screw. Between the two objectives four flint-glass prisms are placed; the circular refracting surface on each is 18 Paris lines in diameter; three of them have a refracting angle of 45°, and the fourth of 60°. Each of the prisms is cemented on to a small brass stand with three set-screws. The telescope B, having a magnifying power of 40, has a horizontal motion with respect to the brass arm; it can be moved about a horizontal axis, and can be drawn in and out in the direction of this axis, as seen in the figure. In setting up this train of prisms, the greatest care must be taken, in the first place, that the axis of the two tubes are in the same horizontal plane, and parallel to that of the iron table; secondly, that the refracting surfaces of the prisms are all perpendicular to this plane; and thirdly, that the prisms are all placed at the angle of minimum deviation for the rays about to be observed (Kirchhoff). A large spectroscope, containing a powerful train of prisms, has been described by Gassiot (Proc. Roy. Soc. 1863, xii. 536), and known as the Kew spectroscope; and a second, containing eleven hollow prisms, filled with carbonic disulphide, is also described by Gassiot (Phil. Mag. [4] xxviii. 69). Wolcott Gibbs (Sill. Am. Journ. [2] xxxv. 110) has also described a large spectroscope. *Fig.* 772 exhibits the "Gassiot" spectroscope with four flint-glass prisms, as manufactured by Mr. Browning of the Minories. The arrangement employed by Huggins (Phil. Trans. 1864, p. 139), in his researches on the spectra of some of the chemical elements, was similar to that used by Kirchhoff; he employed six dispersing and one reflecting prism; the total deviation of the light in passing through the train of prisms was for the D ray 198°, and the distance traversed by the vernier of the telescope in passing from one of the D lines to the other was 75″.

Fig. 771.



Wollaston, who discovered the dark lines in the solar spectrum, was the first to observe the bright lines in the spectrum of the electric spark; but Faraday first asserted that the electric spark consisted solely of the material particles of the poles and of the medium through which it passes. **Wheatstone**, in 1835, showed that the spectra produced by the sparks from different metals were dissimilar, and he concluded that the electric spark results from the volatilisation and ignition, and not the combustion, of the ponderable matter of the poles itself, as the same phenomena were observed in hydrogen. **Wheatstone** (Abstract Brit. Assoc. Report, 1835) writes as follows, concerning the differences observable in the spectra produced by the poles of different metals: "These differences are so obvious, that one metal may instantly be distinguished from another by the appearance of its spark; and we have here a mode of discriminating metallic bodies, more readily applicable even than a chemical examination, which may hereafter be employed for useful purposes." **Angström**, in 1855 (Phil. Mag. [4] ix. 327), pointed out that a

Fig. 772.



twofold spectrum is always seen when we examine the electric spark, one set of lines being derived from the ignition of the particles of air or gas through which the sparks pass, whilst the second set is caused by the incandescence of the metallic particles themselves.

In order to obtain the spark easily and of the requisite degree of intensity, a powerful Ruhmkorff's induction-coil is used (Van der Willigen, Pogg. Ann. cvi. 615; see also p. 458 vol. ii. of this Dictionary); the one employed by Kirchhoff gave, by means of a moderately powerful battery, a spark 0·3 metre in length, whilst the coil used by Huggins gave a spark 3 inches long. In order to intensify the spark, the ends of the secondary coil are placed in contact with the coatings of a large Leyden-jar. The electrodes, also of course connected with the poles of the secondary coil, consist of the metals under examination, either in the form of wire, or of irregular pieces held by forceps on a moveable stand. Many precautions must be taken in working, especially with two different sets of electrodes, as it has been found that the currents of air, caused by the rapid passage of the electric spark between the electrodes, are sufficient to carry over to a second set of electrodes, placed at the distance of a few inches, a very perceptible quantity of the materials undergoing volatilisation. Hence no separate observation of the two spectra (at any rate where volatile metallic compounds are introduced as beads into the spark) can be relied on, unless one is made a considerable space of time after the other, and unless all the electrodes which have been once used are exchanged for new ones (Roscoe and Clifton). For further details of the arrangements, the memoirs of Kirchhoff and Huggins must be consulted.

The positions of the metallic lines have been mapped by Kirchhoff with reference to the dark solar lines, whilst Huggins has employed the bright air-lines as a constant scale upon which to note the position of the metal lines; but both experimenters use an arbitrary scale of divisions, by which the lines can be designated. The following elements were examined by Kirchhoff:

1. Sodium.
2. Calcium.
3. Barium.
4. Magnesium.
5. Iron.
6. Copper.
7. Zinc.
8. Chromium.
9. Strontium.
10. Cadmium.
11. Nickel.
12. Cobalt.
13. Potassium.
14. Rubidium.
15. Lithium.
16. Tin.
17. Antimony.
18. Arsenic.
19. Cerium.
20. Lanthanum.
21. Didymium.
22. Mercury.
23. Silicium.
24. Glucinum.
25. Aluminium.
26. Lead.
27. Silver.
28. Gold.
29. Ruthenium.
30. Iridium.
31. Platinum.
32. Palladium.

The spectrum of each of these metals contains a large number of lines, and these spectra are much more complicated than the flame-spectra: thus, in the green portion alone, there exist no fewer than 70 bright iron lines. Great care is needed, therefore, in the discrimination of metals, although it is easy for a trained eye to distinguish even such closely analogous metals as lanthanum and didymium, or erbium and cerium. In Kirchhoff's maps many of the metallic lines figure as broad bands; this is especially the case with the mercury- and zinc-spectra.

In Kirchhoff's maps the degree of blackness of the solar lines, and the relative intensities of the metallic lines, are denoted by different shades of the same colour, whilst their breadth is likewise represented in the drawing. The maps of the two experimenters do not agree exactly with each other, because Kirchhoff altered the position of his prisms several times during the measurements, in order to bring the different rays as nearly as possible to the point of minimum deviation, whilst Huggins allowed the position of his prisms to remain unaltered. The following metals have been mapped by Huggins:

Na, K, Ca, Ba, Sr, Mn, Tl, Ag, Te, Sn, Fe, Cd, Sb, Au, Bi, Hg, Co, As, Pb, Zn, Cr, Os, Pd, Pt.

In both sets of tables, several of the bright lines of different metals seem to coincide: when, however, these cases of apparent coincidence are narrowly observed in the instrument, most of the lines are found to show real differences of refrangibility; but the following still remain as unresolved coincidences (on Huggins's maps):

Zn, As 909 Na, Ba 1005 Os, As 1737.
Na, Pb 1000 Te, N 1366 Cr, N 2336.

Future research must prove whether these apparent coincidences are resolved on application of a still higher power.

For a description of the individual spectra of these metals, the above-mentioned memoirs and maps must be referred to, as it is impossible, by a brief description, to give any idea of the characteristic features of the masses of bright lines constituting these spectra.

The long Spectrum of the Electric Light.—Stokes (Phil. Trans. 1862, p. 599) has examined the spectrum of the electric spark when the lens and prisms are made of quartz; this substance allows rays of high refrangibility to pass, whereas glass cuts them all off. These rays are invisible to the eye, but can be rendered visible when allowed to fall on a fluorescent body, such as paper moistened with quinine-solution (iii. 633). On forming a pure spectrum of the electric spark from a Leyden jar, and receiving it on a highly fluorescent substance, the existence of rays of light was revealed, at a distance from the last visible violet rays, equal to six times the length of the whole visible spectrum. Each metal exhibits a peculiar series of these bands, and of all the metals, aluminium is found to be the richest in these rays of extreme refrangibility. These rays act chemically, and photographs of the invisible metal lines have been made by Miller (Phil. Trans. 1863, p. 1), whilst the same observer has determined the photographic transparency of different media (iii. 690).

Absorption Spectra.—This subject has already been sufficiently discussed (iii. 636). It only remains to notice a remarkable phenomenon lately observed by Bunsen (Pogg. Ann. cxxxvii. 100) in the absorption-spectrum of didymium. He finds that this spectrum undergoes an alteration if it be viewed by polarised light, according as the ordinary or the extraordinary ray is allowed to pass through the crystal. Bunsen also observed differences in the absorption-spectra of the various didymium-salts.

Projection of the Metal Spectra on a Screen.

The spectra of the metals can be thrown on a screen by help of a Duboscq's electric lamp (ii. 472). The metal or metallic compound of which it is desired to obtain the incandescent vapour, is placed in a small cup hollowed out in the lower carbon; on making contact with a battery of 50 to 60 Grove's cells, the metal is gradually vaporised, and the light passing through the slit and a lens is dispersed by two large prisms filled with carbonic disulphide. A continuously bright spectrum can thus be obtained from the incandescent carbon-points alone, and the presence of the several metals is indicated by the appearance of characteristic bright bands. In this way the bright bands of zinc and copper may be beautifully shown by volatilising brass, whilst silver, tin, and other metals yield their peculiar bands; the salts of the alkalis and alkaline earths, either separately or when mixed together, can also be made to exhibit their bright bands. The spectra thus obtained cannot, however, be compared for purity, fineness of detail, or exactness, with those received on the retina directly from the electric spark, and are therefore unsuited to the purposes of research, partly because the optical arrangement is necessarily imperfect, and also because the impurities (consisting of sodium, lime, &c.) always present in the gas carbon-points, render the spectrum impure. Debray has proposed (Ann. Ch. Phys. [3], lxv. 331) to employ the oxy-hydrogen-flame as the source of heat for the volatilisation of the metals; the projected spectra thus obtained are, however, necessarily much inferior to the electric spectra in brilliancy and distinctness.

The spectra of certain solid elements—such as silicon, sulphur, carbon, phosphorus, &c.—cannot be satisfactorily obtained by means of the ordinary electric spark—either (in the case of silicon, see Kirchhoff) because they cannot be volatilised, or because they yield solid oxidation-products, such as phosphoric pentoxide, giving a continuous spectrum. These latter elements must be vaporised, and their rarefied vapours ignited by the passage of the induction-spark through vacuum-tubes.

Examination of the Spectra of Bodies which are Gaseous at the ordinary Temperatures, or which require to be heated in Vacuum Tubes.

The spectra of the gases can be obtained either—(1) by passing the electric spark, from poles of some metal whose lines are known, through the gas in question, under the common atmospheric pressure; or (2) by observing the spectrum of the induction-spark, passing through a capillary tube (by Geissler's tubes, ii. 390, 472, &c.) containing the gas in an extremely rarefied state. The first of these methods has been followed by Kirchhoff and Huggins (*loc. cit.*), and the second by Plücker. (Pogg. Ann. März 1858, vol. civ.; *ibid.*, Aug. 1858, vol. cv.; *ibid.*, May 1859, vol. cvii. pp. 497, 638; also Plücker and Hittorf, Phil. Trans. 1865, p. 1.)

Spectrum of Atmospheric Air.—The air-lines are present with all electrodes, when the spark is taken in air at the common pressure. The lines thus obtained, between one set of electrodes of platinum and the other of gold, were observed simultaneously; those lines common to both spectra can be measured as those due to the components of air. The spectrum thus obtained remains invariably constant, with reference to the position and relative characteristics of the lines, with all the different metals. The air-spectrum varies *as a whole*, however, in distinctness, according to the metal employed as electrodes, owing to the difference in volatility of the metals, the air in and about the electrodes being more or less replaced by the metallic vapours. The air-spectrum is made up of the spectra of the following components—nitrogen, oxygen, and hydrogen (from aqueous vapour).

The air-lines have been carefully mapped by Huggins, and are employed by him as a scale of reference for the recognition of the lines of the metals; Kirchhoff has noted on his maps only a few of the most important air-lines. Grandeau (Chem. News, ix. 66) has observed the spectrum of a flash of lightning, and, in addition to the hydrogen- and nitrogen-lines, he noticed the bright-yellow sodium-line.

Hydrogen.—The spectrum of hydrogen consists of three bright fine lines—H α (coincident with Fraunhofer's C) in the red, H β (coincident with Fraunhofer's F) in the bluish-green, and H γ in the violet. These lines are exhibited both at the ordinary and at a reduced pressure. If the rarefaction of the gas be greatly increased, the red line H α gradually disappears, whilst H β, though fainter, remains well defined. When the intensity of the spark is increased, the bands H β and H γ begin to enlarge (Plücker); and when the tension of the hydrogen is increased to 360 mm., and a Leyden-jar is introduced to raise the temperature, the bright lines are seen to have given place to a continuous spectrum. This change is never observed when the spark passes through the gas under ordinary pressure. (May this phenomenon not be due to the incandescence of the abraded solid particles of the glass of the fine thermometer-tubing, or of the platinum-electrodes?)

The hydrogen-lines may likewise be obtained by passing the spark through a vacuous tube containing a trace of aqueous vapour, the water being decomposed.

Nitrogen.—The spectrum of nitrogen, taken by a spark through air at the ordinary pressure, is a very complicated one, and especially characterised by an alternation of bright lines and dark spaces in the red, and a succession of bands in the violet. With pure nitrogen a few of the lines of the air-spectrum are wanting, but no new lines appear, and the air-lines which remain in nitrogen preserve unaltered their relative brightness and their distinctive characters. (Huggins.)

Plücker and Hittorf have made some remarkable observations on certain changes which the nitrogen-spectrum, obtained when the gas is highly rarefied, undergoes on intensifying the current. Thus, like other gases, nitrogen in the state of greatest rarefaction does not allow the induction-current to pass; but when its tension is only a fraction of a millimetre, the current begins to pass, and the gas becomes luminous. Below a certain limit of temperature, nitrogen thus ignited emits a golden-coloured light, giving a spectrum of bands; above this temperature the colour becomes bluish-violet, and a new spectrum of bands appears. If a Leyden-jar be added in the circuit, the temperature rises to a second limit, a brilliant white light is emitted, and the spectrum is again changed to one of bright lines on a dark ground; and these lines do not alter in position on further increase of temperature, though the brilliancy of all does not increase in the same ratio. Those spectra which consist of larger bands, showing various appearances from being differently shaded by fine dark lines, are called by Plücker "spectra of the first order," whereas those formed by bright lines on a dark background, or the true spectra, he terms "spectra of the second order." The nitrogen-spectrum of the second order is doubtless that of the air-spectrum. Plücker explains these differences by the assumption of several allotropic modifications of the element existing at the various temperatures.

Oxygen.—It is difficult to obtain all the lines of the oxygen-spectrum; some of them, however, have been tabulated by Huggins. Plücker, operating as with nitrogen, got only one "secondary" spectrum of oxygen, although the lines appeared to expand so as to form a continuous spectrum at the highest temperature. Huggins finds that several lines are apparently common to oxygen and nitrogen, but he regards them as due to the superposition in the air-spectrum of lines of oxygen and nitrogen.

Sulphur.—The flame of sulphur burnt in common air gives a continuous spectrum; if a small quantity of sulphur be introduced into a Geissler's tube, which is then evacuated by a Geissler's exhauster and sealed, the sulphur-spectrum is seen on passing the spark if the tube be warmed. A band-spectrum of the first order is seen at a low temperature, but this changes on continuing to heat the tube, and a spectrum of bright-coloured lines becomes visible. These two spectra are figured by Plücker and Hittorf (*loc. cit.*).

Selenium yields two spectra like sulphur.

Phosphorus, treated like sulphur, yields a spectrum of the second order. The bright lines characteristic of phosphorus are a triple line in the orange, and two bright lines in the green. These green bands may also be seen by observing the spectrum of the green spot which makes its appearance in the interior of a hydrogen-flame, when the slightest trace of a phosphorus-compound is placed in contact with the dissolving zinc. (Christofle and Beilstein, Compt. rend. lvi. 399.)

Arsenic also yields a well-defined spectrum when treated like sulphur and phosphorus.

Chlorine, bromine, and *iodine* yield spectra with bright lines, none of which are coincident. Drawings of these three spectra are given in Plücker and Hittorff's memoir.

In these cases of bodies whose spectra change from bands (first spectrum) to bright lines (second spectrum) on increase of temperature, it is found that on cooling a recombination of the elements occurs, and the spectrum of the compound reappears (Plücker). Alexander Mitscherlich (Pogg. Ann. cxxi. 459; Phil. Mag. [4], xxviii. 169) has examined the spectra of the elements and their compounds. He arrives at the conclusion (already referred to), that compounds whose vapours can be heated up to incandescence without undergoing decomposition, yield spectra different from those of their elementary constituents. The salts of the greater number of the metals (as, for instance, K, Na, Li, Mg, Zn, Cd, Hg, and Ag) decompose at so low a temperature, that the compounds of these metals always yield the metallic spectrum. Certain metallic salts (such as those of copper) require for their decomposition so high a temperature, that the true metal-spectrum can only be obtained when the solid compound is used as the electrode; whilst other compounds, such as those of calcium, strontium, and barium, are partially decomposed at the temperature of the flame of a Bunsen's gas-lamp. The spectra of the elements consist of bright lines, those of their compounds of broad bands with narrow dark spaces (see *ante*), and this division would correspond to Plücker's division of the first and second order of spectra. Mitscherlich observed (like Plücker) that iodine in the spark shows bright lines, whilst in the hydrogen-flame it exhibits broad bands; and hence he draws certain conclusions respecting the probable compound nature of this body. At present, however, we know so little of the state of combination into which bodies in the flame may enter (possible formation of hydriodic acid, for example) that such speculations seem premature. Mitscherlich has also added some singular and somewhat improbable speculations concerning a supposed relation between the atomic weights of the haloïd compounds of barium, and the distance, on an arbitrary scale, read off between the chief lines of their spectra.

Carbon.—Carbon itself, when ignited, always yields a continuous spectrum, but the spectra obtained by the combustion of the various carbon-compounds consist of complicated bright bands, and appear different from one another. Swan (Ed. Phil. Trans. xxi. 411) was the first, in 1856, to examine the lines in the spectrum of the flame of Bunsen's gas-lamp, and of the flames of many hydrocarbons. In the blue portion of the gas-flame, Swan observed four bright-blue lines, and these lines appeared in the flame of a large number of hydrocarbons, their position remaining unaffected by alteration in the composition of the burning body, either in carbon, hydrogen, or oxygen. Swan adds careful measurements of the position of these lines. Attfield (Phil. Trans. 1862, p. 221) examined the lines in the non-illuminating flames of burning hydrocarbons; he obtained similar results to Swan, but observed a larger number of lines. He attributes these lines to the glowing vapour of carbon, as all the carbon-compounds appeared to give the same spectra. Plücker and Hittorf obtained different spectra from different carbon-compounds, especially when their particles were heated in Geissler's tubes. They found that all the lines obtained by all the various carbon-compounds existed in the cyanogen-spectrum, but they express themselves unable to explain fully the various types of spectra of carbon. Dibbits (Pogg. Ann. cxxii. 497) also found a remarkable difference between the spectrum of a hydrocarbon and that of cyanogen burning in oxygen.

The flame issuing from the Bessemer-steel converter, and especially that seen when the specular iron is poured into the molten iron, exhibits the carbon-lines most vividly (Roscoe). Huggins has observed, that when air contains some quantity of carbonic anhydride, several new lines are seen in the air-spectrum, and these coincide with the spectrum of graphite; one of the strongest and most characteristic of these is a red line, rather less refrangible than the hydrogen-line, and this may be used as a test of the presence of carbonic anhydride.

Solar and Stellar Chemistry.

unhofer, in 1814, examined the relative positions of the dark lines observed in
e Moon and Venus (reflected sunlight), and found that in the spectra of
of light, the dark lines were identical in number and position with
spectrum. Fraunhofer saw in Venus-light the double D lines,
and the relative distance from D to E and from E to F was
in the Solar spectrum. He also examined the light given
d stars (Sirius for instance), and found that lines or bands

were present which do not exist in sunlight, direct or reflected. Amongst the lines of Procyon, Fraunhofer recognised the solar line D, and in those of Capella and Betalgeux he found both D and *b*, but all the stellar spectra differed in certain respects from that of sunlight. Hence Fraunhofer concluded that the lines which we notice in the solar spectrum are, in some way or other, produced in the sun. Fraunhofer made another important observation—viz., that of the exact coincidence of the bright sodium-line, Na *α*, with the dark double solar line D. These early observations of Fraunhofer have lately been confirmed by Miller and Huggins (Phil. Trans. 1864, p. 418). It was, however, reserved for Kirchhoff (Monatsber. d. Berlin. Acad. Oct. 20, 1859) definitively to explain this coincidence, and thereby to obtain a key to the determination of the chemical composition of the sun and stars.

The Reversal of the Spectra of Coloured Flames.

In the year 1849 Foucault (Institut. 1849, p. 45) observing the spectrum of the electric arc, and comparing it with the solar spectrum, found that in both spectra the dark double line D was seen, the bright (sodium) lines present being changed into dark bands in the spectrum produced by the light from one of the carbon-poles which had been allowed to pass through the luminous arc. This experiment was in no way explained, nor did it attract much attention at the time, and it was unknown to Kirchhoff and Bunsen when they began their researches in 1859.

The mode in which Kirchhoff first obtained the true explanation of this important point cannot be given more concisely and clearly than in his own words (*Researches*, part i. p. 13): "In order to test, by direct experiment, the truth of the frequently asserted fact of the coincidence of the sodium-lines with the lines D, I obtained a tolerably bright solar spectrum, and brought a flame coloured by sodium-vapour in front of the slit. I then saw the dark lines D change into bright ones. The flame of a Bunsen's lamp threw the bright sodium-lines upon the solar spectrum with unexpected brilliancy. In order to find out the extent to which the intensity of the solar spectrum could be increased, without impairing the distinctness of the sodium-lines, I allowed the full sunlight to shine through the sodium-flame upon the slit, and, to my astonishment, I saw that the dark lines D appeared with an extraordinary degree of clearness. I then exchanged the sunlight for the Drummond's light, giving a continuous spectrum. When this light was allowed to fall through a suitable flame coloured by common salt, dark lines were seen in the spectrum in the position of the sodium-lines. The same phenomenon was observed if, instead of the incandescent lime, a platinum-wire was used, which, being heated in a flame, was brought to a temperature near to its melting-point by passing an electric current through it.

"The phenomenon in question is easily explained upon the supposition that the sodium-flame absorbs rays of the same degree of refrangibility as those it emits, whilst it is perfectly transparent for all other rays. This supposition is rendered probable by the fact, which has long been known, that certain gases, as nitrous acid and iodine-vapour, possess at low temperatures the property of such a selective absorption. The following considerations show that this is the true explanation of the phenomenon. If a sodium-flame be held before an incandescent platinum-wire whose spectrum is being examined, the brightness of the light in the neighbourhood of the sodium-lines would, according to the above supposition, *not* be altered; in the position of the sodium-lines themselves, however, the brightness *is* altered, for two reasons: in the first place, the intensity of the light emitted by the platinum-wire is reduced to a certain fraction of its original amount by absorption in the flame, and secondly, the light of the flame itself is added to that from the wire. It is plain that if the platinum-wire emits a sufficient amount of light, the loss of light occasioned by absorption in the flame must be greater than the gain of light from the luminosity of the flame: the sodium-lines must then appear darker than the surrounding parts, and, by contrast with the neighbouring parts, they may seem to be quite black, although their degree of luminosity is necessarily greater than that which the sodium-flame alone would have produced. The absorptive power of sodium-vapour becomes most apparent when its luminosity is smallest, or when its temperature is lowest."

If the spectrum emitted by a piece of sodium burning in the air be examined, the true sodium-spectrum will be seen to be reversed, exhibiting two dark lines (D) on a background of a continuous spectrum. Here the solid particles of soda give the continuous spectrum, and the sodium-vapour absorbs a great portion of the yellow rays. This can be well shown to an audience, and the black absorption-band projected on a screen, by placing a small piece of sodium on the lower carbon in the electric lamp; by approaching and separating the poles, this black line can be made alternately to appear and disappear for the space of several minutes. Another mode of showing that sodium-vapour is opaque to the light which it emits, is to burn a small jet of hydrogen, in which two soda-beads are placed, in front of a large sheet of flame rendered yellow by burning a piece of sodium near it. If the small flame be now looked at projected on a background of the large yellow flame, the hydrogen-flame appears surrounded by a dark zone, as if it smoked; this is due to the absorption of the yellow light of the large flame, by the vapour of sodium at the outside of the small flame (Crookes). A second method of showing this same property is to seal up some sodium in a vacuous tube; on volatilising the sodium, the vapour of the metal appears colourless by white light, but is dark and opaque when illuminated by the yellow soda-flame. (Roscoe).

Kirchhoff has, in like manner, reversed the red lithium-line Li α; if direct sunlight be allowed to pass through a lithium-flame, the spectrum exhibits, in place of the red lithium-line, a black line, which in distinctness bears comparison with the most remarkable of Fraunhofer's lines, and disappears when the flame is withdrawn. The bright lines of potassium, strontium, calcium, and barium (Kirchhoff and Bunsen), and some of the blue lines in the copper-spectrum (W. A. Miller) have also been *reversed*.

Kirchhoff has added to these discoveries a mathematical treatment of the proposition upon which the phenomena are based (*Ueber den Zusammenhang zwischen Emission und Absorption von Licht und Wärme*, 15 Dec. 1859, Monatsberichte d. Berliner Acad., and Phil. Mag. March 1860). This principle is known as the "Theory of Exchanges," and may be thus expressed: "The relation between the power of emission and power of absorption, for each kind of rays (light or heat), is the same for all bodies at the same temperature. From this proposition it follows that a glowing body which emits only rays of certain wave-lengths likewise absorbs only rays of the same wave-lengths; and from this we learn how the dark lines in the solar spectrum reveal the constituents of the sun's atmosphere." This definite relation, which exists between the radiating and absorbing powers of bodies for definite descriptions of light and heat, is thus clearly expressed by Kirchhoff:

"Let R denote the intensity of radiation of a particle for a given description of light at a given temperature, and let A denote the proportion of rays of this description incident on the particle which it absorbs; then $\frac{R}{A}$ has the same value for all bodies at the same temperature—that is to say, this quotient is a function of the temperature only."

Other physicists had previously approached very close to the "Theory of Exchanges," as expressed by Kirchhoff; thus Balfour Stewart, in 1858 (Trans. Roy. Soc. Edin.), enunciated this principle completely for the heating rays, which indeed had previously been proposed, first by Prevost, and afterwards by Provostaye and Desains. Stewart afterwards (Feb. 1860), applied this theory to the luminous rays, but his publication was later than, although independent of Kirchhoff's. Angström, especially, came near to Kirchhoff's discovery; in his *Optischen Untersuchengen* (Phil. Mag. ix. 329), he states the proposition that a body "in the state of incandescence must emit exactly all those kinds of light which it absorbs at the common temperature." In his further development of the subject there appear to be some contradictions, but he concludes by saying that—"I am convinced that the explanation of the dark lines in the solar spectrum embraces that of the luminous lines in the electric spectrum."

Stokes and William Thomson (Phil. Mag. 1862, p. 158) seem also to have expressed in conversation (although not to have published), the true explanation of the cause of the dark D lines, for some years before Kirchhoff's publication; but still, the experimental verification and scientific proof were wanting, until the latter physicist gave it, partly by his theoretical considerations, and partly by the experiments above referred to. (See Balfour Stewart, *Report on the Theory of Exchanges*, Brit. Assoc. 1861.—Kirchhoff, *On the History of Analysis of the Solar Atmosphere*, Phil. Mag. [4] xxv. 250.—B. Stewart, *Reply to Kirchhoff's Paper on the History*, &c. Phil. Mag. [4], May 1863.)

Euler was the first to predict the existence of the Law of Exchanges, by assuming, as a fundamental principle, that a body absorbs all the series of oscillations which it can itself assume. Stokes (Phil. Mag. 1860), in commenting on Kirchhoff's discovery, illustrates the principle by a dynamical example concerning sound, in which the well-known phenomenon of resonance is the equivalent to the emission and absorption of light.

On the Coincidence of the Bright Rays of certain Metals with the Dark Lines in the Solar Spectrum, and the Existence of certain Metals in the Solar Atmosphere.

The coincidence of the yellow soda-lines with the dark D line was observed by Fraunhofer, and Kirchhoff having discovered the phenomenon of the reversal of the bright lines, concluded that sodium-vapour is present in the solar atmosphere. In order to determine with certainty whether the bright lines of any other metal were coincident with solar lines, Kirchhoff mapped the solar lines with great care, and compared their position with the bright metal lines. *Fig.* 773 gives a representation of his drawings of a very small portion of the spectrum between *b* and F, showing the coincidences of many metallic lines. In thus examining the two spectra, Kirchhoff found that dark lines occur in the solar spectrum in the positions of all (about 80) the bright iron lines, and he believes that each of the coincidences thus observed may be at least as well established as that of the sodium-lines with the D line was up to the present time. Kirchhoff proceeds to calculate, from the average distance between each of the lines, and their number, the probability that this coincidence is a mere work of chance; this he finds to be less than $(\frac{1}{2})^{60}$, or less than $\frac{1}{1,000,000,000,000,000,000}$.

This probability is increased by the fact that the brighter a given iron line is seen to be, the darker, as a rule, does the corresponding solar line appear. Hence this coincidence must be produced by some cause, and a cause can be assigned which affords a perfect explanation of the phenomena. It is explained, if we suppose that the rays of light which we thus examine have at one time been rays of all degrees of refrangibility, such as we get from the Drummond's light; that this light has passed through the vapour of iron; and that this iron-vapour, absorbing exactly the same kind of light which it is capable of emitting, produces the dark lines which we observe. The vapour of iron causing these dark lines, may be present either in our own atmosphere, or in that of the sun. It is, however, very unlikely that there can be sufficient iron-vapour in our atmosphere to effect this alteration, and we observe that the starlight also passing through our atmosphere differs essentially from sunlight; whilst, on the other hand, it does not seem unlikely, owing to the high temperature which we must suppose the sun's atmosphere to possess, that such vapours should be present in it. "Hence," says Kirchhoff, "the observations of the solar spectrum appear to me to prove the presence of iron-vapour in the solar atmosphere, with as great a degree of certainty as we can attain in any question of natural science."

As soon as the existence in the solar atmosphere of one terrestrial element has been discovered, the comparison of the spectra of other metals is immediately suggested, as it is reasonable to suppose that other bodies well known on this earth may in like manner be found to be present in the sun. In this way, coincidences were found to exist between the solar lines and those of the following metals; and although the number of these coincidences for each of these metals is smaller than was observed with iron, yet they are so characteristic and distinct, as to leave no doubt of the presence of these metals in the solar atmosphere:—

1. Sodium.
2. Calcium.
3. Barium.
4. Magnesium.
5. Iron.
6. Chromium.
7. Nickel.
8. Copper.
9. Zinc.
10. Strontium.
11. Cadmium.
12. Cobalt.
13. Hydrogen.

There is some degree of doubt about strontium, cadmium, and cobalt, either because only a few coincidences have been observed, or because one or more prominent metal lines have no dark representative in the solar spectrum. The following elements appear to be absent from the solar atmosphere:—

1. Gold.
2. Silver.
3. Mercury.
4. Aluminium.*
5. Rubidium.
6. Tin.
7. Potassium.
8. Lead.
9. Antimony.
10. Arsenic.
11. Lithium.
12. Silicium.
13. Glucinum.
14. Cerium.
15. Lanthanum.
16. Didymium.
17. Ruthenium.
18. Iridium.
19. Palladium.
20. Platinum.

Hydrogen has been shown by Angström and Plücker to be present in the sun's atmosphere. The cause of many of the best-known of the Fraunhofer's lines has thus been already ascertained:

The line C is caused by hydrogen (Angström).
" " D " " sodium (Kirchhoff).
" " E " " iron "
" " C " " magnesium "
" " F and G " hydrogen "
" " H " " aluminium (Angström).

---

* According to Angström, a line of aluminium corresponds to Fraunhofer's H. Kirchhoff's maps do not extend so far as this.

Longmans & Co.

It is not, however, to be supposed that the whole of the dark lines are produced by absorption in the solar atmosphere; there are certain lines or bands which are doubtless produced by absorption in our own atmosphere. This is ascertained by the fact, that these bands increase in darkness, and new ones become apparent when the sun approaches the horizon, and the light has to pass through a deeper column of air. These air-absorption lines have been studied, and many of them mapped, by Brewster and Gladstone (Phil. Trans. 1860, p. 149). Several have also been mapped by Hofmann, and described in Kirchhoff's second memoir; of these some were found to be coincident with the brightest lines of the air-spectrum, obtained with the spark.

The increase or otherwise of these atmospheric absorption-lines has been applied by Huggins and Miller (Phil. Trans. 1864, p. 420) to the investigation of the question as to the existence of a lunar atmosphere; not the smallest change could be observed in the lines of the spectrum, either as respects relative intensity, or in the addition or disappearance of any lines when the moon's spectrum was examined. Hence the result of the spectrum-analysis of the light reflected by the moon is wholly negative as to the existence of any considerable lunar atmosphere. The light reflected from Jupiter exhibits, on the other hand, a distinct difference, especially from direct sunlight, inasmuch as, especially, one band in the red is seen to appear in light reflected from this planet. Hence spectrum-analysis confirms astronomical observation in the conclusion that Jupiter possesses an atmosphere of considerable density. Some of the lines in Saturn-light, although much weaker, appear to be the same as those seen in the spectrum of Jupiter. Mars does not exhibit the lines characteristic of the atmosphere of Jupiter and Saturn; groups of lines appear in the blue portion of the spectrum, and these, by causing the predominance of the red rays, may be the cause of the red colour which distinguishes the light of this planet. Venus showed no additional lines.

In the case of most of the planets, the solar light is probably reflected, not from the planetary surface, but from clouds at some elevation above it; under such circumstances, the light would not be subjected to the absorbent action of the lower and denser portions of the planet's atmosphere; and it is precisely these in our atmosphere, which are most effectual in producing the so-called atmospheric lines. (Huggins.)

M. Janssen has lately (Compt. rend. lvi. 538; lx. 213) obtained the complete absorption-spectrum of aqueous vapour, by passing the rays from a gas-flame through a tube 40 metres long filled with high-pressure steam. He has observed the coincidence of a very large number of these aqueous lines with lines observed in the solar spectrum, especially when the sun's altitude is low; and hence he has proved that these atmospheric lines are due to the presence of aqueous vapour. Janssen has also observed the existence of these lines in light reflected from Jupiter and Saturn, and hence it appears very probable that the atmospheres of these planets contain aqueous vapour.

A most interesting confirmation of the accuracy of Kirchhoff's drawings of the dark lines has recently been made by Rutherford of New York, who has succeeded in obtaining most exact photographs of the solar spectrum, on a scale nearly equal to that of the drawings; and on comparing the two, the correspondence of line for line is so complete, that it requires a close examination to detect differences which, however, are visible on careful inspection.

For details concerning the physical constitution of the sun, we must refer the reader to the original memoirs, as the questions at issue become purely physical and astronomical. The following extract from Kirchhoff's first memoir must suffice as giving his views on the subject:—

"In order to explain the occurrence of the dark lines in the solar spectrum, we must assume that the solar atmosphere encloses a luminous nucleus producing a continuous spectrum, the brightness of which exceeds a certain limit. The most probable supposition that can be made respecting the sun's constitution, is that it consists of a solid or liquid nucleus, heated to a temperature of the brightest whiteness, surrounded by an atmosphere of a somewhat lower temperature. This supposition is in accordance with Laplace's celebrated nebular hypothesis respecting the formation of our planetary system. If the matter now concentrated in the several heavenly bodies existed in former times as an extended and continuous mass of vapour, by the contraction of which sun, planets, and stars have been formed, all these bodies must necessarily possess mainly the same constitution. Geology teaches us that the earth once existed in a state of fusion; and we are compelled to admit that the same state of things has occurred in the other members of our solar system. The amount of cooling which the various heavenly bodies have undergone, in accordance with the laws of the radiation of heat, differs greatly, mainly owing to difference in their masses. Thus, whilst the moon has become cooler than the earth, the temperature of the sun has not yet sunk below a white heat. Our terrestrial atmosphere, in which now so few elements are found, must have possessed, when the earth was in a state of fusion, a much more complicated composition, as it then contained all those substances which are volatile at a white heat. The solar atmosphere at present possesses such a constitution."

[On the physical constitution of the sun, see "The Heavens," by Guillemin and Lockyer (Bentley, 1866), p. 17, &c.; Brayley, in Companion to the Almanac for 1864 and 1865; Memoirs by Carrington and by De la Rue, Stewart, and Loewy.]

Stellar Chemistry.

It has already been stated, that Fraunhofer was aware that the star-spectra differed from the spectra of the sun, moon, or planets. In 1862 Donati published diagrams of three or four lines in fifteen stars (*Intorno alle strie degli spettri stellari*, Il Nuovo Cimento, xv. 292), but the position of these lines did not correspond with Fraunhofer's results. In February 1863, Huggins and W. A. Miller communicated to the Royal Society some measurements of the lines in Sirius, Aldebaran, and α Orionis, whilst Rutherford about the same time made similar observations (Sill. Am. Journ. xxxv. 71). Secchi (Astronomische Nachrichten, 3. März 1863) also measured a few lines, as also did the Astronomer Royal (Monthly Notices, xxiii. 190). By far the most complete and accurate investigation of the stellar spectra is that by Huggins and W. A. Miller (Phil. Trans. 1864, p. 413). The investigation was carried on at Mr. Huggins's observatory, and the spectroscope, containing two prisms having each a refracting angle of 60°, is fixed to an 8-inch refracting telescope by Alvan Clarke.

In order to obtain evidence of the presence of dark lines in the stellar spectrum, the line of light obtained as the spectrum of the luminous point required to be spread out to a band; this was effected by a cylindrical lens placed within the focus of the object-glass, and immediately in front of the slit of the collimator of the spectroscope. The apparatus, when adjusted, is powerful enough to show the fine nickel line within the double D line in the solar spectrum. A micrometer movement is attached to the spectroscope, by which the position of the lines can be determined to within the $\frac{1}{2000}$ part of the distance of A to H.

Such measurements are, however, not sufficient to determine the chemical constitution of the stellar atmosphere; this can only be done by direct comparison with the metallic spectra, and hence arrangements were made for throwing the light from a flame or from the electric spark into the instrument, so that the two spectra are seen at once.

The following gives the results of careful comparison of the spectra of Aldebaran and Betelgeux (α Orionis) with bright lines of the metals:

ALDEBARAN.

Coincident Elements.		
1. Hydrogen	with	lines C and F.
2. Sodium	,,	double line D.
3. Magnesium	,,	triple line b.
4. Calcium	,,	four lines.
5. Iron	,,	four lines and E.
6. Bismuth	,,	four lines.
7. Tellurium	,,	four lines.
8. Antimony	,,	three lines.
9. Mercury.	,,	four lines.

Non-coincident Elements.		
Nitrogen	with	three lines.
Cobalt	,,	two lines.
Tin	,,	five lines.
Lead	,,	two lines.
Cadmium	,,	three lines.
Barium	,,	two lines.
Lithium	,,	one line.

Seventy lines measured.

BETELGEUX (α ORIONIS).

Coincident Elements.		
1. Sodium	with	double line D.
2. Magnesium	,,	triple line b.
3. Calcium	,,	four lines.
4. Iron	,,	three lines and E.
5. Bismuth	,,	four lines.
6. Thallium (?)		

Non-coincident Elements.		
Hydrogen	with	C and F
Nitrogen	,,	three lines.

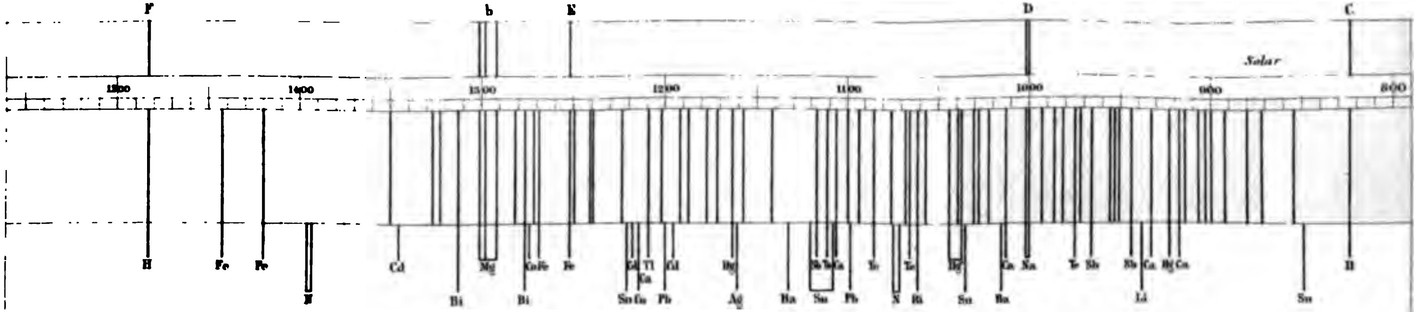
Non-coincident Elements (cont.)		
Tin	with	five lines.
Lead	,,	two lines
Gold(?)		
Cadmium	,,	three lines
Silver	,,	two lines.
Mercury	,,	four lines.
Barium	,,	two lines.
Lithium	,,	one line.

Eighty lines measured.

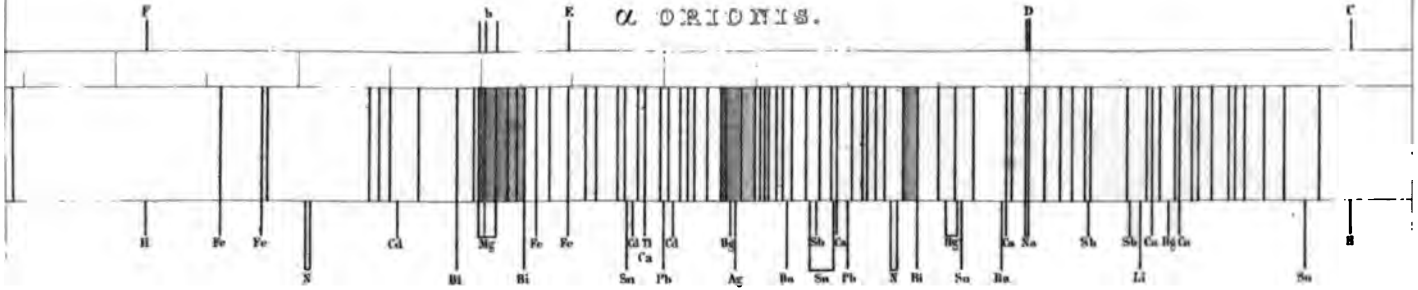
Fig. 774 is a copy of Huggins and Miller's drawing of the spectra of Aldebaran and of Betelgeux (half original size).

The seventy or eighty lines measured indicate only some of the stronger of the numerous lines which are seen in the spectra of these stars. "Some of these are probably due to the vapours of other terrestrial elements which have not been compared with these stars. It would be assumption to suppose that the sixty-five so-called elements constitute the entire primary material of the universe. Doubtless in the

ALDEBARAN.



α ORIONIS.



Longmans & C°

spectra of the stars the chemist is introduced to many new elements—would that it were possible for him to recognise and to isolate them!" (Huggins.)

In only two out of fifty stars examined were the lines of hydrogen, C and F, found absent; these are α Orionis and β Pegasi:

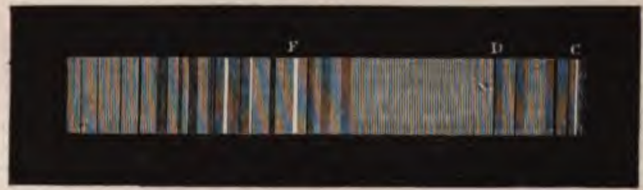
β Pegasi	contains	sodium,	magnesium,	perhaps barium.	
Sirius	,,	,,	,,	iron,	hydrogen.
α Lyræ (Vega)	,,	,,	,,	,,	,,
Pollux	,,	,,	,,	,,	,,

All the stars which have been examined yield spectra containing dark lines, star differing from star only in the grouping and arrangement of the numerous fine lines which cross their spectra. Hence the physical constitution of the fixed stars resembles that of our sun; the source of their light is solid or liquid matter in a state of incandescence, and this nucleus is surrounded by an atmosphere of the vapours of such of the elements of the star as are volatile at their high temperature. The results already obtained respecting the chemical composition of stellar atmospheres have an interesting bearing upon Laplace's nebular theory, as these results appear to show that the visible universe is composed mainly of the same elementary constituents, many of those known on this earth being found in the far-distant stars.

These spectrum-observations also lead to the presumption, that the well-known difference in colour observed in the stars may be caused by a difference in the chemical constitution of the stellar atmospheres, causing a variation in the absorption of the white light of the nucleus, and thus giving a difference in the colour to the starlight as seen by us.

One of the most interesting and extraordinary of astronomical observations ever made with respect to the stars has lately been described by Huggins and Miller (Proc. Roy. Soc. xv. 146, May 17, 1866). On the evening of May 15, Mr. Baxendell, of Manchester (an authority on variable stars), observed a new star. "This," he says, "suddenly burst forth in Corona. It is somewhat less than a degree distant from E of that constellation in a south-easterly direction, and last night (May 15) was fully equal in brilliancy to β Serpentis or ν Hercules, both of the third magnitude;" and Mr. Baxendell describes the star as exhibiting a nebulosity, "as if the yellow of the star were seen through an overlying film of a blue tint." On examining the light of the star, Huggins found that its spectrum was unlike that of any celestial body hitherto examined. The light of the star is compound, and has emanated, as Baxendell surmised, from two sources. Each light forms its own spectrum, and these two spectra appear superposed in the telescope. The chief spectrum is analogous to that of the sun, consisting of dark lines on a bright background, caused by light from a glowing nucleus passing through an absorbing atmosphere; the second spectrum consists of a few bright lines, indicating that the light is formed by matter in the condition of incandescent gas. The spectrum of this star is represented in *fig.* 775.

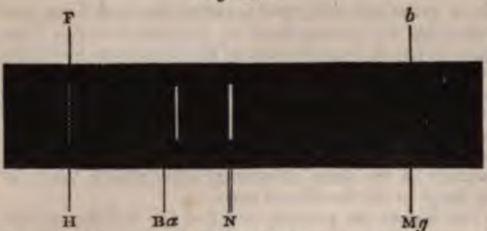
Fig. 775.



The brightest of the bright bands coincided with Fraunhofer's F, and therefore with the blue hydrogen-band; on account of the faintness of the red end of the spectrum, the coincidence of the red band with the red hydrogen-line could not be determined with equal certainty, though it is probable. The physical constitution of the star, as thus seen, must be very remarkable; it must consist of a solid nucleus and gaseous atmosphere, like an ordinary star, together with a separate outburst of ignited gas (probably hydrogen). The luminosity of the star quickly diminished, and on May 24 it had become as low as the eighth magnitude; the bright bands were seen gradually to disappear, whilst the other spectrum remained. Hence the bold speculation suggests itself that large quantities of gas have been evolved by some vast convulsion; that this gas (hydrogen), by burning, was heated to incandescence, and that this heated the whole solid matter and photosphere of the star, but that, as the hydrogen becomes exhausted, all the phenomena diminish in intensity, and the star rapidly wanes.

Spectra of the Nebulæ (Huggins, Phil. Trans. 1864, p. 437).—The special examination of the bodies known as planetary nebulæ has proved that their constitution is totally different from that of sun, planets, and fixed stars. They are all found to yield a spectrum consisting entirely of *bright* lines, without any continuous spectrum. Thus a bright nebula in Draco (No. 4373) gave, on careful examination, a spectrum consisting of one bright line coincident with the brightest of the air (nitrogen) lines, a second less brilliant line nearly coincident with a green barium-band, and a third still more refrangible line very much fainter, and coincident with one of the hydrogen-lines, viz. F of Fraunhofer; a very faint and scarcely visible continuous spectrum was just perceived on each side of the group of bright lines, due probably to the solid or liquid matter of the nucleus, which in this nebula is visible by its greater luminosity in the centre. A second bright nebula in Taurus Poniatowskii (No. 4390) exhibited the same spectrum as the last-mentioned nebulæ, and six other nebulæ showed either some or all of these same three lines. Of the sixty nebulæ examined by Huggins, about one-third exhibited these bright lines, whilst about forty, when spread out by the prism, yielded spectra apparently continuous. It is evident, from these observations, that many of the nebulæ can no longer be regarded as aggregations of suns, after the order to which our own sun and the fixed stars belong. We have in these objects no longer to do with a special modification only of our own type of suns, but find ourselves in the presence of objects possessing a distinct and peculiar plan of structure (Huggins). A question of great interest next presented itself—viz., do those nebulæ, which have certainly been resolved by the telescope into star-clusters, exhibit a spectrum which shows the source of light to be glowing gas? For this purpose Huggins examined the celebrated nebula in the sword-handle of Orion (Proc. Roy. Soc. 1865, p. 39). The light from the brightest part of the nebula, near the trapezium, was resolved by the prisms into three bright lines, similar in all respects to those of the other gaseous nebulæ. When the stars of the trapezium were brought into the slit, a continuous spectrum was at once seen; but the whole of the nebula emits the same kind of light, differing only in intensity. Thus, whilst the evidence afforded by the largest telescopes appears to be that the brighter parts of this nebula consist of a "mass of stars," the conclusions drawn from a prismatic analysis of the light, is that these luminous points are not stars, but masses of gaseous matter. Conclusions respecting the distance of these nebulæ, founded upon the erroneous supposition that they consist of stellar masses, must therefore be given up, as far at least as concerns the nebulæ which are proved to be gaseous.

Fig. 776.



Comets.—The light of comets has not escaped the searching investigation of Huggins's spectroscope (Proc. Roy. Soc. xv. 5; Jan. 1866). He finds that the spectrum of Comet I. 1866 consists of a broad continuous spectrum, with a bright point about midway between *b* and F in the solar spectrum, and coincident with the bright nitrogen-line observed in many nebulæ. Hence we learn that the light from the coma of this comet is different from that of its nucleus. The nucleus is self-luminous, and the matter of which it consists is in the state of ignited gas. As we cannot suppose the coma to consist of incandescent solid matter, the continuous spectrum probably indicates that it shines by reflected sunlight, and this appears to be in accordance with observations on the polarisation of light in the tails of some comets. (Bond.)

Meteors.—Mr. Alexander Herschel has recently succeeded in observing the spectrum of a bright meteor, and also the spectra of some of the trains which meteors leave behind them. A remarkable result of his observations is, that sodium exists in the state of luminous vapour in the trains of most meteors.

The results of the examination of the spectra of the stellar bodies may be shortly summed up in the words of Mr. Huggins (Lecture at Nottingham Meeting of the British Assoc. 1866):

1. All the brighter stars, at least, have a structure analogous to that of the sun.
2. The stars contain material elements common to the earth and sun.
3. The colours of the stars have their origin in the chemical constitution of the atmospheres which surround them.

4. The changes in brightness of some of the variable stars are attended with changes in the lines of absorption of their spectra.

5. The phenomena of the star in Corona appear to show that in this object at least, great physical changes are in operation.

6. There exist in the heavens *true nebulæ*. These objects consist of luminous gas.

7. The material of comets is very similar to the matter of gaseous nebulæ, and may be identical with it.

8. The bright points of the star-clusters may not be in all cases stars of the same order as the separate bright stars. H. E. R.

SPECULAR IRON. Syn. with red hæmatite, or native ferric oxide (iii. 338, 339).

SPECULUM METAL. An alloy of tin and copper, with a small proportion of arsenic, sometimes also containing zinc. (See COPPER, ALLOYS OF, ii. 44.)

SPEISS. A mixture of the sulphides, arsenides, or antimonides of nickel, iron, and copper, which collects at the bottom of the pot when ores of cobalt or lead, containing sulphur and arsenic or antimony, are melted with fluxes. The term is applied chiefly to the nickeliferous product which is obtained in the preparation of smalt (p. 313), and used as a source of nickel.

SPELTER. A commercial name of zinc.

SPERMACETI. The fatty substance found in peculiar cavities in the head of the sperm-whale (*Physeter macrocephalus*), also of *Ph. Tursio* and others, and of the *Delphinus edentulus*, being kept in solution in the sperm-oil by the heat of the animal's body, and crystallising out after death. It is freed as much as possible from oil by filtration and by treatment with potash-ley, and then melted. The fused and solidified mass, constituting the spermaceti of commerce, is white, scaly, brittle, soft to the touch, of specific gravity 0·943 at 15° (0·843 at 50°, 0·824 at 81°, 0·813 at 94°, the specific gravity of water at 15° being taken as 1—Saussure); melting-point from 38° to 47°; neutral, inodorous, and nearly tasteless.

Spermaceti is also found in small quantity in the blubber of the *Balæna rostrata* (Scharling, J. pr. Chem. xliii. 257), and, with but slightly different properties, in the oil of *Delphinus globiceps*. (Chevreul.)

When spermaceti is freed from adhering sperm-oil by means of cold alcohol, and the residue repeatedly crystallised from hot alcohol, the spermaceti-fat (or *cetin* of Chevreul) is obtained. This may be still further purified by crystallisation from boiling ether (i. 838).

SPERM-OIL. This oil occurs, together with spermaceti—from which it is separated by mechanical means—in the head of *Physeter macrocephalus*, &c.

When freed as completely as possible from admixed spermaceti-fat, by leaving the latter to crystallise out, it is neutral, remains liquid at 18°, is saponified with difficulty by potash, and yields by that process the same fatty acids as spermaceti-fat; but instead of ethal, a neutral product melting at 23° (Chevreul, *Recherches*, p. 237). Sperm-oil appears to be isomeric with spermaceti-fat or cetin (Stenhouse).—The oil which runs off from the spermaceti-fat solidifies almost completely at 0°, to a compact light-brown mass, in consequence of still retaining spermaceti-fat. When saponified it gives off ammonia, with traces of methylamine, and yields physetoleic acid (iv. 634), valerianic acid, small quantities of solid fatty acids, with a small quantity of glycerin. (Hofstädter.)

SPERMATIC FLUID. The sexual secretion of the male, supplied mainly by the *testes*, but receiving some of its constituents from other glands (*prostate*, &c.)—a ropy, whitish, neutral or faintly alkaline fluid, of a peculiar odour. It contains remarkable minute locomotive bodies called *spermatozoa* (the essential agents of fecundation), swimming, together with sperm-corpuscles, mucus-corpuscles, and epithelium-scales, in an albuminous medium. The spermatozoa, which are but very slowly affected by processes of decomposition, and whose movements are variously modified by saline solutions of various degrees of concentration, and by other chemical agents, are rich in protagon, and appear to be composed, in part at least, of some albuminoïd substance; but they offer great resistance to reagents, and lose their outlines only in warm concentrated solutions of caustic alkalis. The fluid in which they swim contains an albuminoïd matter, resembling to some extent both mucin and casein, to which the name of *spermatin* has been given. It is coagulated by alcohol, but not by heat; acetic acid produces a precipitate which is soluble in an excess of the reagent, but can be reprecipitated from the acid solution by ferrocyanide of potassium. Spermatin when dried becomes insoluble in water, but soluble in dilute alkalis, from which it may be precipitated by the addition of concentrated solutions of the alkaline carbonates.

Spermatic fluid is rich in salts, especially in earthy phosphates; crystals of triple phosphate very speedily appear in decomposing specimens. According to **Köllicker**, 100 parts of the spermatic fluid of the ox contain 17·94 solid matters, of which 15·3 are albuminoïd and extractives, 2·16 fat, and 2·637 salts. The secretion of the prostate of the dog contains, according to **Buxmann** (Henle und Meissner's Bericht, 1864, p. 286) 98·5 per cent. of water, 4·5 per cent., and nearly 1 per cent. of chloride of sodium, together with small quantities of sulphate and phosphate of potassium and calcium. M. F.

SPESSARTIN. Manganese garnet (ii. 772).

SPHÆRIA DEUSTA. This fungus yields (? air-dried) 6·5 per cent. of an alkaline ash, containing ferric oxide and a large quantity of silica. Moderately dilute hydrochloric acid extracts from the plant about half its fixed constituents, leaving a dark-brown or black residue, which withstands the action of all concentrated mineral acids (except nitric acid), imparts only a slight colour to boiling potash-ley, and yields (dried at 120°, and calculated upon the substance free from ash), 61·6 per cent. C, 4·0 H, 1·2 N, and 33·2 O. The fungus yields, by dry distillation, an acid fetid distillate. (A. and W. **Knop**, Pharm. Centr. 1851, p. 648.)

SPHÆROCOCCUS LICHENOÏDES. According to **Gonnermann** and **Ludwig** (Arch. Pharm. [2] cxi. 204), this alga (from Ceylon) contains in its cells true starch-grains, which are at first coloured yellowish by iodine, and turn blue only on warming.

SPHAGNUM. A club-moss which grows chiefly on peat-moors, and often plays an essential part in their formation. *Sph. acutifolium* contains, according to C. **Sprengel** (J. techn. Chem. xv. 32), 3·05 per cent. ash (*a*); according to **Vohl**, (Ann. Ch. Pharm. cix. 185), the same from a high moor in the Canton of Zurich contains 0·92 per cent. of ash (*b*); and *Sph. cuspidatum*, from Upper Bavaria, contains, according to **Wittstein** (Jahresb. 1862, p. 510), 2·014 per cent. ash, composed of—

	K^2O.	Na^2O.	CaO.	MgO.	Al^2O^3.	Fe^2O^3.	SO^3.	P^2O^5.	SiO^2.	CO^2.	Cl.	NaCl.	
Sph. acutifolium (*a*).	10·9	13·9	. .	5·8	3·4	7·0	4·0	. .	43·8	. .	11·2	. .	= 100
„ „ (*b*).	8·02	1·84	3·17	4·92	5·89	6·35*	4·33	1·06	41·69	. .	. .	19·92	= 97·19

SPHALERITE. Syn. with Blende. (See Zinc.)

SPHENE. A calcic silico-titanate, occurring in monoclinic crystals having the axis $a : b : c = 1·326 : 1 : 0·5678$; angle of inclined axes $(b, c) = 60° 27'$; $\infty P : \infty P = 113° 28'$; $oP : P\infty = 159° 34'$. Cleavage sometimes distinct, parallel to ∞P; less distinct, parallel to the orthodiagonal and to $- P$. The mineral sometimes also occurs massive, rarely lamellar. Hardness = 5—5·5. Specific gravity = 3·4—3·56. Lustre adamantine to resinous. Colour brown, grey, yellow, green, and black. Streak white, slightly reddish in greenovite. Transparent to opaque. Brittle. The yellow varieties do not alter in colour before the blowpipe; the others turn yellow; they all slightly intumesce, and fuse on the edges to a black enamel. With borax they yield a clear yellowish-green glass. The mineral is imperfectly soluble in hot hydrochloric acid, and, if the solution be concentrated in contact with tin, assumes a fine violet colour.

Analyses.—*a.* From the St. Gothard (**Cordier**, J. des Mines, No. lxxiii. 67).—*b.* Felberthal in the Pingzau (**Klaproth**, *Beiträge*, i. 245; v. 239).—*c.* Schwarzenstein in the Zillerthal: yellow-green; specific gravity = 3·535 (H. **Rose**, Gilb. Ann. lxxiii. 94; Pogg. Ann. lxii. 253).—*d.* Arendal: brown (**Rosales**, see H. **Rose**).—*e.* Passau: brown (**Brooks**, see H. **Rose**).—*f.* St. Marcel, Piedmont: *Greenovite* (**Delesse**, Ann. Min. [4], vi. 825).—*g.* The same (**Marignac**, Ann. Ch. Phys. [3], xiv. 47).—*h.* Frugard, Finland: black-brown; specific gravity = 3·45 (**Arppe**, Analyser af finsk. Min. p. 34).—*i.* Grenville, Canada: brown; specific gravity = 3·49—3·51 (**Hunt**, Sill. Am. J. [2], xv. 442):

* With trace of manganic oxide.

Most of these analyses may be nearly represented by the formula $\mathrm{Ca''O}\left\{\begin{matrix}\frac{1}{2}\ \mathrm{SiO^2}\\ \frac{1}{2}\ \mathrm{TiO^2}\end{matrix}\right. =$ $\mathrm{Ca''SiO^3.Ca''TiO^3}$, requiring 31·13 silica, 40·49 titanic oxide, and 28·38 lime. In the brown varieties of sphene the lime is partly replaced by ferrous oxide, in the mineral from Arendal to the amount of one-seventh.

The species was formerly divided into sphene and titanite, the former including the lighter-coloured, the latter the brown and black varieties. The name sphene is derived from σφὴν, a wedge, alluding to the usual form of the crystals.—*Greenovite*, from St. Marcel, was shown to be identical in crystalline form with sphene by Breithaupt (Pogg. Ann. lviii. 257) and Descloizeaux (Ann. Ch. Phys. [3], xx. 84).—*Ligurite*, from a talcose rock in the Apennines, has, according to Dufrenoy, the angles and characters of sphene.

Sphene occurs in imbedded crystals, in gneiss, granite, mica-slate, and granular limestone; also in beds of iron-ore, in syenite, as at Strontian in Argyleshire, and in volcanic rocks, as at Lake Laach, and Andernach on the Rhine. (Dana, ii. 269.)

SPHENOCLASE. A mineral occurring in parallel layers of various thickness in a bluish granular limestone at Gjellebäck in Norway. It is of a pale greyish-yellow colour, translucent on the edges, has a splintery fracture, and often breaks into wedge-shaped fragments when struck. Specific gravity = 3·2. Hardness nearly equal to that of orthoclase. Fusible. Gives by analysis:

$\mathrm{SiO^2}$.	$\mathrm{Al^2O^3}$.	$\mathrm{Fe^2O^3}$	CaO.	MgO.	MnO.
46·08	13·04	4·77	26·50	6·25	3·23

leading to the formula $\mathrm{3(4M''O.3SiO^2).(2R^2O^3.3SiO^2)}$. (Von Kobell, J. pr. Chem. xci. 344.)

SPHENOMITE. Shepard's name for a peculiar mineral resembling sphene, which he supposes to exist in certain meteorites.

SPHEROÏDAL STATE. See HEAT (iii. 88).

SPHEROSIDERITE. A variety of native ferrous carbonate, occurring in greenstone at Hanhau, Steinheim, Dransberg, and other places.

SPHEROSTILBITE. See STILBITE.

SPHERULITE. *Kidneystone.* These names are applied to certain spherical granules occurring imbedded in pitchstone and pearlstone. They are of grey, yellow, or red colour, with little or no lustre, translucent or opaque, and have a splintery fracture; hardness = 7: specific gravity = 2·4 to 2·5. Analysis by Erdmann (J. techn. Chem. xv. 32), 77·20 per cent. $\mathrm{SiO^2}$, 12·47 $\mathrm{Al^2O^3}$, 2·27 $\mathrm{Fe^2O^3}$, 3·34 CaO, 0·73 MgO, 4·27 $\mathrm{Na^2O}$ and $\mathrm{K^2O}$ (= 100·28).

SPIDER. Spider-threads appear to consist essentially of the same substance as silk and gossamer-threads, viz. sericin (p. 235).—The excrements of the spider contain guanine. (Handw. d. Chem. viii. 99.)

SPIGELIA. A genus of plants belonging to the gentianaceous order. *Sp. anthelmintica*, a South American annual, contains, according to Feneulle (J. Pharm. ix. 197), in the leaves, together with fixed oil, and in the root together with volatile oil, an amorphous, very bitter, nauseous substance, soluble in water and in alcohol, to which he attributes the anthelmintic action. Ricord-Madiana (Brandes, Archiv. xxv. 28), on the other hand, did not find any such substance.

SPIKE-OIL. *Oleum spicæ.*—A volatile oil, obtained by distilling *Lavandula Spica* with water. It has a less agreeable odour than true lavender-oil, is specifically heavier, and is said to deposit a larger quantity of camphor. According to Gastell, spike-oil is obtained from the leaves and stalks, true lavender-oil from the flowers, of several species of *Lavandula*. Spike-oil is frequently adulterated with oil of turpentine, which may be detected by its smaller solubility in alcohol. According to Gastell, pure spike-oil does not require more than 5 pts. alcohol, of specific gravity 0·894, to dissolve it.

SPILANTHES OLERACEA. An annual synantherous plant, indigenous in India and in South America. It has a sharp taste, apparently due to the presence of a volatile oil. The alcoholic tincture of the leaves and flowers is known as Paraguay red.

Spilanthes tinctoria contains a substance which yields indigo on exposure to the air.

SPINACH. *Spinacia oleracea.*—The leaves of this well-known culinary herb, belonging to the chenopodiaceous order, contain, according to Braconnot, acid oxalates, malates, and phosphates. Richardson (Jahresb. 1847, p. 1074) found in the air-dried plant 2·03 per cent. ash; and Saalmüller (Ann. Ch. Pharm. lviii. 389) found in the plant, dried at 100°, 10·7 per cent. ash, containing:

K^2O.	Na^2O.	CaO.	MgO.	SO^3.	SiO^2.	P^2O^5.	$Fe'''PO^4$.	$NaCl$.	Fe^2O^3.	
9·7	35·0	13·1	5·3	9·3	3·1	7·9	8·7	7·9	. .	Richardson.
23·4	24·6	10·6	7·5	4·4	5·9	8·6	. .	12·8	2·1	Saalmüller.

SPINDLE-TREE. *Euonymus europæus.* A celastraceous tree, the light wood of which yields good charcoal for gunpowder. The red seed-capsules have a saline taste, and contain grape-sugar, cerin, tannin, resins, citric acid, &c. The orange-coloured seed-coating contains a fat oil, which dissolves out the colouring-matter when expressed.

The rose-coloured shell of the seed contains tannic acid, gum, mineral constituents, &c.; the kernels contain 3·9 per cent. resin and 28·1 fat oil, together with emulsin, sugar, &c.

SPINDLE-TREE OIL. The fatty oil expressed from the seeds of the spindle-tree is clear, viscid, red-brown, yellow in thin layers, has a repulsive odour, and a bitter taste, with irritating after-taste. Specific gravity = 0·938. It is sparingly soluble in alcohol, easily in ether. It solidifies between 12° and 16°, a considerable portion of the colouring-matter separating out with the fat, and remaining, if the oil is carefully melted, in beautiful red granules on the sides of the vessel.

The oil contains, in addition to the colouring-matter, a bitter resin called by Riederer (Buchner's Repert. [2], xliv. 1) *spindle-tree bitter* or *euonymin*; also volatile acids. By the saponification of the fat-oil, Schweizer (J. pr. Chem. liii. 437) obtained oleic and margaric, together with acetic and benzoic acids, the last two remaining in the under-ley after the saponification of the oil.

Spindle-tree oil is prepared chiefly in Switzerland, where it is used for burning in lamps, and for destroying vermin in the hair of men and animals, also as an application to wounds.

SPINEL. *Spinelle*, including *Ceylanite* or *Pleonaste*, *Spinelle Ruby*, *Balas Ruby*, *Almandine Ruby*, *Candite*, *Gahnite* or *Automolite*, *Dysluite*, *Hercinite*, *Kreittonite*, *Chlorospinel.*—A mineral species represented by the general formula $M''O.\bar{R}^2O^3$, in which M'' = Mg, Fe, Ca, Zn, and Mn; and $\bar{R}'''$ = Al or Fe. The crystalline form is monometric, generally the cube, rhombic dodecahedron, and intermediate forms, also with cubic faces (CRYSTALLOGRAPHY, *figs*. 172, 174, 175, 176, 178, 199, 200.) Cleavage octahedral. Twins like *fig*. 319 (ii. 160).

Hardness = 8. Specific gravity = 3·5—4·9. Lustre vitreous. Colour red, especially carmine-red; also bluish-red to blue, brown, or yellow; pure magnesic aluminate, $MgAl^2O^4$, is colourless. Transparent to nearly opaque. Fracture conchoïdal, brittle. Infusible before the blowpipe. Insoluble in acids, but becomes completely soluble after fusion with acid potassic sulphate. Gives with fluxes the reactions of iron, and occasionally of chromium.

The name *spinel* is restricted by Rammelsberg and others to the varieties consisting of nearly pure magnesic aluminate, and having only a small proportion of the magnesia replaced by ferrous oxide; while those in which the proportion of iron is larger are regarded as forming a distinct species, called *Ceylanite*, *Pleonaste*, *Candite*, or *Chrysomelane*: they all, however, crystallise in the same forms, and the gradations of chemical composition are not very sharply defined.

Pure magnesian spinel, $MgO.Al^2O^3$, would contain 71·97 per cent. aluminium and 28·03 magnesia. Red (precious) spinel from Ceylon contains, according to Abich's analysis (corrected by Rammelsberg), 70·43 alumina, 1·12 chromic oxide, 26·75 magnesia, and 0·73 ferrous oxide; blue spinel from Aker in Sweden contains, according to the same authority, 70·53 alumina, 26·31 magnesia, and 3·57 ferrous oxide. Precious spinel is distinguished by several names, according to its colour, the deep red variety being called *ruby spinel*, the pale red *balas ruby*, the brownish-red (from its resemblance to some garnets) *almandine ruby*, and the yellowish-red *rubicelle*.

The following are analyses of the more ferruginous varieties, ceylanite or pleonaste (*Rammelsberg's Mineralchemie*, p. 162):

A. *Containing all the iron as ferrous oxide.*—*a.* Härmala in Finland (Thoreld).—*b.* Barsowskoi, near Kyschtimsk in the Ural (Abich).—*c.* Tunaberg in Sweden: dark-green (A. Erdmann).—*d.* Ronsperg in Bohemia, *Hercinite* (Quadrat).

B. *Containing ferric as well as ferrous oxide.*—*a.* Vesuvius (Abich).—*b.* Franklin, New Jersey: large greenish-black octahedrons, accompanied by red zinc-ore and calcspar (Vogel).—*c.* Stulgrabe, near Arendal in Norway (Scheerer).—*d.* Ceylon (C. Gmelin).—*e.* Iserwiese in the Riesengebirge (Abich):

	A.				B.				
	a.	*b.*	*c.*	*d.*	*a.*	*b.*	*c.*	*d.*	*e.*
Alumina	67·90	66·95	62·95	61·17	68·31	67·01	58·12	59·00	61·30
Ferric oxide	. .	. .	. .	. .	3·37	2·47	11·41	10·54	7·09

Magnesia	19·00	18·03	13·03	2·92	26·26	21·97	18·59	18·60	18·19
Zinc-oxide	1·38								
	100·16	99·31	99·44	99·76	100·00	100·00	100·00	100·00	100·00

Gahnite or *Automolite*, from Fahlun in Sweden, is a spinel in which the magnesium is wholly or in great part replaced by zinc (ii. 757).

Kreittonite is a black spinel, of specific gravity 4·49, nearly allied to gahnite, and containing, according to v. Kobell, 49·62 per cent. Al^2O^3, 18·48 Fe^2O^3, 26·67 ZnO, 3·40 MgO, and 1·44 MnO (= 99·61).

Dysluite (ii. 360) from Sterling, New Jersey, is a ferrico-aluminate of zinc and manganese, containing 30·49 per cent. Al^2O^3, 41·93 Fe^2O^3, 16·80 ZnO, 7·60 MnO, 2·96 silica, and 0·40 water. (Thomson.)

Chlorospinel is a grass-green spinel from Slatoust, of specific gravity 3·591—3·594, containing, according to H. Rose:

Al^2O^3.	Fe^2O^3.	MgO.	CuO.	CaO.		
64·13	8·70	26·77	0·27	0·27	=	100·14
57·34	14·77	27·49	0·62	. .	=	100·22

Spinel occurs imbedded in granular limestone, and with calcareous spar in serpentine and gneiss; it also occupies the cavities of volcanic rocks. In Ceylon, Siam, and other Eastern countries, it occurs of beautiful colours, as rolled pebbles in the channels of rivers.

SPINELLANE. A blue variety of nosean (iv. 135).

SPINTHENE. Syn. with SPHENE (p. 398).

SPIRÆA ULMARIA. *Meadow-sweet.*—The flowers of this rosaceous plant yield by distillation with water, a volatile oil consisting for the most part of salicylol (p. 167), which however appears not to exist ready-formed in the plant, but to be produced by the action of water; it contains also a neutral oil (likewise obtained by agitating the distilled water with ether), composed of 71·2 per cent. carbon, 10·1 hydrogen, and 18·7 oxygen, and a camphoroïdal substance, which crystallises in white nacreous scales, and remains solid at ordinary temperatures.

When the dried flowers of meadow-sweet are exhausted with ether, a colouring-matter called spiræin is dissolved out, together with fat, wax, traces of a neutral volatile oil, and a volatile acid, but no salicylol. The volatile oil is the same that is obtained, together with salicylol, by distilling the flowers with water. The volatile acid just mentioned is found also in the watery distillate; it crystallises in colourless needles, dissolves easily in water, with difficulty in ether, and colours ferric salts red. (Handw. d. Chem. viii. 100.)

SPIRÆIN. (Löwig and Weidmann, J. pr. Chem. xix. 236.)—The yellow colouring-matter of the flowers of *Spiræa ulmaria*, whence it may be extracted by ether. The ethereal solution is precipitated by water, the precipitate is dissolved in hot alcohol, which on cooling deposits a quantity of fatty matter; the filtered liquid is evaporated; and the spiræin thereby deposited is dissolved several times in alcohol.

Spiræin thus obtained is a yellow crystalline powder, insoluble in water, very soluble in ether and in alcohol; the solutions are of a deep green colour when concentrated, yellow when dilute, and redden litmus slightly. Spiræin is not volatile without decomposition. It gave by analysis 59·62—59·94 per cent. carbon and 5·32—5·14 hydrogen, whence Löwig and Weidmann deduce the formula $C^{30}H^{30}O^{14}$, requiring 58·6 C, 4·9 H, and 36·5 O. Gerhardt suggested $C^{21}H^{24}O^{10}$, which however does not agree so well with the analysis.

Hot concentrated *nitric acid* dissolves spiræin, forming a red solution, and decomposes it only after prolonged boiling, but without formation of oxalic acid. It dissolves without alteration in *sulphuric acid*, and is precipitated therefrom by water. Hydrochloric acid has no action upon it.—With *bromine* it forms a red mass, consisting of several substitution-products.—When oxidised by *chromic acid*, it yields formic and carbonic acids.—It dissolves with yellow colour in caustic *alkalis*, decomposes *potassic carbonate* when heated, and is precipitated from its alkaline solutions by acids. The same solutions turn brown and decompose on exposure to the air.

The alcoholic solution of spiræin forms yellow precipitates with *baryta-water*, *sulphate of aluminium*, and *tartar-emetic*; with *acetate of lead* a crimson precipitate, which blackens on drying; with *ferrous salts* a dark-green, with *ferric salts* a black precipitate; with *zinc-salts* mixed with a little ammonia, a yellow precipitate soluble in excess of ammonia; with *cupric salts* a grass-green precipitate; with *nitrate of silver* on addition of ammonia, a black precipitate insoluble in ammonia; with *mercurous nitrate* a yellowish-brown precipitate which soon becomes dark-brown; no precipitate with mercuric or platinic chloride.

---

* With manganous oxide.

SPIRIT. *Spiritus.*—The word spirit was used in old chemical language as a generic name for liquids obtained by distillation. At the present day it is applied in ordinary language chiefly to ethylic alcohol, which is called *spirit of wine*, and methylic alcohol, which is also called *wood-spirit*. In pharmaceutical language it is still used as a generic name for aromatic alcoholic distillates and certain alcoholic solutions—e.g., *Spiritus cochleariæ, Sp. lavandulæ, Sp. camphoratus, Sp. saponatus.*

Spiritus abstractus, Sp. aromaticus.—These names, especially the latter, are applied to odoriferous products obtained by distilling various substances with moderately strong aqueous alcohol; they are further distinguished as *Spiritus aromaticus simplex*, and *compositus.*

Spiritus aceti dulcificatus, s. *Sp. dulcis* } or *Liquor anodinus vegetabilis.* A solution
Spiritus acetico-æthereus } of acetic ether in alcohol.

Spiritus Aeruginis, s. *Sp. Veneris, Spirit of Verdigris.*—An old name of the concentrated acetic acid obtained by distilling crystallised cupric acetate (i. 10).

Spiritus aromaticus, s. *Sp. abstractus.*

Spiritus Ceræ, Spirit of Wax.—The watery liquid containing empyreumatic oils, acetic acid, &c., obtained by the dry distillation of wax.

Spiritus Cornu Cervi, Spirit of Hartshorn.—The solution of impure ammonium-carbonate obtained by the distillation of animal matters (i. 190).

Spiritus Mindereri.—An aqueous solution of ammonium-acetate (i. 13).

Spiritus muriatico-æthereus, s. *Spiritus Salis dulcis, Sweet Spirit of Salt, Heavy Hydrochloric Ether.*—The product obtained by saturating alcohol with hydrochloric acid and distilling it over peroxide of manganese, or by distilling a mixture of alcohol and sulphuric acid over a mixture of common salt and peroxide of manganese (ii. 532).

Spiritus muriaticus.—Hydrochloric acid.

Spiritus nitro-acidus.—Nitric acid.

Spiritus nitro-æthereus, s. *Sp. dulcis, Sweet Spirit of Nitre.*—(See NITROUS ETHERS, iv. 76.)

Spiritus rector.—Boerhave supposed that volatile oils were compounds of resins, with a peculiar odoriferous substance which he called by this name.

Spiritus Sali ammoniacus, Salmiakgeist.—Aqueous ammonia.

Spiritus Salis dulcis.—See *Spiritus muriatico-æthereus.*

Spiritus Salis fumans, or *Sp. Salis fumans Glauberi.*—Fuming hydrochloric acid.

Spiritus sulphurico-æthereus.—Common ether containing alcohol.

Spiritus Sulphuris per campanam.—Obsolete name for aqueous sulphurous acid.

Spiritus Sulphuris, s. *Sp. sulphuratus volatile Beguini.*—A solution of various polysulphides of ammonium, strong enough to fume in the air (i. 194).

Spiritus sylvestris, Gas sylvestre.—An old name of carbonic anhydride.

Spiritus Tartari, Liquor pyrotartaricus.—An old name for the brownish empyreumatic liquid, containing empyreumatic oils, pyrotartaric acid, acetic acid, and (according to Göbel) formic acid, obtained by dry distillation of tartar.

Spiritus Veneris.—See *Spiritus Aeruginis.*

Spiritus Vini, Spirit of Wine.—Aqueous alcohol.

Spiritus Vitrioli.—Dilute sulphuric acid.

Spiritus Vitrioli coagulabilis.—An old name of potassic sulphate.

SPIROGYRA QUININA. A fresh-water alga, which contains 97·5 parts water to 2·5 dry substance, the latter containing 7·5 per cent. nitrogen and 0·8 ash. The ash yields 35·8 per cent. carbonates and sulphates of the alkali-metals and chloride of sodium, 1·5 carbonate of calcium, 9·8 carbonate of magnesium, 18·4 phosphate of calcium, 3·4 phosphate of magnesium, and 31·6 silica, with traces of ferric oxide. (Handw. d. Chem. viii. 150.)

SPIROL. A name applied to phenylic alcohol, because it may be obtained from spiroylic (salicylic) acid, in the same way as benzol from benzoic acid.

SPIROYL. Löwig's name for the radicle $C^7H^5O^2$ (more generally called *salicyl*, or *salicosyl*), which may be supposed to exist in oil of spiræa (salicylol). (See pp. 150, 167.)

SPIROYLIC ACID. Syn. with SALICYLIC ACID.

SPIROYLOUS ACID. Syn. with SALICYLOL.

SPIRYL, SPIRYLIC ACID, &c. Names given by Berzelius to Salicyl, Salicylic acid, &c.

SPLEEN. The largest of the "vascular" or "ductless glands" of the body. Besides albuminoïd matters (among them one precipitable by acetic acid, and containing much iron, possibly as phosphate), pigments, fats, and cholesterin, there have been found in the spleen, formic, acetic, butyric, lactic, succinic, and uric acids (the juice of spleen is acid), inosite, sarcine, xanthine, leucine, and tyrosine. In 100 parts of spleen are found water 74·031, organic matter 24·866, inorganic matters 1·103. The following table (from Ludwig) gives the percentage composition of the ashes of spleen, according to Oidtmann:

	Cl.	P^2O^5.	SO^3.	SiO^2.	K^2O.	Na^2O.	CaO.	MgO.	Fe^2O^3.	MnO.	CuO.	PbO.
Man	·55	27·11	2·54	·07	9·19	43·30	7·50	·39	7·27	·08	·01	
Woman	1·31	18·87	1·43	·72	17·41	35·12	7·26	1·02	16·20	·04	·40	·03
Infant	33·03	9·53	·50	·95	43·87		3·35	·20				

SPLINT-COAL. A hard kind of coal having a brown-black to deep black colour, resinous lustre, splintery cross-fracture, and uneven principal fracture: it is less easily inflammable than caking coal, but, when once set on fire, burns with a bright flame and great evolution of heat.

SPODUMENE. *Triphane. Swedish Zeolite.*—A silicate of aluminium and lithium (potassium and sodium), occurring in monoclinic prisms, isomorphous with augite, especially with diopside. Angle of inclined axes = 69° 40′; $\infty P : \infty P = 87°$; $oP : [2P\infty] = 130° 30'$. The crystals are usually large, exhibiting very perfect cleavage parallel to $\infty P \infty$; distinct also parallel to ∞P; in traces parallel to $[P\infty]$; seen in striæ on $[\infty P\infty]$. Twins occur with face of composition parallel to $\infty P\infty$. The mineral also occurs in cleavable masses.

Hardness = 6·5 to 7. Specific gravity = 3·132—3·137 (Rammelsberg). Lustre pearly, vitreous on the cross-fracture. Colour greyish-green, passing into greenish-white and greyish-white, rarely faintly reddish. Streak uncoloured. Translucent to subtranslucent. Fracture uneven. Before the blowpipe it loses its transparency and colour, intumesces, and melts to a glass globule; gives the reactions of lithia.

Analyses (Rammelsberg's *Mineralchemie*, p. 500).—1. Island of Utö, Südermanland, Sweden. Specific gravity = 3·133 (Rammelsberg).—2. Sterzing in the Tyrol: specific gravity = 3·137 (R.).—3. Sterling, Massachusetts; specific gravity = 3·182 (Brush); 3·073 (R.).—4. Norwich, Massachusetts: specific gravity = 3·18 (Brush):

The analyses by Hagen and Rammelsberg lead to the formula $3(Li^2O.SiO^2).4(Al^2O^3.3SiO^2)$, the lithia being partly replaced by potash and soda. A pure lithia-spodumene thus composed would contain 64·98 per cent. silica, 28·88 alumina, and 6·14 lithia. The North American specimens, except the last, had undergone some decomposition.

Spodumene occurs also at Lisens in the Tyrol, at Killiney Bay near Dublin, and at Peterhead in Scotland; also at Goshen and other localities in Massachusetts, at Windham in Maine, and Brookfield in Connecticut.

SPONGE. Sponges are organisms living in water, and consisting of a soft gelatinous mass, mostly supported by an internal skeleton composed of reticular anastomosing hairy fibres, in or among which are usually imbedded calcareous or sometimes silicious spiculæ. They are found adhering to rocks, chiefly in the Mediterranean, where they are collected by divers, and treated with hydrochloric acid to remove the lime. Two or three species are found in fresh water.

Sponge has, by some naturalists, been referred to the vegetable, by others to the animal kingdom; of late years, however, the evidence has appeared to be conclusive as to its animal nature.

The organic matter of sponges was formerly regarded as identical with horny tissue, till Posselt (Ann. Ch. Pharm. xlv. 192) and Crookewit (*ibid.* xlviii. 43) showed that it exhibits, in many respects, the same characters as the fibroïn of silk and of gossamer-threads. Städeler, however (*ibid.* cxi. 12), has shown that the organic matter of silk, when treated with sulphuric acid, yields leucine and tyrosine, whereas that of sponge yields leucine and glycocine, without a trace of tyrosine: he accordingly designates the organic matter of sponges as spongin, restricting the name fibroïn to that of silk and gossamer-threads. Schlossberger, on the other hand, designates the former as fibroïn, the latter as sericin. In some sponges, the fibroïn is combined with iodine, sulphur, and phosphorus.

Charred or burnt sponge, *Spongia usta*, has long been used in medicine; its action is, doubtless, to be attributed to the iodine which it contains. Herberger found in it 1·16 per cent. potassium-iodide, 0·702 potassium-bromide, and traces of cupric oxide. Preuss found 2·14 per cent. KI, and 0·76 NaBr. In preparing burnt sponge, care must be taken not to employ too high a temperature, as a loss of iodine may thereby be occasioned.

SPONGIN. Städeler's name for the organic matter of sponge. He prepares it by exhausting the sponge, cut up into small pieces, with dilute hydrochloric acid, then with weak soda-ley, washing it thoroughly, and drying.

SPRAT. *Clupea Sprattus*; Fr. *Espret*; Ital. *Sardino.*—These fishes, when pressed and dried, contain, in 100 parts, 64 parts water, 19 fat, and 1·94 nitrogen, equivalent to 12·3 per cent. albuminoïdal substance. They yield 2·1 per cent. ash, containing, according to Way (Jahresb. 1849, p. 658):

K^2O.	Na^2O.	CaO.	MgO.	Fe^2O^3.	SO^3.	SiO^2.	P^2O^5.	KCl.	NaCl.		
17·2	1·2	23·6	3·0	0·3	trace	trace	43·5	. .	11·2	=	100
21·9	. .	27·2	3·4	0·6	1·4	0·3	40·5	2·3	2·3	=	100

Sprats are caught in large quantities on the coasts of Sussex, Kent, and Essex, and are there used for the preparation of artificial manure.

SQUALUS. The liver of the Basking Shark, *Squalus maximus* (Linn.), yields about 80 per cent. of oil, which has a faint yellow colour, a density of 0·870 to 9·876, and a repulsive odour; does not solidify at a few degrees below 0°. By dry distillation it yields a yellow oil having the odour of acrolein, but no sebacic acid. It appears to contain a peculiar oleic acid. (Ronalds, Chem. Gaz. 1852, p. 420.)

STALAGMITES and **STALACTITES.** Deposits formed in caverns, chiefly in limestone rocks, by water filtering through the rock and taking up some of its substance, and subsequently dripping from the roof. The solution (of calcic carbonate, for instance), on exposure to the air, deposits the solid matter, which partly forms stalactites, depending from the roof like icicles, partly deposits called stalagmites, on the floor of the cavern.

STALAGMOMETER (*σταλαγμός*, drop; *μετρεῖν*, measure). An instrument employed by Guthrie for measuring the size of drops. A drop is defined as a more or less spherical mass of liquid matter, which has been separated from other matter by gravitation. Such a definition is necessary, because the term "drop" is frequently applied to a variety of liquid matters, having little or nothing in common, except shape, either as to origin or condition.

The substances concerned in drop-formation are—1. The substance to which the drop clings; 2. The substance of which it is formed; 3. The medium in which it is formed. If the drop be formed in a liquid medium more dense than the drop, the drop rises. If the dropping fluid be a gas, and the medium a liquid, the drop becomes a bubble. Hence there is no essential difference between the formation of a drop and that of a bubble; there is also an agreement in the laws which govern the sizes of the two.

The factors which are found experimentally to be most concerned in determining the size of a drop in the case of a liquid dropping from a solid through a gas are:

1. The rate at which the dropping takes place, or the growth-time, *gt*, of the drop.—2. The quantity and chemical nature of the solid matter which the dropping liquid holds in solution.—3. The chemical nature of the dropping liquid.—4. The size and shape of the solid at the part from which the drop falls.—5. The chemical nature of the solid from which the drop falls.—6. The temperature at which the dropping takes place.

In the case of a liquid dropping through a liquid, the additional factors are—7, the chemical nature, and 8, the density of the liquid medium.

The stalagmometer consists of two parts: the first to produce a perfectly uniform flow of the dropping liquid; the second to collect, and either measure or weigh, a given number of drops formed under various conditions. For particulars of the experiments and description of the different forms of stalagmometer, see Proc. Roy. Soc. (xiii. 444, 457; xiv. 22).

The following are the main laws which have been deduced:

A. *When, from a solid, a liquid drops through a gas.*

1. The drop-size depends upon the rate of dropping. Generally, the quicker the succession of the drops, the greater is the drop. The slower the rate, the more strictly is this the case. *Example:*

$$\frac{\text{Drop-size of cocoanut-oil, } gt = 0\cdot5''}{\text{Drop-size of cocoanut-oil, } gt = 12\cdot0''} = \frac{80\cdot17}{52\cdot00}$$

2. The drop-size depends upon the nature and quantity of the solid which the dropping liquid holds in solution. If the liquid stands in no direct chemical relation to the solid, the drop-size, in general, diminishes as the quantity of solid contained in the liquid increases.

3. The drop-size depends upon the chemical nature of the dropping liquid, and little or not at all upon its density; or, rather, increase of density implies increase of cohesion. Of all the liquids examined, water has the greatest and acetic hydrate the smallest drops. Water = 148·2. Glycerin = 102·8. Butyric acid = 58·0. Mercury = 57·9. Benzene = 55·2. Oil of turpentine = 50·1. Alcohol = 49·6. Acetic ether = 46·4. Acetic hydrate = 43·0.

4. The drop-size depends upon the geometric relation between the solid and liquid. If the solid be spherical, the largest drops fall from the largest spheres. The drops are largest which fall from a plane. Absolute difference in radius takes a greater effect upon the drops formed from smaller than upon those formed from larger spheres. Of circular horizontal planes, within certain limits towards the minimum size, the drop-size varies directly with the size of the plane. *Examples:*

Drop-size of water from sphere of radius		∞	=	26·5
„	„	113·1	=	24·8
„	„	47·2	=	22·6
„	„	10·0	=	14·3
„	„	7·1	=	12·8
Drop-size of water from disc of radius		5	=	16·3
„	„	4	=	14·9
„	„	3	=	9·6
„	„	2	=	7·3
„	„	1	=	4·1

5. The drop-size depends upon the chemical nature of the solid from which the drop falls, and little or not at all upon its density. Of all the solids examined, antimony delivers the least and tin the largest drops. *Example:*

Drop-size of water from		antimony	=	119·8
„	„	sulphur	=	120·2
„	„	cadmium	=	121·8
„	„	zinc	=	122·4
„	„	lead	=	122·6
„	„	phosphorus	=	122 7
„	„	bismuth	=	122·8
„	„	tin	=	124·2

6. The drop-size depends upon temperature. Generally, the higher the temperature the smaller the drop. *Example:*

Drop-size of water at		20·4° C.	=	132·6
„	„	30·6° C.	=	130·6
„	„	40 3° C.	=	129·8

B. *When, from a solid, a liquid drops through a liquid.*

7. The drop-size does not depend mainly upon the density of the medium, and consequent variation of the weight, in the medium, of the dropping liquid.

8. If there be two liquids, A and B, which drop under like conditions through air, and the drop-size of the one, A, be greater than that of the other, B, then, if a third liquid, C, be made to drop through A and through B, its drop-size through A will be greater than its drop-size through B.

9. If the drop-size of A through B be greater than the drop-size of A through C, then the drop-size of D through B will also be greater than the drop-size of D through C.

10. If a liquid, A, drop under like conditions in succession through two liquids, B and C, then its drop-size through any mixture of B and C is intermediate between its drop-size through B and its drop-size through C; and the greater the proportion of $\frac{B}{C}$ in the mixture, the more nearly does the drop-size of A through the mixture approach to the drop-size of A through $\frac{B}{C}$ alone.

11. The drop-size of any mixture of two liquids, A and B, dropping through a third liquid, C, is intermediate between the drop-size of A through C and that of B through C; and the greater the proportion of $\genfrac{}{}{0pt}{}{A}{B}$ in the mixture, the more nearly does the drop-size of the mixture approach to the drop-size of $\genfrac{}{}{0pt}{}{A}{B}$ alone, whether the dropping liquid be heavier or lighter than the liquid medium.

12. If the liquid X has a larger drop-size than the liquid Y in the liquid Z, then the liquid Z has a larger drop-size in X than it has in Y.

13. If a liquid X has a larger drop-size in air than a liquid Y, then the drop-size of X through Y is larger than the drop-size of Y through X.

14. If the drop-size of X be greater than the drop-size of Y in air, and the drop-size of Y greater than the drop-size of Z in air, then the ratio between the drop-sizes of X in any mixture of Y and Z, and the drop-size of that mixture of Y and Z through X, is greatest when the ratio between Y and Z is unity.

Laws 10 and 11 may be applied to quantitative analysis. Thus, a mixture of benzene and oil of turpentine causes water to assume a greater or less drop-size, according to the proportion of its constituents. It is easy by means of the stalagmometer to detect a difference of one per cent. in the proportion of either of the constituents.

The term "bubble" is also in common speech applied to a variety of dissimilar things. The definition adopted has been already given in speaking of drops.

In measuring the size of a drop, the barometric pressure is found to have little or no influence. In the case of bubbles it forms an important factor. Also the temperature is of greater influence with bubbles than with drops. The chief points of interest with regard to bubble-size are the influences of change in the chemical nature of the gas and of the liquid medium.

The chief results at present obtained with regard to bubble-size are these:—

15. Every different liquid causes the same gas which bubbles through it under the like conditions to assume a different bubble-size.

16. If the bubble-size of a gas through a liquid, A, be greater than its bubble-size through B, then its bubble-size through any mixture of A and B is intermediate between its bubble-size through A and its bubble-size through B.

This law is quite analogous to Law 10. Further, the singular connection between drops and bubbles is shown in the following law:—

17. If the liquid A has a larger drop-size than the liquid B in dropping through the gas C, then the gas C, in bubbling through the liquid A, has a larger bubble-size than in bubbling through the liquid B. F. G.

STANNAMYL. See Tin-radicles, Organic.

STANNATES. Salts of stannic acid. (See Tin, Oxides of.)

STANNETHYL. See Tin-radicles, Organic.

STANNIC ACID, STANNIC OXIDE. See Tin, Oxides of.

STANNIN. Syn. with Tin-Pyrites (*q.v.*).

STANNITES. Salts of stannous oxide (see Tin, Oxides of.)

STANN-METHYL. See Tin-radicles, Organic.

STANNOUS ACID, STANNOUS OXIDE. See Tin, Oxides of.

STANNUM. Syn. with Tin.

STANZAITE. Syn. with Andalusite (i. 291).

STAPELIA. A genus of apocynaceous plants, indigenous at the Cape of Good Hope. *Stapelia hirsuta*, after being scratched with a knife, yields a limpid gummy juice, which hardens to an amorphous mass on exposure to the air, and contains a bitter substance soluble in water, alcohol, and ether. (Bernap, Repert. Pharm. lxxxviii. 95.)

STAPHISAGRIC ACID. A peculiar acid, said by Hofschläger (Brandes Archiv. xix. 160) to exist in the seeds of *Delphinium Staphisagria.* It is described as white, crystalline, sublimable, and as exerting an emetic action; but the statements respecting it are very doubtful.

STAPHISAGRINE. An alkaloïd existing, according to Couerbe (Ann. Ch. Phys. [2], lii. 352), in the seeds of *Delphinium Staphisagria,* and constituting the matter insoluble in ether, obtained in the preparation of delphinine (ii. 310) from that plant. It is a slightly yellowish body, having a sharp taste, nearly insoluble in water and in ether, easily soluble in alcohol. It dissolves also in acids, but without neutralising them. It is decomposed by chlorine, and converted by hot nitric acid into a bitter resinous substance.

STAPHISAINE. Syn. with STAPHISAGRINE.

STAR-ANISE OIL. A volatile oil obtained from the seeds and seed-capsules of *Illicium anisatum*, a magnoliaceous tree indigenous in China and Japan. It has a pale-yellow colour, and resembles anise-oil from *Pimpinella Anisum* (i. 297) in taste and odour, but is more mobile, and remains liquid at + 2°. At lower temperatures it deposits a camphor or stearoptene identical with that of ordinary anise-oil. Star-anise oil likewise agrees with ordinary anise-oil in nearly all its reactions; but, according to Limpricht and Ritter, it is not directly converted by nitric acid into anisol and anisic acid, but yields an intermediate product which they designate as *anisoic acid* (i. 304).

STARCH. $C^6H^{10}O^5$ or $C^{12}H^{20}O^{10}$. *Fecula, Amidin, Amidon, Amylum, Matière amylacée. Stärke, Satzmehl, Kraftmehl.* (For a complete list of memoirs relating to Starch, down to 1862, see *Gmelin's Handbook*, xv. 72.)

This substance is very widely diffused in the vegetable kingdom, occurring in variable quantity, for a time at least, in every plant that has been examined. It is especially abundant in certain families of plants, and often occurs in very large quantity, especially in the albumen of the seed, in the cotyledons of the embryo, in the pith of stems and stalks, in bulbs, tubers, rhizomes, and roots; also in the bark and splint of trees in the winter season; sometimes in flowers.

Starch is formed in plants only when the nutriment is in excess, and is dissolved and used up at a later stage of the vegetative process, when the nutriment becomes deficient (Payen); it is probably formed from vegetable mucus (Schleiden). Before the starch appears in the cells, they are filled with a granular or a homogeneous mass, the development of which is slower than that of the cell; so that it spreads itself, in a layer of varying thickness, over the inner surface of the cell, enveloping the nucleus perhaps already present, and sometimes spreading in a thread-like form over its surface; the starch is most frequently formed in this protoplasma, more rarely on the surface or in the interior of the nucleus. (Trécul, Compt. rend. xlvii. 782.)

The following table exhibits the proportions of starch in various alimentary substances, as determined by Krocker (Ann. Ch. Pharm. lviii. 212):

Alimentary substance	Quantity of Starch in 100 pts. substance. I.	II.
Pure flour of Haricot-beans	99·96	
Wheat-flour, No. 1	65·21	66·16
„ No. 2	66·93	67·42
„ No. 3	57·70	57·21
Talavera wheat	55·92	56·29
Whittington „	53·06	51·84
Sandonier „	53·83	52·92
Rye-flour, No. 1	61·26	60·56

Preparation: 1. From *Wheat.*—Wheat, after being softened in cold water, is pressed under millstones or rollers, or in bags under water, as long as milky water runs off from it. This liquid, when left to itself, deposits starch containing gluten; the latter, however, dissolves for the most part in the supernatant liquid, which gradually turns sour: and on decanting this acid liquid, repeatedly stirring up the starch with fresh water, and leaving it to settle, it is at length obtained pure, and may be dried in suitable desiccating chambers. Or wheat-flour is mixed with four to five volumes of water, and $\frac{1}{8}$ to $\frac{1}{10}$ vol. sour water obtained from former operations: this sets up a fermentation, which lasts from two to four weeks, according to the temperature, and is interrupted as soon as the nitrogenised substances are decomposed and dissolved. The sediment of starch, which remains at the end of a fermentation, is repeatedly washed with water, sifted, and dried in desiccating chambers. Starch may be freed from gluten by means of cold dilute potash-ley (Kirchhoff), or distilled vinegar (Saussure); from pieces of fat and other matter, by prolonged treatment with cold water, alcohol, or ether.

2. From *Potatoes.*—Washed and rasped potatoes are drenched in a sieve with a continued stream of cold water, and the milky liquid which runs through is set aside for a few minutes, till the heavier impurities have settled down, and then left to stand for three or four hours in another pan. The starch which collects at the bottom of the clear liquid is stirred up with water, poured through hair-sieves, then left to settle, repeatedly washed with cold water, and dried, first on plates of gypsum, afterwards in desiccating chambers. The starch thus obtained is purified by successive washing with the following liquids:—1. Cold alcohol.—2. Water.—3. Water containing 0·002 per cent. hydrochloric acid.—4. Water.—5. Water containing 0·005 per cent. potash.—6. Water (Payen). After this treatment, the starch contains hydrochloric acid (Jacquelain, Gerhardt, *Traité*, ii. 486), but may be purified by boiling with alcohol containing 0·1 per cent. hydrate of potash, then washing with pure alcohol and with water.

3. From *the root-sprouts of Maranta indica and M. arundinacea:* American starch, Arrowroot.—Mode of preparation the same as from potatoes.

4. From *the roots of Janipha Manihot:* Tapioca.—The washed and bruised roots are pressed in bags under water; the starch which separates from the milky liquid is *mealy tapioca;* after drying upon hot plates, it becomes *granular tapioca;* the portion of the pulp which remains after washing and pressing is spread out on iron plates, in a layer one or two inches deep, and strongly dried into cakes; this is *Cassava-bread;* when pulverised it forms *Manjok flour*, and when again heated on iron plates till it swells up, *Mandiokka.* (Sureau, J. Pharm. xx. 622.)

5. From *the stems of several species of Sagus and Cycas:* Sago.—The starch is washed out of the pith of the stems on sieves in a stream of water, then left to settle, washed on cloths or mats, rubbed when half dry through metal sieves; and when thus granulated, it is dried at about 60° in ovens of peculiar construction.

6. From *Rice.*—Rice is heated with weak soda-ley, which dissolves the nitrogenous impurities, and leaves pure starch; then with a solution of borax, cream of tartar, or some other salts, to facilitate the separation of the starch from gluten.

7. From *Horse-chestnuts, &c.*—The same method as in 2, excepting that the starch is likewise well washed with aqueous sodic carbonate to remove the bitter principle (Flandin, Compt. rend. xxvii. 349); or merely with water, like potato-starch. (Belloc, *ibid.* xxviii. 83.)

For details on the manufacture of Starch, see Ure's *Dictionary of Arts, &c.*, iii. 745.

Properties.—Starch is a white shining powder, soft to the touch, grating between the fingers or the teeth, sometimes consisting of amorphous masses, but more frequently of granules recognisable by the microscope. These granules, of various diameter [from $\frac{1}{30}$ to $\frac{1}{800}$ of a line (Fritzsche), from ·185 to ·002 millimetre (Payen)], and various form, have commonly a small eccentric nucleus, surrounded by layers arranged concentrically one over the other. These envelopes increase by the successive deposition of new layers within the old ones, so that each layer is younger and less compactly aggregated than the one which immediately surrounds it; and since the layers are for the most part of variable thickness, they cause the granule to deviate gradually in form from the originally spherical nucleus, and assume for the most part an ovoid form. According to Maschke, the starch-granules appear like bundles of three to six concentric bladders, with light and dark rings, the light rings being formed of insoluble, the dark of soluble starch, and enclosing the central cavity of the innermost bladder, which is either empty, or filled with liquid amylone.

The following table exhibits the greatest diameter of several kinds of starch-granules, according to Payen:—

Starch from:	Millimetre.
Large Rohan potatoes	0·185
Menispermum fenestratum (colombo-root)	·180
Rhizomes of *Canna gigantea*	·175
„ „ *Canna discolor*	·150
„ „ *Maranta arundinacea* (arrowroot)	·140
Various kinds of potato	·140
Bulbs of the lily	·115
Tubers of *Oxalis crenata*	·100

Stem of a very large *Echinocactus erinaceus* (imported)	·075
Sago	·070
Broad beans	·075
Lentils	·067
Haricot-beans	·063
Peas	·050
Grain of white wheat	·050
Fresh pith of sago-tree (*Cycadeæ*)	·045
Hyacinth-bulbs	·045
Tubers of Spanish potato (*Batatas edulis*)	·045
Corms of *Orchis latifolia* and *O. bifolia*	·045
Maize (white, yellow, and violet)	·030
Fruit of Chinese sugarcane (*Sorghum saccharatum*)	·030
Stem of *Cactus peruvianus*	·030
Seeds of *Naïas major*	·030
Stem of *Cactus pereskia grandiflora*	·0225
Seeds of *Aponogeton distachyum*	·0225
Stem of *Ginkgo biloba* (*Salisburia adianthifolia*)	·022
" *Cactus brasiliensis*	·020
Fruit of *Panicum italicum*	·016
Half-grown seeds of *Naïas major*	·016
Pollen of *Globba nutans*	·015
Stem of *Cactus flagelliformis*	·015
" *Echinocactus erinaceus* (grown in hothouse)	·012
Pollen of *Rupia maritima*	·011
Stem of *Opuntia tuna* and *Ficus indica*	·010
" *Opuntia curassavica*	·010
Fruit of *Panicum miliaceum* (millet)	·010
Stem of *Cactus mammilaria discolor*	·008
Bark of *Aglanthus glandulosa*	·008
Stem of *Cactus serpentinus*	·0075
Parsneps	·0075
Pollen of *Naïas major*	·0075
Stem of *Cactus monstruosus*	·006
Seeds of beetroot	·004
" *Chenopodium Quinoa*	·002

The specific gravity of starch is 1·505 at 19·7° (Payen). When pure it is neutral, and has neither taste nor smell. It may be dried completely in a vacuum at 100°, but at ordinary temperatures it always retains a certain quantity of water (from 12 to 18 per cent.) mechanically interposed between the granules.

Starch heated to 160° is converted into dextrin (ii. 318); first, however, according to Maschke, into the soluble modification of starch mentioned below.

By dry distillation it yields carbonic anhydride, gaseous hydrocarbons, water, acetic acid, and empyreumatic oil, and leaves a porous cinder. In the open fire it softens, swells up, evolves choking vapours, and at last burns with a bright flame.

It is oxidised slowly by *oxygen*, more quickly by *ozonised air*, yielding but little carbonic anhydride. By distillation with *manganic peroxide* and *dilute sulphuric acid*, it yields carbonic anhydride, aqueous formic acid, and furfurol.

Starch, so long as it retains its natural state of aggregation, is insoluble in *water*, *alcohol*, and *ether*; but when it is placed in contact with *hot water*, the water penetrates between the different layers of which the granules are composed, swelling them up, and forming a gelatinous mass known as starch-paste, and used for stiffening linen, &c. If this paste be largely diluted with water, the swollen starch-granules slowly subside, whilst a certain quantity of amylaceous matter remains in solution.

When water into which one or two hundredths of starch has been introduced is heated to boiling, the grains swell, and disintegrate till they appear to be dissolved in the water; but on exposing the liquid to a temperature below 0°, the water freezes, and the starch, recovering a certain degree of aggregation, separates from the liquid in the form of small pellicles.

When starch is boiled under pressure at about 150°, with from 5 to 15 times its weight of water, a thin solution is obtained, which may be filtered from the insoluble portion; this liquid, as it cools, deposits minute spherical granules, which, when dried, have the whiteness of starch without its glistening aspect. These granules are slightly soluble in cold water, but are readily dissolved when the water is heated to 70° or upwards. This soluble starch, which is distinguished from dextrin (ii. 312) by being turned blue by iodine, and by possessing a greater dextro-rotatory power (=211° according to Béchamp, whereas that of dextrin is 176°), is likewise produced from common starch by the action of *diastase* at ordinary temperatures; by heating it for a certain time with *dilute sulphuric acid*; by heating with *glacial acetic acid* in a sealed tube, or with strong *nitric acid* till red vapours begin to pass off; by boiling with *chloride of zinc*; and by trituration for a short time in the cold with *strong sulphuric acid*. If, however, the action of the diastase takes place at a temperature of 65°—80° (it is completely interrupted by boiling), or if the heating with dilute acids be continued beyond a certain time, the starch is converted into dextrin, and ultimately into dextroglucose.

Starch is also converted into dextrin and sugar by boiling with aqueous *oxalic* or *dilute acetic acid*; by contact with *glutin* at a moderately high temperature, also by contact with *saliva*; into sugar also by contact with *beer-yeast*, and with various animal substances—viz., *pancreatic juice*, *gelatin*, *mucous membrane*, *urine*, *bile*, *spermatic fluid*, *blood-serum*, *animal tissue*, and by watery infusions prepared at 40° from the *heart*, *brain*, *lungs*, *liver*, *kidneys*, *spleen*, and *muscles*. (Gm. xv. 92.)

On the conversion of starch into dextrin and sugar, see also Musculus (Compt. rend. liv. 194; Ann. Ch. Phys. [3], lx. 203; Jahresb. 1860, p. 502; 1861, p. 717.)

Starch dissolves in *glycerin* when heated therewith for a considerable time, and is precipitated in the soluble modification by addition of alcohol to the solution. (W. Kabsch, Zeitschr. anal. Chem. ii. 216.)

Starch triturated in the cold with *oil of vitriol*, is converted successively into soluble starch, sulphamidonic acid, dextrin, and sugar.

With *nitric acid*, starch yields various products, according to the strength of the acid, the temperature, and the duration of the action:

a. Cold concentrated nitric acid (specific gravity = 1·52) dissolves starch without evolution of gas; water added to the solution precipitates xyloïdin or nitramidin, $C^6H^9(NO^2)O^5$, as a white powder (Braconnot, Pelouze). If water is added immediately, nothing remains dissolved; but if the solution is allowed to stand, it gives with water less and less xyloïdin, and at last none, while a substance resembling saccharic acid remains in solution. (Pelouze, Compt. rend. vii. 713.)

b. If starch is mixed with its own weight of concentrated nitric acid, and twice its weight of ordinary nitric acid ($2NHO^3.3H^2O$), and allowed to stand for 24 or 30 hours at the mean temperature, or if it is mixed with enough common nitric acid to form a thick mud, and heated in the water-bath until red fumes are evolved, unorganised insoluble starch is at first produced, then starch soluble in hot water, and lastly starch soluble in cold water (Béchamp).—Starch that has been moistened with $\frac{2}{10}$ per cent. nitric acid and water, and then allowed to dry spontaneously, yields dextrin when heated (Payen). A mixture of starch with 2 per cent. nitric acid and 4 per cent. water, dried at first in the air, afterwards in a water-bath, gives, with 5 parts of warm water, a solution which solidifies to a jelly like lichenin on cooling, and gives sugar when boiled with acids. (Mitscherlich, Pogg. Ann. lv. 121.)

c. Hot nitric acid, either concentrated or dilute, employed in excess, evolves nitrous gas and forms oxalic acid, together with malic and acetic acids.—*Nitric peroxide* acting on starch neither evolves gas nor produces oxalic acid. (Bouijs-Ballot, J. pr. Chem. xxxi. 211.)

A mixture of strong *nitric* and *sulphuric acids* converts starch into an explosive compound, analogous to or identical with gun-cotton (De Vrij, Compt. rend. xii. 126). According to Béchamp (Ann. Ch. Phys. [3], lxiv. 322), the product consists of nitroxyloïdin or dinitramidin, $C^6H^8(NO^2)^2O^5$.

Chlorine-gas, either dry or moist, does not act upon starch either at ordinary temperatures or at 100°; when starch is exposed under water to the action of chlorine for eight hours, only $\frac{1}{30}$ is decomposed, with evolution of carbonic anhydride (Liebig).—Starch distilled with *hydrochloric acid* and *manganic peroxide* yields, among other products, trichlorinated acetic aldehyde (chloral) and pentachlorinated propionic aldehyde.

When *bromine-water* is added to a solution of starch in dilute hydrochloric acid, an orange-yellow powder is formed, consisting of a compound of starch with bromine, which, however, cannot be dried without loss of bromine.

Starch-paste is coloured deep-blue by an aqueous solution of *iodine*, or by mixing it with solution of potassic iodide, and then adding a drop of chlorine-water, nitrous acid, sulphuric acid, &c., to set the iodine free. This blue coloration, which affords an extremely delicate test either for starch or for iodine, is due to the formation of a loose combination of starch and iodine, or perhaps to the mere mechanical precipitation of the iodine upon the starch, inasmuch as it is destroyed by alcohol, potash, sulphydric acid, and in general by all liquids which take up the iodine. The liquid may also be decolorised by ebullition, whereby the iodine is volatilised; if, however, the boiling be not continued for a sufficient time to volatilise the whole of the iodine, the blue colour reappears as the liquid cools. When potato-starch is powdered in a mortar with cold water, the filtered liquid is coloured blue by iodine; this effect is not observed with wheat-starch, the grains of which, being smaller, are not crushed under the pestle (Redwood, Repert. Pharm. [3], xxxix. 84). Respecting the various circumstances which affect and modify the blue colour, see *Gmelin's Handbook*, xv. 97.

Starch slowly absorbs *fluoride of boron*, becoming liquid, but without coloration.

Starch heated with five times its weight of *potassic hydrate* and a little water, gives off hydrogen at a temperature much below redness, and forms potassic oxalate (Gay-Lussac). By digestion with potash-ley for twelve hours, at 50° or 60°, it is converted into dextrin (Payen). *Soda* acts in like manner.

Starch-paste yields, with *baryta-* and *lime-water*, precipitates consisting of compounds called Amilate of barium or calcium. A dilute solution of starch, mixed with ammoniacal acetate of lead, yields a precipitate of plumbic amilate, $C^{12}H^{18}Pb''O^{10}.Pb''O$.

According to Blondeau (Compt. rend. lix. 403), starch unites with *ammonia*, forming the compound, $C^6H^{10}O^5.NH^3$ called amidia, which acts like a weak base, uniting with acids, but is not capable of decomposing metallic salts.

The aqueous solution of starch is precipitated by *tannic acid*.

Estimation and Separation of Starch.—The following method of estimating starch in vegetable organs, &c., given by Dragendorff (Jahresb. 1862, p. 631), depends upon the insolubility of starch in alcoholic potash, and its solubility in diastase and when heated with dilute acids. Two or three grains of the substance dried at 100°, and pulverised, are mixed with 25 to 30 grains of a solution of 5 to 6 pts. potassic hydrate in 94 to 96 pts. of absolute alcohol, and digested at 100° for 18 to 30 hours in a sealed tube (or a flask which can be closed airtight); and the contents are thrown, while still hot, on a weighed filter and thoroughly washed, first with hot absolute alcohol, then with cold spirit of ordinary strength, and finally with distilled water mixed (in the case of gummy substances) with a small quantity of alcohol. The filter, with its contents, is dried, first at 50°, then at 100°, and weighed. The difference between the weight thus obtained and that of the original substance gives the quantity of protein-substances, fat, sugar, and part of the salts present. The residue, together with the filter cut in pieces, is next heated with water containing 5 per cent. hydrochloric acid, till a sample is no longer turned blue by solution of iodine; and the residue separated from the acid liquid is washed, dried at 100°, and weighed. The loss of weight thus found gives very nearly the quantity of starch in the substance under examination. Any mineral substances insoluble in potash, alcohol, and water, but soluble in hydrochloric acid, that would introduce an error, may be estimated by evaporating the acid liquid to dryness, and incinerating the residue at as low a temperature as possible. This error may also be avoided by extracting the starch with concentrated extract of malt at 56°, instead of acidulated water. In the case of substances which contain a large quantity of mucus, it is best to perform the extraction with a concentrated solution of common salt slightly acidulated with hydrochloric acid, and wash the insoluble residue with weak spirit.

The residue left after the extraction of the starch contains cellulose, mucus, lignin, cuticula, and cork-substance, the last four of which may be separated from the cellulose by digestion with chlorate of potassium and dilute nitric acid.

Starch may also be estimated by converting it into glucose, and determining the quantity of that product. For this purpose Siegert (Jahresb. 1865, p. 743) digests one gramme of the air-dried substance (potatoes for instance) with 50 c.c. water and 2 grammes oil of vitriol on the water-bath for two hours; then dilutes to 100 c.c., and again warms 50 c.c. of the filtered liquid with 4 grammes of sulphuric acid to 95° for seven or eight hours. The sugar-solution thus obtained is then made up to 100 c.c. with water, or, if very much coloured, with basic acetate of lead, and the amount of sugar is determined with an alkaline cupric solution in the usual way (ii. 865).

Starch immersed in a saturated solution of *bromide* or *iodide of potassium* swells up to a pasty mass of 20 to 30 times its original volume, which dissolves in water, leaving only a very small quantity of membrane; and on adding iodine-water to the solution, the blue compound of starch and iodine is precipitated in flocks. As cellulose is not affected by bromide or iodide of potassium, these salts may be employed for detecting and separating starch in vegetable tissues. Dilute solutions act less strongly.

Animal Starch (?)—A substance, supposed to be starch, has been observed in certain parts of the animal body. Granules, which after being moistened with oil of vitriol turn blue on addition of iodine, occur in the brain, and formations of similar character occur in the spleen, liver, kidneys, and mucous membranes in certain states of disease, and in small quantity even in health. This substance, however, is not true starch, as it contains nitrogen, and does not yield sugar when heated with dilute acids.

Glycogen, the sugar-forming substance of the liver, has the same composition as starch (ii. 906).

STARS, SPECTRA OF. See SPECTRAL ANALYSIS (p. 394).

STASSFURTHITE. A borato-chloride of magnesium, occurring in the salt-beds of Stassfurth near Magdeburg, in masses having a microcrystalline structure: hardness = 4 to 5, and specific gravity = 2·913. Contains, according to the mean of recent analyses by Heintz and Ludwig, 8·20 per cent. chlorine, 2·77 magnesium, 26·24 magnesia, 60·82 boric anhydride, and 1·97 water, agreeing nearly with the formula $Mg''Cl^2.2(3Mg''O.4B^2O^3) + 4\,aq.$ (*Rammelsberg's Mineralchemie*, p. 256.)

STATICE. A genus of plumbaginaceous plants, growing in the neighbourhood of the sea or of salt-springs, and containing considerable quantities of common salt. 100 pts. of *Statice Gmelini*, air-dried, yield 7·7 per cent. ash, of which 11·5 per cent. are soluble in water, and 88·5 per cent. insoluble. *St. suffruticosa* yields 5·7 per cent. ash, of which 45·75 per cent. is soluble in water. The soluble portions of the two contain, in 100 pts.:

	K^2SO^4.	Na^2SO^4.	$NaCl$.	Na^2CO^3.	$NaHO$.
Statice Gmelini .	22·2	29·7	29·0	7·0	
Statice suffruticosa	18·4	24·8	46·0	2·7	·2

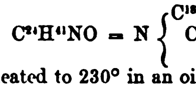
STAUROLITE. *Staurotide, Granatite, Croisette, Pierre de Croix, Schorl cruciforme grénatite.*—These names are applied to certain silicates of aluminium occurring in trimetric crystals, often forming cruciform groups, on the St. Gothard, in the Ural, and other localities. Staurolite from the St. Gothard has the composition $4Al^2O^3.3SiO^2$; that from Airolo, in Tessin, is $10Al^2O^3.9SiO^2$; that from Polewskoi, in the Ural, is $8Al^2O^3.9SiO^2$; that from Bretagne is $5Al^2O^3.6SiO^2$. (See SILICATES, p. 255; also Dana, ii. 261; Rammelsberg, p. 567.)

The name *staurolite* is also used as a synonym of harmotome.

STAUROSCOPE. An optical instrument, invented by F. v. Kobell, for examining the polarising structure of crystalline bodies. (Pogg. Ann. xcv. 320; J. pr. Chem. lxiv. 389.)

STAUROTIDE. Syn. with STAUROLITE.

STEARAMIDE. $C^{18}H^{37}NO = N\left\{\begin{matrix}C^{18}H^{35}O\\H^2\end{matrix}\right.$.—Obtained by heating ethylic stearate with alcoholic ammonia for 20 to 25 days in a sealed tube immersed in a salt-bath, and purified by recrystallisation from hot alcohol and repeated washing with cold ether. After melting it solidifies at 107·5°. (Carlet, Bull. Soc. Chim. [1859], i. 76.)



STEARANILIDE. *Phenyl-stearamide.* $C^{24}H^{41}NO = N\left\{\begin{matrix}C^{18}H^{35}O\\C^6H^5\\H\end{matrix}\right.$.—When an excess of aniline is distilled over stearic acid heated to 230° in an oil-bath, the whole of the stearic acid is converted into anilide. The product is purified by repeated crystallisation from alcohol:

$$C^{18}H^{36}O^2 + C^6H^7N = C^{24}H^{41}NO + H^2O.$$

It forms white, delicate, shining needles, melting at 93·6°, and solidifying to a mass of radiated crystals.—An alcoholic solution does not precipitate nitrate of silver.

STEARENE. See STEARONE.

STEARERIN. The fat contained in the wool of Merino sheep is, according to Chevreul (J. Pharm. xxvi. 123), a mixture of a more liquid fat, elaerin, and a more solid fat, stearerin. This latter melts at 60°, and dissolves only in 100 pts. alcohol of specific gravity 0·805, whereby it may be separated from the much more soluble elaerin. When treated with strong potash-ley, it yields a salt, stearerate of potassium, which is more like a resin-salt than a true soap. The fat is probably only a mixture.

STEARIC ACID. $C^{18}H^{36}O^2 = \left.\begin{matrix}C^{18}H^{35}O\\H\end{matrix}\right\}O$.—*Acide stéarique, Acide margareux, Talgsäure.* (Chevreul, Ann. Chim. lxxxviii. 225: Ann. Ch. Phys. [2], ii. 354; xxiii. 19; *Recherches sur les corps gras.*—Braconnot, Ann. Chim. xciii. 250.—Redtenbacher, Ann. Ch. Pharm. xxxv. 46.—Bromeis, *ibid.* xxxv. 86; xxxvii. 303.—Stenhouse, *ibid.* xxxvi. 57.—Erdmann, J. pr. Chem. xxv. 497.—Francis, Ann. Ch. Pharm. xlii. 256.—Gottlieb, *ibid.* lvii. 35.—Laurent and Gerhardt, *ibid.* lxxii. 272.—Hardwick, Chem. Soc. Qu. J. ii. 232.—Crowder, Phil. Mag. [4], iv. 21.—Heintz, see references under MYRISTIC ACID, iii. 1069.—Berthelot, Ann. Ch. Phys. [3], xli. 216, 432; xlvii. 297.—Pebal, Ann. Ch. Pharm. xci. 138.—Gm. xvii. 103.)

Stearic acid was discovered by Chevreul as a constituent of the more solid fats of the animal kingdom. It is most abundant in these, especially in beef- and mutton-suet; but exists also, together with palmitic, myristic acid, &c., in the softer fats, such as the butter of cow's milk, human fat, in that of the goose, of serpents, of cantharides, and in spermaceti. It occurs also in vegetable fats, especially in cacao-fat; less abundantly in olive-oil, in the fat-oil of black mustard, in the fat of *Brindonia indica*, and many others. The stearophanic acid, prepared by Francis from the berries of *Cocculus indicus*, and the bassic acid, obtained by Hardwick from bassia-oil, have been shown by Crowder to be identical with each other, and by Heintz to be identical with the stearic acid obtained from mutton-suet. Stearic acid appears, then, to be a frequent constituent of fats, both of the animal and of the vegetable kingdoms; it rarely, however, occurs in the free state, but almost always as a glyceride, viz. in the form of tristearin (p. 422). In the fat of cocculus-grains, part of the stearic acid is in the free state.

Preparation.—Stearic acid is prepared from beef- or mutton-suet, or better from cacao-fat, by saponifying the fat with soda-ley, heating the soap-paste with water and dilute sulphuric acid, removing the separated fatty acids after cooling, washing them with water, and then dissolving them in as small a quantity as possible of hot alcohol. On cooling, the greater part of the solid acid separates out, while the oleic acid remains in solution; and may be separated by subjecting the mass, after draining, to strong pressure, redissolving the residue in a small quantity of hot alcohol, leaving it to separate by cooling, and again pressing the solid mass. From the mixture of solid fatty acids thus obtained, the stearic acid may be separated, in a comparatively pure state, by repeated crystallisation from considerable quantities of alcohol, only the portion which first separates being each time selected. But to obtain pure stearic acid, it is better to subject the alcoholic solution of stearic and palmitic acids to fractional precipitation with acetate of lead, barium, or magnesium, the stearate then separating out first.

For this purpose Heintz dissolves the impure stearic acid (4 pts.), melting at about 60°, in such a quantity of hot alcohol that nothing will separate out on cooling, even to 0°, and mixes the hot liquid with a boiling alcoholic solution of magnesic acetate (1 pt.). The magnesium-salt which separates on cooling, is pressed and boiled for some time with a large quantity of dilute hydrochloric acid, and the stearic acid thereby separated is repeatedly crystallised from alcohol, till it melts constantly between 69° and 70°.

Stearic acid is also easily prepared from stearophanin (? tristearin), the fat of cocculus-berries, by saponifying it with potash, salting out the soap, decomposing it with hydrochloric acid, and crystallising the separated fat from alcohol. The fatty acid is thus obtained in small needles, melting at 68°: probably not quite pure stearic acid.

According to Buff and Oudemanns (J. pr. Chem. lxxxix. 215), the best material for the preparation of stearic acid is shea-butter, which contains about 70 per cent. stearic and 30 per cent. oleic acid, but no other solid fatty acid.

On the large scale, impure stearic acid is prepared for the manufacture of stearin-candles by saponifying some of the harder fats, generally with lime. The resulting lime-soap, decomposed by sulphuric acid, yields a mixture of fatty acids, which are pressed first in the cold, and afterwards at a higher temperature, in order to separate the oleic acid from the less fusible palmitic and stearic acids.

Another method, applied chiefly to palm-oil, consists in decomposing the fat with superheated steam, as described under GLYCERIN (ii. 885).—A third method consists in treating the fat with sulphuric acid and distilling the product. When a hot fat is brought in contact with strong sulphuric acid, it is immediately resolved into fatty acid and glycerin, which unites with the sulphuric acid, forming glyceryl-sulphuric acid. In the original process, patented by Gwynne, Wilson, and Jones, 37 per cent. sulphuric acid of 60°. Bm. was introduced into the hot fat, and the mixture was heated for 24 hours to 90°—92°. It was soon found, however, that the quantity of sulphuric acid might be considerably diminished (5 to 9 per cent. being sufficient for many fats), provided the temperature was raised proportionately higher (to 155° when the quantity of sulphuric acid was small). (For details of the stearin-candle manufacture, see *Ure's Dictionary of Arts*, &c., iii. 754; *Chemical Technology*, vol. i. part ii. p. 432; *Handw. d. Chem.* viii. 201.)

Properties.—Pure stearic acid crystallises from alcohol in nacreous laminæ or needles; it is tasteless and inodorous, and has a distinct acid reaction (Chevreul, Heintz). At low temperatures it is heavier than water, having a specific gravity of 1·01 at 0° (Saussure); but between 9° and 10°, its specific gravity is the same as that of water. It melts at 69°—69·2° (Heintz) to a colourless oil, which on cooling solidifies to a white, scaly, crystalline mass, lamino-crystalline on the recently-fractured surfaces. The impure acid solidifies in masses of acicular or wavellitic structure. The melting-point was found by Chevreul to be 75° (solidifying-point 70°), by Duffy 68° (solidifying-point 65·8°), by Stenhouse 69°; by Redtenbacher, Kopp, and others, 70°; by Hardwick, 70·5°. Pebal found that the purest acid melted at 69·2°.

When stearic acid is melted with more fusible fatty acids, the mixture fuses, not at the medium fusing-point, but mostly at a lower temperature, often even below that of the most fusible acid in the mixture: this phenomenon is similar to that which is exhibited by many metallic alloys, as of lead with tin, or with tin and bismuth. The following tables exhibit the melting-points and modes of solidification of mixtures of stearic acid with lauric, myristic, and palmitic acids, in various proportions, as determined by Heintz:

1. *Stearic and Lauric Acids.*

A mixture of:—

Stearic acid.	Lauric acid.	Melts at	Mode of solidifying.
10	90	41·5°	Non-crystalline
20	80	38·5	Non-crystalline, warty
30	70	43·4	Small shining crystalline facets on the surface
40	60	50·8	Warty, non-crystalline
50	50	55·8	Scarcely crystalline, slightly granular
60	40	59·0	More distinctly granular; commencement of scaly crystallisation
70	30	62·0	Somewhat more distinctly granulo-scaly
80	20	64·7	Distinctly scaly-crystalline
90	10	67·0	The same

2. *Stearic and Myristic Acids.*

A mixture of:—

Stearic acid.	Myristic acid.	Melts at	Mode of solidifying.
10	90	51·7°	Non-crystalline, opaque
20	80	47·8	Indistinctly crystalline
30	70	48·2	Lamino-crystalline
40	60	50·4	Beautiful broad laminæ
50	50	54·5	Non-crystalline, opaque
60	40	59·8	Neither needles nor laminæ; commencement of scaly crystallisation.
70	30	62·8	More distinctly scaly
80	20	65·0	Still more distinctly scaly
90	10	67·1	Scaly-crystalline

3. *Stearic and Palmitic Acids.*

A mixture of:—

Stearic acid.	Palmitic acid.	Melts at	Solidifies at	Mode of solidifying.
90	10	67·2°	62·5°	Scaly-crystalline
80	20	65·3	60·3	Finely aciculo-crystalline
70	30	62·9	59·3	The same
60	40	60·3	56·5	Rough, non-crystalline
50	50	56·6	55·0	Broad, lamino-crystalline
40	60	56·3	54·5	The same
35	65	55·6	54·3	Non-crystalline, wavy, shining
32·5	67·5	55·2	54·0	The same
30	70	55·1	54·0	Non-crystalline, wavy, dull
20	80	57·5	53·8	Scarcely acicular
01	90	60·1	54·5	Beautifully acicular

4. *Stearic, Palmitic, and Myristic Acids.*—The melting-point of a mixture of 32·5 r cent. palmitic acid with 67·5 per cent. myristic acid, which is situated at 46·2°,

sinks lower when to 20 pts. of this mixture there are added from 1 to 7 pts. of stearic acid; the melting-points of the several mixtures are as follows:—

With 1 pt. stearic acid the melting-point is		45·2°
2	„ „	44·5
3	„ „	44·0
4	„ „	43·8
5	„ „	44·6
6	„ „	45·4
7	„ „	46·0
8	„ „	46·5

These mixtures solidify to non-crystalline masses. (Heintz.)

5. *Stearic and Margaric Acids.*—Mixtures of these two acids melt more easily than stearic acid, but only a few of them less easily than margaric acid. They solidify almost in the same manner as unmixed fatty acids, differing therefore in this respect from mixtures of stearic with palmitic acid. (Heintz.)

A mixture of:—

Stearic acid.	Margaric acid.	Melts at	Mode of solidifying.
10	90	59·5°	Scaly-crystalline
20	80	59·8	The same, but less distinctly
30	70	60·8	Like the last
40	60	61·2	The same
50	50	62·0	The same, but less pearly
60	40	63·1	The same
70	30	64·7	The same
80	20	66·2	The same
90	10	67·6	Scaly-crystalline

Pure stearic acid expands very strongly when heated, especially at the moment of fusion (about 11 per cent.), and contracts so much in solidifying that cast lumps appear porous. Its volume, that at 0° being taken for unity, is 1·038 at 50°, 1·054 at 60°, 1·079 at 70°, and by fusion the volume at 70° increases to 1·198.

The volume of the solid acid at different temperatures is expressed by the formula:

$$V = 1 + 0{\cdot}0013490\, t + 0{\cdot}000034007\, t^2 + 0{\cdot}0000044180\, t^3;$$

and that of the liquid acid by—

$$V = 1{\cdot}1980 + 0{\cdot}0010098, \text{or } V' = 1 + 0{\cdot}000842\delta;$$

where V is the volume of the solid acid, = 1 at 0°; V', the volume of the liquid acid, = 1 at 70°; t denotes temperatures below 70°, and δ temperatures above 70° (Kopp, Ann. Ch. Pharm. xciii. 184). The specific gravity of the fused acid = 0·854 (Saussure). It solidifies on cooling in a scaly crystalline mass, or in shining needles.

Stearic acid distils in a vacuum, and in quantities of 15 to 20 grammes, under the ordinary atmospheric pressure, for the most part without alteration. When heated to 300—330° in a sealed tube for several hours, it does not alter either its appearance or its melting-point, or give off either gas or water. (Berthelot.)

Stearic acid is insoluble in *water*, moderately soluble in *alcohol*, more readily in *ether*, *benzene*, *sulphide of carbon*, and *oils*, both *fixed* and *volatile*.

The composition of stearic acid is determined by the following analyses:

	Calculation.		Chevreul.	Redtenbacher.	Stenhouse.	Erdmann.	Hardwick.	Francis.
C^{18} . . .	216	76·06	76·30	75·51	75·75	76·50	76·13	74·73

	100·00	100·00	100·00	100·00		

The formulæ $C^{70}H^{70}O^7$ (Chevreul), $C^{68}H^{68}O^7$ (Redtenbacher, Erdmann) $C^{68}H^{66}O^7$ (Stenhouse), $C^{36}H^{36}O^4$, or $C^{18}H^{36}O^2$ (Gerhardt), have been successively proposed for stearic acid. Laurent and Gerhardt gave the formula $C^{34}H^{34}O^{4}$, or $C^{17}H^{34}O^{2}$, according to which stearic acid would be isomeric with margaric acid. The above formula, first proposed by Hardwick for stearic acid separated from bassia-oil (bassic acid), then adopted by Crowder for the stearophanic acid of Francis, has been recognised by Heintz as the true formula of stearic acid.

Decompositions.—1. When 90 grms. of stearic acid are subjected to dry distillation, the greater part passes over unchanged, but a smaller portion is resolved into carbonic anhydride, water, and stearone; the distillate likewise contains acetic acid, butyric acid, a fatty acid of lower melting-point than stearic acid; also a hydrocarbon of the formula $C^{n}H^{2n}$, and ketones richer in oxygen than stearone—these, as well as the hydrocarbons, probably resulting from further decomposition of the stearone. The black-brown residue in the retort still contains stearone, but scarcely any fatty acids. (Heintz.)

2. Stearic acid mixed with platinum-black, and heated to 100° in *oxygen-gas*, forms carbonic anhydride, and at 200° is completely converted into carbonic anhydride and water (Reiset and Millon [3], Ann. Ch. Phys. viii. 285). It burns in the air like wax, and when heated to 180° in oxygen-gas it burns with a dazzling light. With ozone it behaves like palmitic acid (iv. 334).

3. Heated with *chromic acid*, sulphuric acid, and water, it yields chromic oxide, and an acid melting at 64—65°, the alcoholic solution of which first deposits unaltered stearic acid, then an acid (Redtenbacher's margaric acid) melting between 59° and 60°. (Redtenbacher.)

4. *Permanganate of potassium* converts stearic acid into stearate and carbonate of potassium. (Cloez and Guignet, Compt. rend. xlvi. 1110.)

5. *Nitric acid* forms from stearic acid small portions of volatile acids, which mix with the unaltered stearic acid, and lower its melting-point (Heintz). When stearic acid is heated with 2 or 3 pts. nitric acid, violent action takes place after half an hour, nitric acid and pungent gases being given off, and the fused acid being converted into a tenacious frothy mass, then becoming clear and mobile, and finally solidifying as it cools to a tallowy mas, which melts at 35° to 45°. According to Bromeis, this mass contains margaric acid, and if crude stearic acid has been used, an oil formed from oleic acid, and coloured blood-red by potash. After several days' treatment with nitric acid, the stearic acid disappears completely, being converted into sebacic and succinic acids (Bromeis). In later experiments, Bromeis obtained also azoleic acid (an acid isomeric with œnanthylic acid), and produced, according to Arppe,.by the action of nitric acid on oleic acid.

6. Stearic acid fused with *phosphoric anhydride* forms a yellow mass, which, when freed from the unaltered stearic acid, melts at 54—60°, and contains, on the average, 80·4 per cent. C, 12·9 H, and 6·7 O ($C^{18}H^{34}O^{2}$ = 81·2 per cent. C, 12·77 H, and 6·03 O), and is converted by hot nitric acid into a brittle waxy mass containing 77·25 per cent. C, 12·22 H, and 10·53 O. (Erdmann, J. pr. Chem. xxv. 500.)

7. Dry *chlorine gas* at 100° converts stearic into chlorostearic acid. (Hardwick.)

8. *Bromine* heated with stearic acid and water in a sealed tube, forms a dark-brown liquid, which does not alter perceptibly at 100°, but between 130° and 140° is slowly converted into a yellow oily mixture of bromo- and dibromo-stearic acids, mixed with unaltered stearic acid. Formation of bromostearic acid:

$$C^{18}H^{36}O^{2} \quad + \quad Br^{2} \quad = \quad C^{18}H^{35}BrO^{2} \quad + \quad HBr.$$

When more than 2 at. bromine is used to 1 at. stearic acid, a large quantity of dibromostearic acid is produced, but even then a part of the stearic acid remains unaltered. If the heat is raised above 140°, the mass remains brown, or charcoal separates from it. (Oudemanns, J. pr. Chem. lxxxix. 193.)

9. *Pentachloride of phosphorus* brought in contact with stearic acid at a moderate heat, forms a colourless mass, which soon becomes heated to 150°, turning brown and black. When distilled it gives off hydrochloric acid, a small quantity of water, a hydrocarbon, stearic acid, and a solid product less soluble in alcohol than stearic acid. (Chiozza, *Gerhardt's Traité*, ii. 851.)

11. Stearate of potassium, in contact with *oxychloride of phosphorus*, becomes slightly heated, and at 150° swells up to a dark jelly, perhaps forming chloride of stearyl, inasmuch as the product treated with alcohol yields stearate of ethyl. (Pebal.)

12. When stearic acid is heated with an equal weight of *sulphur*, a trace of sulphuric acid is given off, and the same products are formed as when stearic acid is heated by itself. (Anderson, Ann. Ch. Pharm. lxiii. 373.)

13. The acid heated with *oil of vitriol* to 100°, for several hours, is decomposed, with evolution of sulphurous anhydride, and carbonises at a higher temperature. (Chevreul.)

14. Stearate of *calcium*, subjected to dry distillation, gives off marsh-gas and olefiant gas (or gases having the same composition as the latter), and yields a distillate containing a large quantity of stearone, with small quantities of other ketones, while carbonate of calcium remains behind. The distillate does not contain any fatty acid (Heintz). See STEARONE.

15. Stearic acid distilled with excess of *aniline*, yields phenyl-stearamide. From its alcoholic solution mixed with aniline, however, it crystallises unaltered. (Pebal.)

16. Stearic acid, heated with *methylic*, *ethylic*, and the *homologous alcohols*, with *mannite*, *quercite*, *pinite*, and *sugars*, with *glycerin*, *orcin*, *meconin*, *erythroglucin*, and *cholesterin*, yields ethereal compounds, formed from the acid and the other body, with elimination of water. When heated for thirty-six hours with *pyrogallic acid* to 200°, it forms a crystalline compound. (Rösing, Compt. rend. xiv. 1149.)

Stearates.—Stearic acid dissolves in a cold aqueous solution of alkaline carbonate, probably from formation of acid carbonate, but does not expel the carbonic acid, and form a mono-acid salt, till heated to about 100°. On the other hand, the stearates are decomposed by most other acids, the separated stearic acid rising to the surface as an oil when the liquid is warm. The stearates have the consistence of hard soaps and plasters, and are mostly insoluble in water.

Stearate of Ammonium.—Stearic acid, either in the fused or in the solid state, absorbs ammonia-gas without elimination of water, the quantity absorbed amounting after a month, when the absorption ceases, to 6·68 pts. ammonia for every 100 pts. of acid (1 at. NH^3 = 5·9 pts.). The compound is solid, white, inodorous, has an alkaline taste, may be sublimed in a vacuum, and then gives off ammonia, but takes it up again on cooling. When heated in a vessel containing air, it gives off ammonia and water, and yields a sublimate of acid salt, mixed with empyreumatic oil. The neutral salt, when protected from the air, dissolves in hot water, especially in ammoniacal water, and the solution on cooling deposits the acid salt in nacreous laminæ (Chevreul). The solution of stearic acid in hot dilute aqueous ammonia deposits small needles on cooling. When heated for some time, it becomes turbid, and is then not clarified by further addition of ammonia. The needles dissolve in alcohol and in ether. (Crowder.)

Stearate of Barium, $C^{36}H^{70}Ba''O^4$, is obtained by precipitating the hot alcoholic solution of an alkaline stearate with a hot solution of barium-chloride, or a hot alcoholic solution of stearic acid with a hot aqueous solution of baric acetate. It is a white crystalline powder, consisting of microscopic laminæ, and having a nacreous lustre when dry. It is insoluble in water, and decomposes without melting when heated.

Stearate of Calcium, $C^{36}H^{70}Ca''O^4$, obtained by precipitating chloride of calcium with a boiling solution of potassic stearate, and washing the precipitate with boiling water, is a white, fusible, tasteless powder.

Stearate of Copper, $C^{36}H^{70}Cu''O^4$.—Light-blue, bulky, amorphous powder; melts when heated to a green liquid, easily decomposing at the same time. (Heintz.)

Stearates of Lead.—The *monoplumbic salt*, $C^{36}H^{70}Pb''O^4$, is formed by precipitating a hot alcoholic solution of the neutral sodic salt with a hot aqueous solution of plumbic nitrate, or of the acetate containing a slight excess of acetic acid; the precipitate is washed first with alcohol, then with water. When dry it forms a heavy amorphous powder, which is not wetted by water, melts at about 125° to a colourless liquid, and solidifies to an opaque amorphous mass. It is insoluble in ether.

The *diplumbic salt*, $C^{36}H^{70}Pb''O^4.Pb''O$, is prepared by boiling stearic acid in a close vessel with triplumbic acetate, and boiling the product first with water, then with alcohol. It forms a white, transparent, friable soap-liquid at 100°. (Chevreul.)

Stearate of Magnesium, $C^{36}H^{70}Mg''O^4$, is obtained by precipitating the neutral sodic salt with sulphate of magnesium, or by supersaturating a hot alcoholic solution of stearic acid with ammonia, adding a sufficient quantity of sal-ammoniac, and then an excess of dissolved sulphate of magnesium. After recrystallisation from alcohol, it forms dazzling white flocks, consisting of microscopic laminæ, which dry up to a light fusible powder. (Heintz.)

Stearates of Mercury.—The *mercuric salt*, obtained by precipitation with mercuric nitrate, is a white easily fusible powder, which softens between the fingers.—The *mercurous salt*, obtained by precipitation with mercurous nitrate, is while moist a white granular powder, but becomes grey when dry. It is insoluble in water and in cold alcohol, slightly soluble in hot alcohol, more soluble in ether, and easily fusible.

Stearates of Potassium.—*a.* The *neutral salt*, $C^{18}H^{35}KO^2$, separates on cooling from a solution of 1 pt. stearic acid and 1 pt. potassic hydrate in 10 pts. water, in white opaque granules, and may be purified by pressure, solution in 18 pts. alcohol of specific gravity 0·821, and washing the needles, which then separate, with cold alcohol (Chevreul). According to Heintz, it is most easily obtained in the pure state, by mixing a boiling alcoholic solution of the acid with a hot aqueous solution of potassic carbonate in excess, evaporating the mass to dryness, exhausting the residue with boiling absolute alcohol, and leaving the filtered solution to crystallise. It forms shining delicate needles, scales, and laminæ, which aggregate into a hard soap; it has a faint alkaline taste.

In air saturated with moisture, it takes up one-tenth of its weight of water. One pt. of the salt forms, with 10 pts. of cold water, an opaque gum, which melts at 99°, and solidifies to a pearly gum on cooling. One pt. of the salt dissolves completely in 25 pts. of boiling water, forming a liquid which is still limpid at 92°, and solidifies to a pearly mass on cooling.

The solution of 1 pt. of the salt in 100 pts. of hot water deposits on cooling a mixture of neutral and acid stearate of potassium, while one-fourth of the entire quantity of potash remains dissolved. When the solution of the salt in alcohol, or in 20 pts. of boiling water, is mixed with 1,000 pts. of boiling water, or 5,000 pts. of cold water, it deposits all the stearic acid as acid salt, whilst half the potash remains dissolved in the water. In like manner the neutral salt, when drenched with 5000 pts. of cold water, gives up half its potash, and is converted into the acid salt without forming a gum. In these cases the alkaline water contains a trace of stearic acid in solution (Chevreul). It dissolves at 10° in 231 pts. alcohol of specific gravity 0·794, in 10 pts. at 66°, the latter solution becoming turbid at 55°, and solidifying at 38°; in 6·7 pts. of boiling alcohol of specific gravity 0·794, forming a liquid which gelatinises on cooling. It dissolves in ether-alcohol, and crystallises therefrom (Crowder, Hardwick). Boiling ether withdraws from the neutral salt a certain quantity of stearic acid, leaving a compound richer in potash. (Chevreul.)

β. The *acid salt*, $C^{18}H^{35}KO^2.C^{18}H^{36}O^2$, is obtained by decomposing the neutral salt with 1,000 pts. or more of water. When pressed, dried, and dissolved in boiling alcohol, it separates on cooling in silvery scales, inodorous, and soft to the touch. It does not melt at 100°. It is not altered by cold water, but, when boiled with 1,000 pts. of water, yields a milky liquid, consisting of a solution of the neutral salt, in which a more acid salt is suspended; towards 75° this liquid becomes clearer, but again turbid at 67°; if the liquid be filtered at the boiling heat, the more acid salt remains on the filter.

100 pts. of absolute alcohol dissolve 27 pts. of acid potassic stearate at the boiling heat, but retain only 0·36 pt. of it after cooling to 24°. In consequence of the tendency of the alcohol to decompose the acid salt into the neutral salt and stearic acid, the portion which remains dissolved contains a salt richer in stearic acid than the crystallised salt. When the acid stearate is dissolved in boiling aqueous alcohol, and the solution is mixed drop by drop with infusion of blue litmus, the liquid is ultimately reddened by the excess of acid in the salt; but on adding a larger quantity of water, which precipitates a hyperacid salt, and sets free a certain quantity of alkali, the blue colour is restored.

γ. *Hyperacid salt*, $C^{18}H^{35}KO^2.3C^{18}H^{36}O^2$ (?).—Produced when the acid salt β is decomposed by boiling water. It melts in boiling water, and solidifies on cooling; swells up in cold water. When dissolved in boiling alcohol, it separates into the acid salt which is deposited, and stearic acid which remains dissolved.

Stearate of Silver, $C^{18}H^{35}AgO^2$.—Obtained by adding a solution of 20 grms. of the sodium-salt in 5 or 6 oz. of strong alcohol to a solution of 12 to 13 grms. silver-nitrate in an equal quantity of alcohol (Crowder). Amorphous white precipitate, very loose, and strongly electric when dry. Assumes a purple colour when exposed to light in the moist state; not altered by light when dry. Insoluble in water, alcohol, and ether, easily soluble in aqueous ammonia.

Stearates of Sodium.—*a*. The *neutral* salt, $C^{18}H^{35}NaO^2$, is obtained, like the potassium-salt, by treating a hot alcoholic solution of stearic acid with excess of sodic carbonate, evaporating the solution to dryness with addition of a little water, and boiling the finely-pulverised residue with absolute alcohol, which leaves the sodic carbonate undissolved. The hot-filtered alcoholic solution is then immediately mixed with $\frac{1}{8}$ of its volume of hot water, whereupon the greater part of the sodic stearate separates on cooling in the form of a jelly, while the water retains in solution the small quantity of sodic carbonate still present. The sodic stearate thus separated is then strongly pressed, and dried between 100° and 120°.

Neutral sodic stearate is very much like the potassium-salt, but harder. From a hot, concentrated, alcoholic solution it separates as a jelly, which, on standing, is converted into shining translucent laminæ. Francis obtained it (from stearophanic acid) in prismatic crystals, having a fine mother-of-pearl lustre. It is tasteless at first, but after some time produces a distinct alkaline taste. It is permanent in air; in moderately dry air, and even from air saturated with moisture, it absorbs only 7·5 per cent. water in twelve days, afterwards not any perceptible quantity. It dissolves in 10 pts. boiling water, to a thick semitransparent mass, which solidifies and becomes opaque at 62°. When covered with 600 pts. of cold water, it becomes more opaque in 14 days by taking up water, and gives up to the water a trace of soda. With 10 pts. water at 90°, it forms a thick, nearly transparent solution, which solidifies to a white mass at 62°; and this, when heated with 40 pts. more water, forms a solution which is still filtrable below 100°, and when mixed with 2,000 pts. more water, deposits the acid salt on cooling, while half the soda and a trace of stearic acid remain in solution. It is this decomposition by water which renders the soap available for washing. It dissolves at 10° in 499 pts. alcohol of specific gravity 0·821, and in 20 pts. at the boiling heat; the latter solution becomes turbid at 70°, and solidifies on cooling to a transparent jelly, which afterwards becomes opaque, and contracts, from formation of numerous shining crystals. Boiling ether withdraws from the salt a small quantity of stearic acid, together with a trace of soda, and yields a slight deposit on cooling. (Chevreul.)

β. The *acid salt*, $C^{18}H^{35}NaO^{2}.C^{18}H^{36}O^{2}$, is formed, as above mentioned, when a solution of the neutral salt in 10 to 40 pts. of hot water is mixed with 2,000 pts. or more of cold water, or when a solution of the same salt in 2,000 to 3,000 pts. of boiling water is left to cool. It then separates in nacreous laminæ. It dissolves in alcohol, forming a solution which reddens litmus; and on addition of a large quantity of water, deposits a still more acid salt, while free alkali remains in solution.

Stearate of Strontium, $C^{36}H^{70}Sr''O^{4}$, is prepared by precipitation, like the barium-salt, which it resembles in every respect.

Substitution-derivatives of Stearic Acid.

Bromostearic Acid, $C^{18}H^{35}BrO^{2}$. (Oudemanns, J. pr. Chem. lxxxix. 195.)—Obtained by heating stearic acid (7 pts.) with water and bromine (4 pts.), in a sealed tube, to 130° or 140° at most, till the brown colour of the bromine disappears, and the mixture assumes the appearance of a yellow oil, cooling to a crystalline solid. After washing away the hydrobromic acid, the contents of the tube are dissolved in 20 times their weight of warm alcohol of 80 per cent., and the unchanged stearic acid is separated by cooling to −10°. The liquid is then mixed with an equal volume of water and an excess of crystallised sodic carbonate, and evaporated to dryness over the water-bath. The tough saline mass thus obtained is boiled with 10 volumes of alcohol of 80 per cent., and filtered as hot as possible; and the crystals of sodic bromostearate, which form in the filtrate (and of which more may be obtained by evaporating the solution), are collected and purified by repeated crystallisation from alcohol. The mother-liquor contains dibromostearate of sodium.

From the sodium-salt the bromostearic acid is separated by dilute sulphuric acid, as a yellow indistinctly crystalline mass, melting at 41°, and of specific gravity 1·0653 at 20°.

It is very slowly decomposed by heating with excess of *caustic potash*. Bromostearate of silver, heated with water, forms bromide of silver and stearidic acid, $C^{18}H^{34}O^{2}$.

The acid is insoluble in *water*, but dissolves easily in alcohol and in ether. It forms with the alkalis soap-like compounds, which crystallise from alcohol.—*Bromostearate of potassium* is more soluble than the sodium-salt. The alkaline bromostearates form precipitates with most metallic salts.

Dibromostearic Acid, $C^{18}H^{34}Br^{2}O^{2}$.—Formed as above in the preparation of bromostearic acid, and obtained in the form of an uncrystallisable sodium-salt. This salt is brown, tenacious, very hygroscopic, dissolves easily in alcohol, and forms with water an opaque soapy solution. After drying at 130°, it contains 32·5 per cent. of bromine and 6·59 of soda, approximating to the formula $C^{18}H^{33}NaBr$. (Oudemanns, *loc. cit.*).

Chlorostearic Acid, $C^{18}H^{35}ClO^{2}$. *Chlorobassic acid* (Hardwick, Chem. Soc. Qu. J. ii. 232).—Formed by treating stearic acid at 100° with dry chlorine, whereupon it first becomes thicker, and is ultimately converted into a solid resin, which forms with *potash* an amorphous soap, not crystallisable from alcohol. The *barium-salt* and *lead-salt* are insoluble in water.

STEARIC ANHYDRIDE. $C^{36}H^{70}O^{3} = (C^{18}H^{35}O)^{2}O$.—Obtained in a similar manner to benzoic anhydride (i. 557), but difficult to free from stearic acid. (Chiozza, Ann. Ch. Pharm. xci. 104.)

Benzostearic Anhydride, Benzoic Stearate, or *Stearic Benzoate,* $C^{25}H^{40}O^{3} = (C^{7}H^{5}O)(C^{18}H^{35}O)O$.—Obtained by heating potassic stearate with benzoic chloride to

100°, and exhausting the product with ether. Crystallises in shining laminæ, which melt at 100°. (Chiozza.)

STEARIC ETHERS. *a. Stearic Ethers containing the Alcohol-radicles*, C^nH^{2n+1} and $(C^nH^{2n})''$. METHYLIC STEARATE, or *Methylstearic Ether*, $C^{19}H^{38}O^2 = C^{18}H^{35}(CH^3)O^2$. (Lassaigne, Ann. Ch. Pharm. xiii. 168.)—Produced by heating 2 pts. methylic alcohol with 2 pts. sulphuric acid and 1 pt. stearic acid, or by heating stearic acid with methylic alcohol in a sealed tube for a day. It is a neutral, crystalline, semitransparent mass, insoluble in water, melting at 85°? (Lassaigne); at 38°. (Hanhart, Compt. rend. xlvii. 230.)

ETHYLIC STEARATE, commonly called *Stearic Ether*, $C^{20}H^{40}O^2 = C^{18}H^{35}(C^2H^5)O^2$. (Lassaigne, *loc. cit.*—Redtenbacher, Ann. Ch. Pharm. xxxv. 51.—Stenhouse, *ibid.* xxxvi. 58.—Francis, *ibid.* xlii. 261.—Crowder, J. pr. Chem. lvii. 292.—Heintz, see Memoirs cited, iii. 1069.—Duffy, Chem. Soc. Qu. J. v. 197.—Pebal, Ann. Ch. Pharm. xci. 153.—Berthelot, *ibid.* lxxxviii. 312.—Hanhart, Compt. rend. xlvii. 230.—Berthelot and Fleurien, Ann. Ch. Phys. [3], lxvii. 79.)—This ether is produced: 1. By heating stearic acid with alcohol to 200°; small quantities are produced also by heating the materials together to 100° for 102 hours (Berthelot); or by boiling stearic acid with alcohol (Lassaigne).—2. By passing hydrochloric acid gas into an alcoholic solution of stearic acid (Redtenbacher); by heating alcoholic stearic acid with acetic acid to 100°, the whole of the stearic acid then entering into combination in 102 hours (Berthelot).—3. By the action of alcohol on the product formed by heating stearic acid with pentachloride of phosphorus (Pebal).—4. By boiling tristearin with a solution of sodium in absolute alcohol (Duffy), or by heating tristearin with small quantities of alcoholic potash. (Bouis, Compt. rend. xlv. 35.)

Properties.—Ethylic stearate is a crystalline mass, semitransparent, and resembling white wax. Melts at 33·7° (Duffy, Heintz); at 27° (Lassaigne); 30°—31° (Redtenbacher); 31° (Hanhart); 32° (Francis); 32·9° (Pebal); 33·3° (Crowder). Solidifies to a translucent mass (Duffy); to a crystalline mass, soft at first, afterwards becoming hard and brittle (Heintz). Volatilises a little at the heat of the water-bath (Crowder); boils at 224° with partial decomposition, leaving a residue of charcoal (Duffy). Tasteless; melts on the tongue, producing a sensation of cold (Crowder); has a buttery taste (Francis). Inodorous in the cold; smells faintly when heated. (Francis.)

It dissolves very easily in *alcohol* and in *ether*, and crystallises from alcohol, but not from ether. (Duffy.)

Decompositions.—1. For the decomposition by heat, see above.—2. By water at 100°, it is partially resolved in 102 hours into alcohol and stearic acid, more abundantly by a mixture of 1 vol. acetic acid and 2 to 3 vols. water, the latter reaction taking place without any formation of acetic ether (Berthelot).—3. Fuming *hydrochloric acid* at 100°, converts it in 106 hours into chloride of ethyl and stearic acid (Berthelot).—4. It is decomposed by alcoholic but not by aqueous *potash* (Duffy).—5. Anhydrous *baryta* heated with the ether to 200° in a sealed tube, decomposes it completely, and the product heated with water yields alcoholate and stearate of barium:

$$2C^{20}H^{40}O^2 + 2Ba''O = C^{36}H^{70}Ba''O^4 + C^4H^{10}Ba''O^2.$$

These are the only products; no ethylic ether is formed (Berthelot and Fleurien).—6. Heated to 100° with *glycerin*, it does not yield stearin, even in presence of hydrochloric acid. (Berthelot.)

ETHYLENIC STEARATE, $C^{38}H^{74}O^4 + \left.\begin{matrix}(C^{18}H^{35}O)^2 \\ (C^2H^4)''\end{matrix}\right\}O^2$ (Wurtz, Ann. Ch. Phys. [3], lv. 436). *Glycolic Bistearate. Glycol distéarique.*—Obtained by the action of bromide of ethylene on stearate of silver. The product is exhausted with ether, the ethereal solution treated with potassic hydrate, and the filtrate left to evaporate. It forms light shining laminæ, melting at 76°, and resembling tristearin.

AMYLIC STEARATE, $C^{23}H^{46}O^2 = C^{18}H^{35}(C^5H^{11})O$.—Obtained by heating stearic acid with amylic alcohol to 200° in a sealed tube for a day; or by passing hydrochloric acid gas into a solution of the acid in amylic alcohol, or by boiling tristearin with a solution of sodium in amylic alcohol. It is a neutral, soft, viscous, transparent mass, melting at 25·5° (Duffy); at 25° (Hanhart). It is decomposed by alcoholic but not by aqueous potash; dissolves slightly in alcohol, the solution solidifying to a jelly. The ethereal solution does not yield crystals.

OCTYLIC STEARATE, $C^{26}H^{52}O^2 = C^{18}H^{35}(C^8H^{17})O^2$.—Obtained by heating stearic acid with octylic alcohol to 200° in a sealed tube for a day. It is colourless, inodorous, tasteless, neutral, and melts at 45°. (Hanhart, *loc. cit.*)

Cetylic Stearate, $C^{34}H^{68}O^2 = C^{18}H^{35}(C^{16}H^{33})O^2$. (Berthelot, Ann. Ch. Phys. [3] lvi. 70.)—A mixture of 1 part of ethal with 4 or 5 parts of stearic acid is heated to 200° in a sealed tube, for 8 or 10 hours. The product is mixed first with a little ether, and then with slaked lime, which takes up the uncombined stearic acid; and the whole is heated to 100° for some minutes, and afterwards boiled with ether, whereby the ethal and cetylic stearate are dissolved, and remain behind on evaporating the solution. From the mixture thus obtained, the free ethal is removed by boiling five or six times with 6 to 10 pts. of alcohol, and the undissolved cetyl-compound is then allowed to crystallise from ether. It forms broad shining laminæ, resembling spermaceti, melting at 55° to 60°, and cooling to a crystalline solid. It is neutral, but decomposes partly by volatilisation, with formation of a little free acid.

β. *Stearic Ethers containing other Organic Radicles.*—Berthelot (Ann. Ch. Phys. [3] xlvii. 324; *Chimie organique*, ii. 191—219), by heating stearic acid with *glucose, mannite, dulcite, pinite,* and *quercite*, and purifying the product in the manner described under Mannite (iii. 824), has obtained the following fatty compounds resembling stearin and palmitin:

Glucic Distearate	$C^{42}H^{78}O^7 = \left.\begin{matrix}(C^6H^6)^{vi} \\ (C^{18}H^{35}O)^2 \\ H^3\end{matrix}\right\}O^5.$
Dulcitic, Mannitic, Pinitic, Quercitic Distearate .	$C^{42}H^{80}O^7 = \left.\begin{matrix}(C^6H^8)^{vi} \\ (C^{18}H^{35}O)^2 \\ H^2\end{matrix}\right\}O^5.$
Dulcitic Tetrastearate	$C^{78}H^{146}O^9 = \left.\begin{matrix}(C^6H^6)^{vi} \\ (C^{18}H^{35}O)^4\end{matrix}\right\}O^5.$
Mannitic and Pinitic Tetrastearate . . .	$C^{78}H^{152}O^{11} = \left.\begin{matrix}(C^6H^8)^{vi} \\ (C^{18}H^{35}O)^4 \\ H^4\end{matrix}\right\}O^7.$
Mannitic Hexstearate	$C^{113}H^{216}O^{11}$?

All these compounds, when heated with hydrate of barium, are resolved into stearic acid and the respective sugars. Their formulæ require confirmation.

Camphic Stearate, $C^{28}H^{52}O^2 = \left.\begin{matrix}C^{10}H^{17} \\ C^{18}H^{35}O\end{matrix}\right\}O$? *Stearate of Camphyl. Camphol stéarique. Stearinsaures Borneol.*—Obtained by heating stearic acid with borneol (i. 626) to 200° for eight or ten hours in a sealed tube; water is then eliminated, and a mass is formed, from which the uncombined stearic acid is removed by cautious and rapid treatment with ether and slaked lime, and the free borneol by heating the evaporated ethereal solution to 150° in an air-bath for half a day or longer.

It is a thick, colourless, and inodorous oil, which solidifies to a crystalline mass after some days or months; neutral when freshly prepared; volatile (without decomposition?), decomposed by alkalis into stearic acid and borneol.—Dissolves slightly in cold, and easily in boiling alcohol and in ether. (Berthelot, Ann. Ch. Phys. [3] lvi. 89.)

Glyceric Stearates. See Stearins.
